product review

NAP™-columns for DNA and Oligonucleotide Purification

The Choice is Yours

HIGH YIELDS: 90 % or more sample recovery. The columns contain Pharmacia's new Sephadex DNA Grade This gel is function tested with nick-translated DNA.

REPRODUCIBLE: Every lot is extensively quality controlled including sample recovery and chromatographic separation.

TIME SAVING: Maximum separation time is 15 minutes. The columns are prepacked using fixed volumes and are ready to use.

EASY TO USE: A step-by-step protocol is included in each package.

APPLICATIONS: Desalting, buffer exchange and removal of phenol from DNA and oligonucleotides.

Maximum sample volumes: 0.5, 1.0 and 2.5 ml.

For further information please contact your local Pharmacia representative today.

ATURE VOL. 321 1 MAY 1986

Pollen tubes entering individual ovules in an ovary of the wild-tomato *Lycopersicon peruvianum*. Successful pollination in this species, as in many other plants, is determined by a highly polymorphic genetic locus (the *S*-gene) in such a way that self-fertilization is prevented. The cloning of the *S*-gene of tobacco (*Nicotiana alata*) is reported on pages 38 – 44 of *Nature*, and discussed in News and Views on page 20.

The Quest for Process Perfection – Q and S Sepharose® Fast Flow Gels

Q and S Sepharose Fast Flow gels are strong ion exchangers that have been developed for the biotechnology industry where biologically active compounds are purified from large volumes of raw material. Processing time is now minimized without compromise in end-product quality.

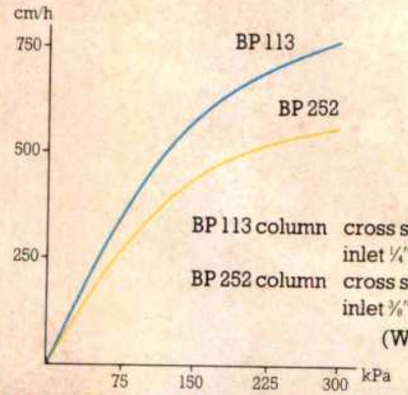
Industrially dedicated

Physical stability

The rigidity of the matrix allows for outstanding flow rates, compatible with production requirements, even at elevated pressures.

Chemical stability

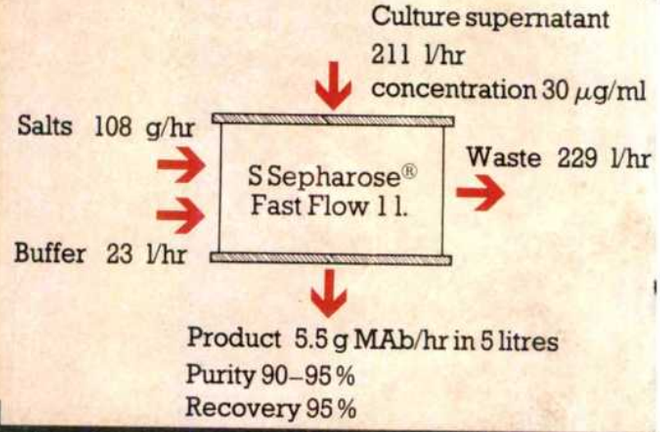
The outstanding gel performance enables effective operation in industrial environments. The gel may be stored at 40°C in 2 M NaOH for at least 7 days with no change in gel properties. This stability allows for;



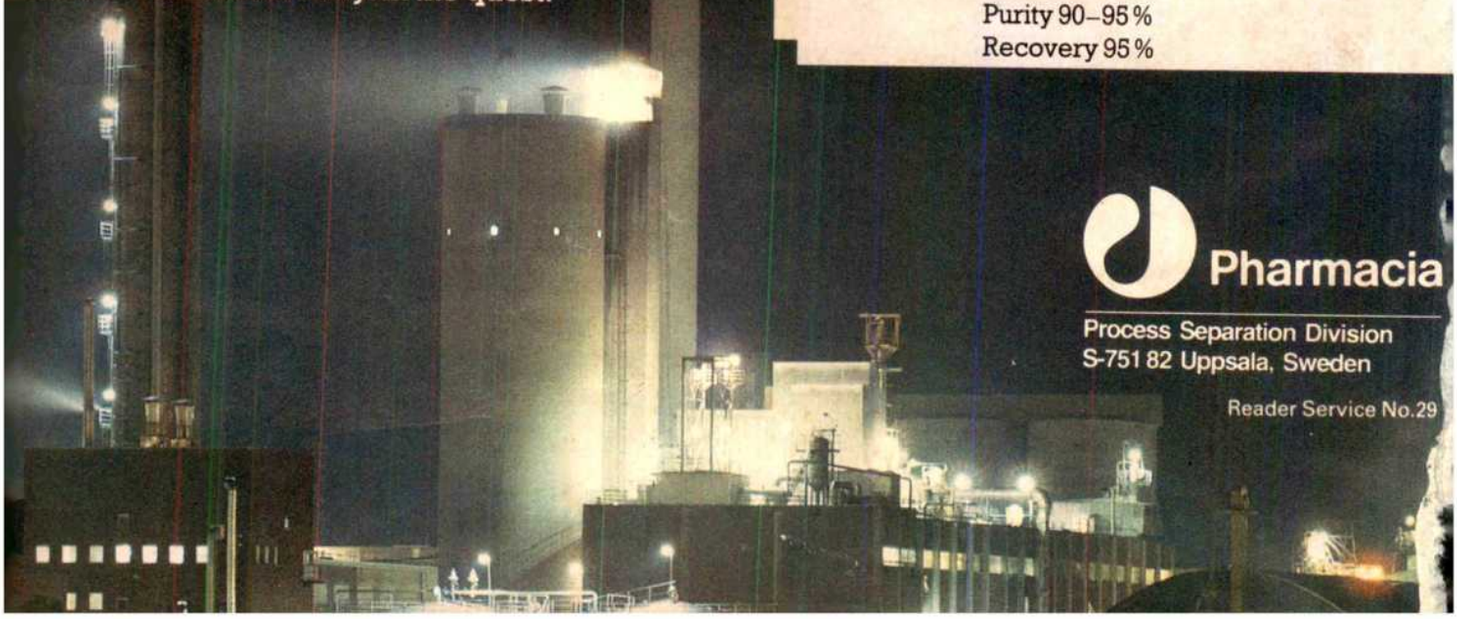
- Process directed sanitation.
- Cleaning in place procedures.

Pharmacia is dedicated to developing media to meet the exacting demands of your industry.

Try Q and S Sepharose Fast Flow today, contact Pharmacia and join the quest.



Process Scale Flow Rates



Pressure/flow rate curves for Q Sepharose Fast Flow

HALLEY'S COMET

SPECIAL SUPPLEMENT

Nature's May 15 issue will carry a 100 page supplement on Halley's Comet.

The supplement brings together for the first time the results of missions being carried out from Russia, Europe and Japan.

Among other items, reports will include extensive data on the composition of cometary gases, the density of the dust storm near the comet's core and the interactions between the comet and the solar winds buffeting it, as well as the first ever photos of the comet's nucleus.

RESERVE YOUR EXTRA COPIES OF THE SUPPLEMENT TODAY BY WRITING TO OUR BASINGSTOKE OFFICE (prices as for back issues below).

Supply can be guaranteed only if we receive your order before May 9.

- Comet Halley coma structures
- Benzodiazepines and the biological clock
- Mechanism of flying in bats
- South China Sea spreading
- Protein translocation across membranes

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

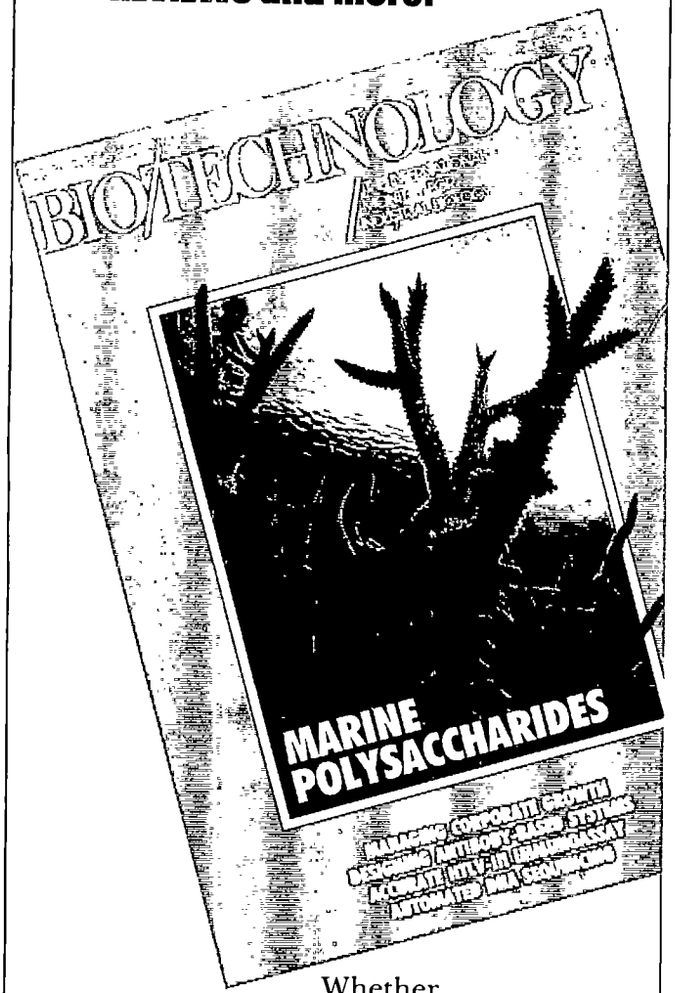
Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.



References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

NATURE VOL. 321 8 MAY 1986

Air vortices in the wake of a flying bat, visualized by a cloud of helium-filled soap bubbles. As described on pages 162–164 of this issue, these vortex patterns allow the gait of flying bats to be visualized, and have shown how the gait changes with flight speed. These observations are discussed in News and Views on page 113.

New from Beckman

The Most Advanced Robot To Enter The Laboratory

The Biomek™ 1000 Automated Laboratory Workstation. It's a new concept in laboratory automation, and it's changing the way researchers spend their time.

Ideal for immunoassays such as ELISA, hybridoma screening and selection, or other bioassays, Biomek takes over all liquid handling steps. Pipetting, diluting, dispensing, plate washing, even photometry can be completed at this single workstation.

Fast

With Biomek™ 1000, plate-based enzyme immunoassays, from sample transfer to OD measurement, can take just 12 minutes, excluding incubations. And a tenfold, 96-tube serial dilution and transfer, with tip changes, can be completed in just over 3 minutes.

Flexible

With Biomek™ 1000, you're not restricted to a manufacturer-supplied program. Biomek does your work the way *you* want it done. A proprietary assay language lets you easily program methods from simple to complex. And you can use labware you're accustomed to: multiwell plates, cryovials, tubes, or our new modular reservoirs.

As cost and labor savings become more critical to the research lab, the demand grows for instruments that speed research and stretch research dollars. Biomek 1000 does both.

To find out more, call toll-free (800) 742-2345, or write to Beckman Instruments, Inc., Spinco Division, 1050 Page Mill Rd., Palo Alto, CA 94304. Offices in major cities worldwide.

1. With the Biomek™ 1000 Automated Laboratory Workstation, you can use the labware you're accustomed to.
2. Complex procedures, from pipetting through photometry, can be performed at this single workstation.

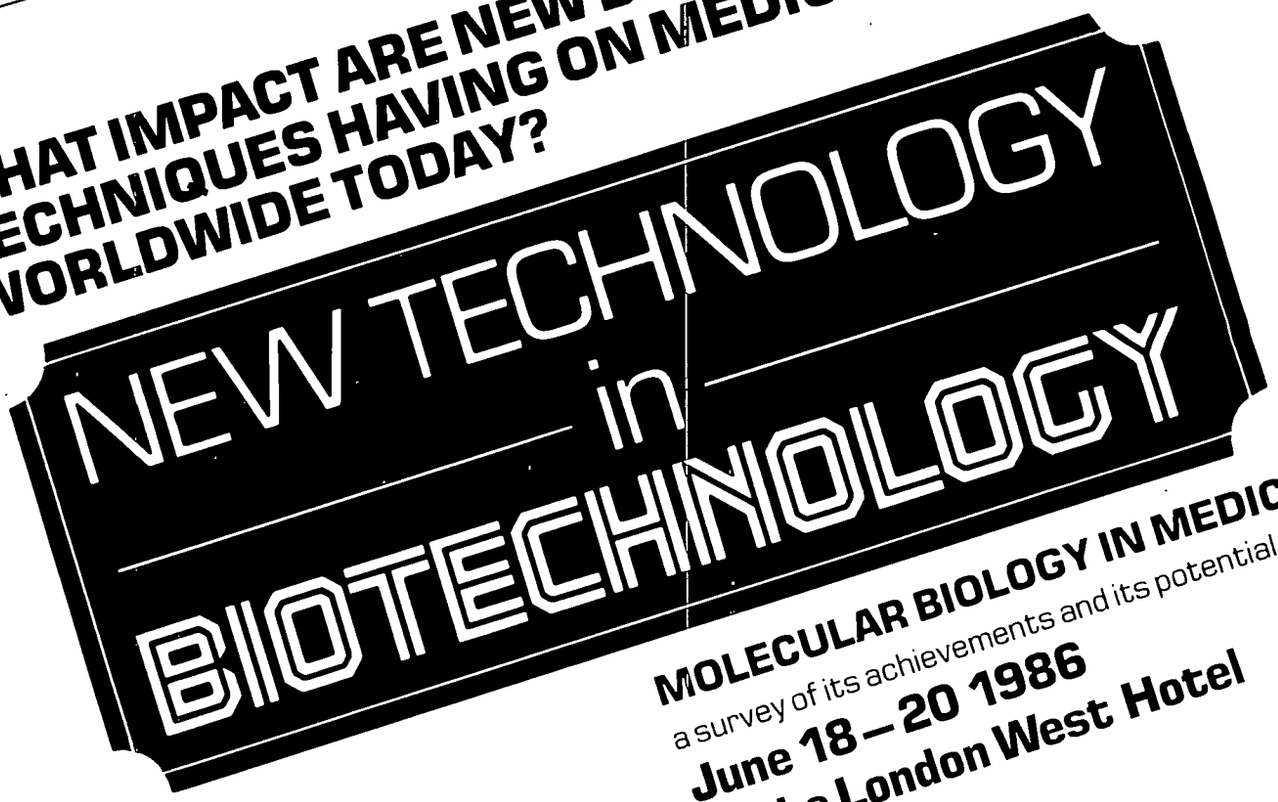
Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.



Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

WHAT IMPACT ARE NEW BIOTECHNOLOGY TECHNIQUES HAVING ON MEDICINE WORLDWIDE TODAY?

MOLECULAR BIOLOGY IN MEDICI

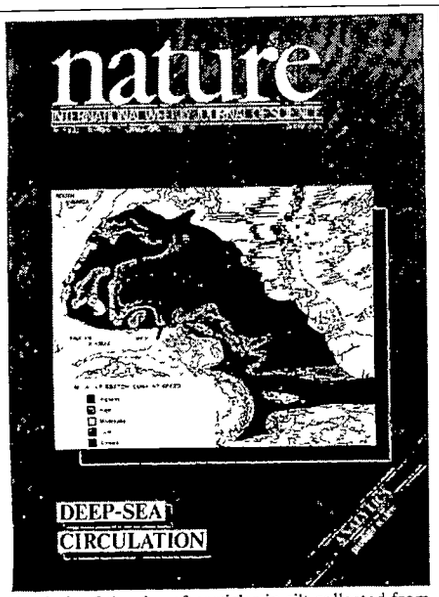
a survey of its achievements and its potential

June 18–20 1986

at the London West Hotel

It is clear that the modern techniques of biotechnology are set to have a major impact on medicine. Over the next few years many new opportunities will emerge. This important conference will provide a wide-ranging survey of the most recent research in the fast changing field of molecular biology in medicine, and a look into the future. If you want an opportunity to see and hear for yourself what leading exponents have achieved in recent years – and to learn what new opportunities are on the horizon, come and join us.

The **CONFERENCE FEE** is just £189 plus VAT for the three days of the conference. This includes entrance to all sessions, mid-morning coffee, afternoon tea and reading material. Group discounts are available on application to Janine Slipman, see booking form for address and phone no.



ACCOMMODATION has been reserved in the London West Hotel for conference participants. A booking form will be sent to you as soon as we receive your registration.

TECHNICAL SEMINARS and **POSTER SESSIONS** will be held each day. Anybody wishing to present a poster should send a title and a brief synopsis.

To: Dr Peter Newmark Deputy Editor Nature

NATURE VOL. 321 22 MAY 1986

Analysis of the size of particles in silt collected from the sea bed can be used to work out the patterns of ocean currents at great depths. Here the contours represent mean silt particle size in the region of the Argentine Basin. See p.423. This week's Product Review (p.451) includes details of new instruments on display at the Analytica exhibition in Munich.

CUSTOM SYNTHETIZED DNA AT EXTREMELY LOW PRICES

Prices (USD) per purified oligomer up to the length of 35:

		Basic fee	Per base
0.05	A260 units (~ 1.5 μg)	85	5.50
0.2	A260 units (~ 6 μg)	125	7.50
1	A260 unit (~30 μg)	170	10.00

SPECIAL OFFER: FREE OLIGONUCLEOTIDES

FOR EVERY FIVE OLIGOMERS YOU BUY
YOU GET ONE ADDITIONAL OLIGOMER FOR FREE

WHY BUY MORE THAN YOU ACTUALLY NEED?

1 μg OF OLIGONUCLEOTIDE IS SUFFICIENT FOR:

- 10 oligonucleotide-directed mutagenisis experiments.
- 100 hybridization and gene synthesis experiments.
- 1000 dideoxy sequencing experiments.
- More than 1000 cloning experiments.

SEE YOU AT "THE WEEK"!

The British Laboratory Week is Britain's leading scientific event – by a mile.

This year TWO new disciplines will be introduced.

Firstly, Bio '86, the exhibition and conference for bio-technology and genetic engineering.

Secondly, the Computer-Aided-Sciences exhibition and conference. C-A-S for short.

With "The Week's" cornerstone – Laboratory '86 exhibition and Analyticon conference – now in its ninth year – plus Medical Laboratory Sciences Exhibition (MLSE), there will be no less than FOUR exhibitions and THREE conferences to attend.

In fact, with the products on display, and the subjects for discussion, that we've got lined up, you'd be crazy to stay away.

CUT OUT AND MAIL FOR YOUR FREE TICKET!

To: Brian Curtis, Organiser, British Laboratory Week, The Hub, Emson Close, Saffron Walden, Essex CB10 1HL, United Kingdom.

Please send me_____FREE ticket(s) to "The Week" and information on my principal area of interest:

BIOSYSTEMS UPDATE

For People who make Peptides

Here are five reasons why.

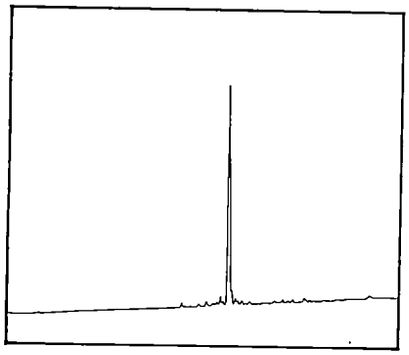
1 It's the Truly Efficient Way to Make Peptides

The Model 430A Peptide Synthesizer doesn't waste time, amino acids, or reagents. It consistently produces high yields of quality peptide which reduces post-synthesis purification and characterization significantly. You get more peptide for your effort *and* for your dollar.

2 It's More Flexible, Easier to Operate

The 430A meets the needs of every user whether new to peptide synthesis or very experienced. Software is written in plain English using familiar terminology. All control is implemented by simply touching the screen. Standard synthesis cycles and functions can be selected or new ones designed quickly and easily.

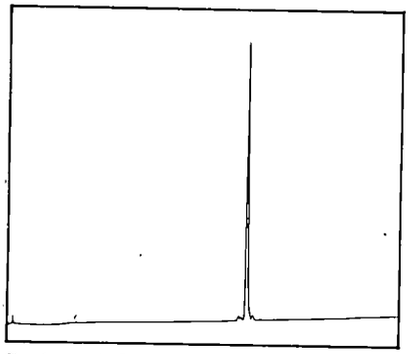
3 Its Chemistry is Proven and Unique



High stepwise yields, high purity and reproducibility are routine. Each step of the chemistry is specific to the requirements of the various amino acids. Coupling failures are eliminated or greatly reduced resulting in fewer double couplings. Both *t*-BOC and FMOC chemistries can be accommodated.

4 It Produces Superb Short Peptides

Step Yield (% Coupled) Standard ABI *t*-boc cycles, version 1.0



PEPTIDE SEQUENCE	LEU	HIS	PHE	PRO	HIS	ILE	TYR	VAL	ARG	ASP	AVG. STP. YIELD %
Ninhydrin Analysis	•	96.7	99.7	99.7	†99.6	98.9	99.5	98.3	99.5	99.4	99.0

Angiotensin I, Crude

mobile phase	0.1% TFA/CH_3CN
gradient	0 to 60% in 60 minutes
flow rate	1.0 mL/min
detector	216 nm
column	Brownlee, C-8, 300Å, 10μm 4.6 mm x 250 mm

Angiotensin I, HPLC Purified

mobile phase	0.1% TFA/CH_3CN
gradient	0 to 60% in 60 minutes
flow rate	1.0 mL/min
detector	216 nm
column	Brownlee, C-8, 300Å, 10μm 4.6 mm x 250 mm

Panels A, B and C are isometric responses of two different Ile^5-Angiotensin I—a synthetic standard and the 430A-produced, purified peptide—on three separate rabbit aortic strips. The responses produced by the Applied Biosystems Ile^5-Angiotensin I were not significantly different than those of the standard. Sample concentrations were: in panel A, 564 ng/mL; in panels B and C, 500 ng/mL.

These response data were furnished by Drs. M. C. Khosla and A. Husein of the Cleveland Clinic Foundation.

*These are amino acid resin samples from the first coupling of the HOBT ester double couple cycles used for the Arg, Asn and Gln couplings. The calculation of the average step yield excludes these (*) residues. †Ninhydrin values for amino acids coupled to proline are not quantitative.

M-67-G ($CONH_2$), Crude

mobile phase	0.1% TFA/CH_3CN
gradient	0 to 60% in 60 minutes
flow rate	1.0 mL/min
detector	214 nm
column	Brownlee, C-8, 300Å, 10 µm 4.6 mm x 100 mm

M-67-G, ($CONH_2$), Purified

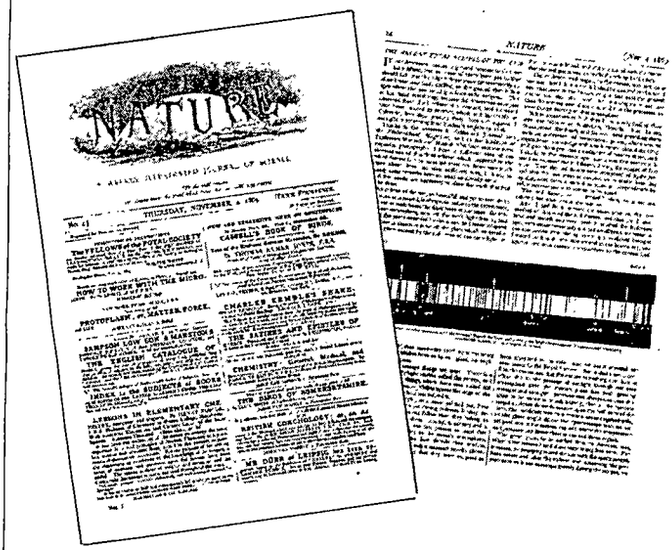
mobile phase	0.1% TFA/CH_3CN
gradient	0 to 60% in 60 minutes
flow rate	1.0 mL/min
detector	214 nm
column	Brownlee, C-8, 300Å, 10 µm 4.6 mm x 250 mm

Met-67-Gly ($CONH_2$) is a 69-residue peptide that is part of a 124k-dalton plant protein, Avena Phytochrome. This peptide is from an area of the Phytochrome protein that has been shown to be essential for complete biological activity. Although sequence analysis suggests the purified product contains minor peptide impurities, initial experiments have shown good peptide binding activity to antibodies made against the native protein. Work is continuing with efforts to map the exact reading frame of these antibodies by using deprotected, resin-bound peptides directly in the antibody binding assays.

This peptide was synthesized for collaborative research with Dr. Peter Quail, University of Wisconsin—Madison

You Can Prove It for Yourself

Compare a 430A-synthesized peptide made to *your* specifications (and at a very reasonable price) with what you've been getting so far. The quality will convince you that the 430A is the first choice of more people who make peptides.



For more information, contact Jan Bowen at our U.S.A. office, your local Applied Biosystems Representative, or indicate Reader Service Number 218

NATURE VOL. 321 5 JUNE 1986

Voltage-sensitive dyes reveal a modular organization of ocular dominance and orientation selectivity in the monkey striate cortex. In the cover picture (part of Fig. 5*b* on page 583), colours represent a gradient of orientation selectivity, with orange, yellow, green, blue, red and black indicating increasingly rapid rates of change in the orientation response. See also *News and Views* page 564.

Heraeus

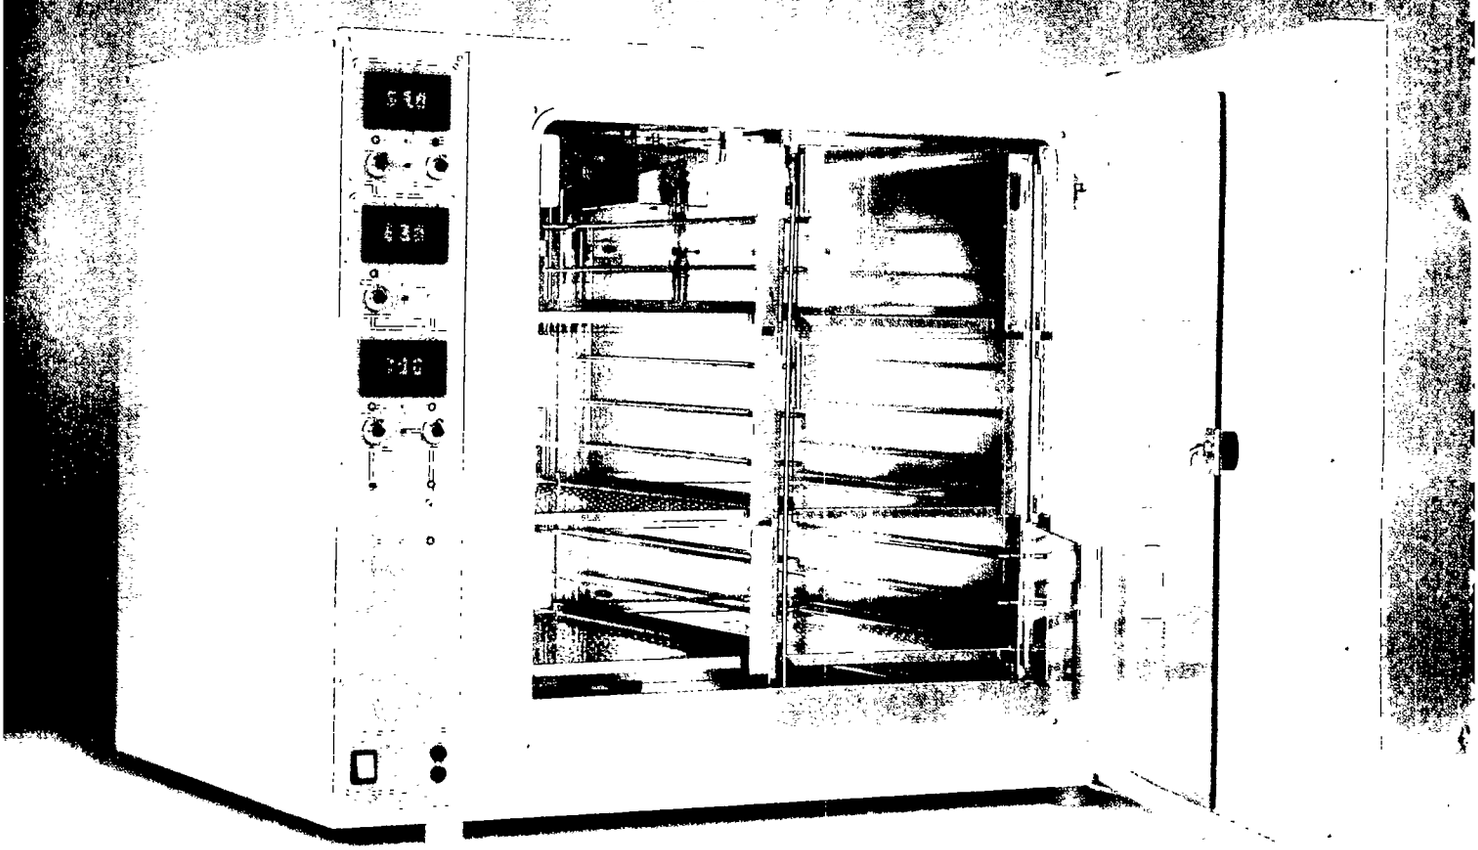
CO_2 Incubators

Experience and service: Nothing can replace them

- Competent supplier of equipment for cell labs worldwide
- More than 20 years of experience with high-quality CO_2 incubators
- Close co-operation with leading research institutes at home and abroad
- Detailed sales guidance and instruction
- Installation and putting into operation by own team of specialists
- Everything from one supplier: numerous peripheral units and special fittings available

Indispensable technical advantages

- Exact adherence to in vivo parameters by means of patented CO_2-Auto-Zero system: no drifting of the CO_2 content
- O_2 Clark electrode: automatic zero correction at the press of a button
- High constant humidity or psychrometric humidity control
- Perfect protection against contamination provided by copper inner casing or heat sterilization
- Exceptionally short recovery times due to heavy-duty heating and control system



Heraeus: Recognized symbol of quality in cell research

Heraeus incubators are trend-setters in their quality, perfection and built-in know-how. So before you buy a CO_2 or O_2 incubator, make sure to find out in detail about the many advantages and extras of the Heraeus models

- B 5061 CO_2-Auto-Zero
- Cytoperm® and
- B 5060.

The scope of our range means that we provide "the perfect fit" for every in vivo situation.

Heraeus: For decades a leader in the sector of accurate cell research

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

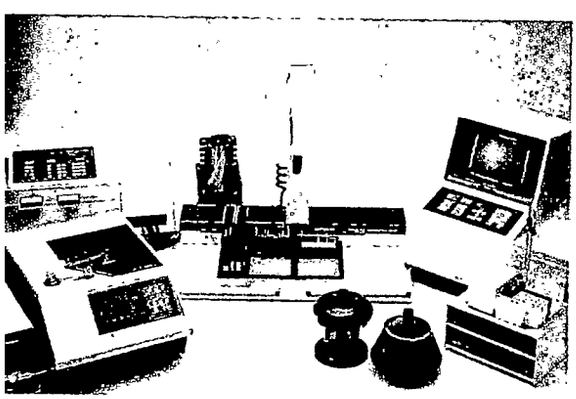
Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.



Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts or proofs sent by air courier should be declared as "manuscripts" and "value $5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

LIFE SCIENCE LEADERSHIP:

We're with you every step of the way... and before.

Before?

The accuracy of the analytical process is only as good as the preparation that takes place before the measurements are made.

But in addition to the care which must be exercised, sample preparation and handling can be tedious and extremely labor intensive.

Beckman's commitment to provide solutions to this crucial area of laboratory operations continues with new advances that increase lab productivity and optimize efficiency.

It begins with our new Biomek™ 1000 Automated Laboratory Workstation, a unique robotic system designed specifically to improve throughput and productivity in sample preparation and handling.

The new Biomek 1000 joins an illustrious line-up of sample preparation and handling solutions that includes batch and automatic samplers for virtually unattended analyses of large sample batches using HPLC systems and UV/Visible spectrophotometers. And a self-operating dissolution testing system that integrates sample handling with data gathering.

The Biomek 1000 and other Beckman systems for sample handling and preparation exemplify our commitment to being with you in every step of your laboratory process. Not surprisingly because, here at Beckman, we consider our efforts to be part of a permanent partnership with the entire life science process.

The commitment continues. For more product information, contact your local Beckman representative. Or write to: Beckman Instruments, Inc., 2500 Harbor Boulevard, Mail Station E-33-D, Fullerton, CA 92634-3100.

Reader Service No.19

nature

NATURE VOL. 321 12 JUNE 1986

A new theoretical model for the tip splitting phenomenon: an object initially grows by adding successive circular rings, then suddenly forms a random proliferation of bifurcations. This ubiquitous phenomenon is especially striking in developmental biology and fluid mechanics. Six successive snapshots of this growing fractal structure are indicated by six different colours. The tips screen the inner regions, as a newly formed region rarely touches the older regions. See p. 663.

FPLC*pure*™ MODIFYING ENZYMES

Pharmacia's 30 years of pioneering in biomolecule purification techniques has resulted in the remarkable state-of-the-art FPLC® System.

Pharmacia P-L purification expertise utilizes optimized FPLC technology and offers you modifying enzymes of unsurpassed purity and reproducibility unique in the biotechnology market.

The label FPLC*pure* on the package of a Pharmacia Modifying Enzyme is your guarantee that this batch of enzyme is functionally identical to the last batch you bought and will give the same outstanding performance.

A working partnership with Pharmacia gives you dependability and unique solutions that greatly improve your molecular biology applications.

Next week in *Nature*:

- Merging galaxies
- Earth's orbit and climate
- Antarctic ozone depletion
- Sweden's acid rain
- Ancient zircons
- Man's arrival in South America
- α-Thalassaemia and malaria
- Inhibins and FSH
- Primate α-globins
- Axon growth
- Prehistoric oligonucleotide synthesis

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc., should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts or proofs sent by air courier should be declared as "manuscripts" and "value $5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

WHAT IMPACT ARE NEW BIOTECHNOLOGY TECHNIQUES HAVING ON MEDICINE WORLDWIDE TODAY?

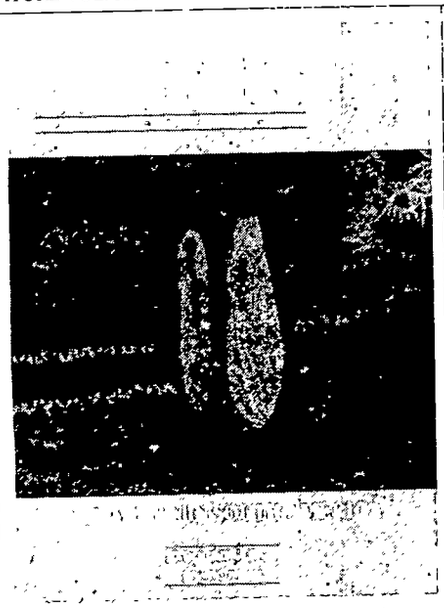
NEW TECHNOLOGY in BIOTECHNOLOGY

MOLECULAR BIOLOGY IN MEDICIN
a survey of its achievements and its potential

June 18–20 1986
at the London West Hotel

It is clear that the modern techniques of biotechnology are set to have a major impact on medicine. Over the next few years many new opportunities will emerge. This important conference will provide a wide-ranging survey of the most recent research in the fast changing field of molecular biology in medicine, and a look into the future. If you want an opportunity to see and hear for yourself what leading exponents have achieved in recent years — and to learn what new opportunities are on the horizon, come and join us.

The **CONFERENCE FEE** is just £189 plus VAT for the three days of the conference. The daily rate is £69 plus VAT. This includes entrance to all sessions, mid-morning coffee, afternoon tea and reading material. Group discounts are available on application to Janine Slipman, see booking form for address and phone no.



ACCOMMODATION has been reserved in the London West Hotel for conference participants. A booking form will be sent to you as soon as we receive your registration.

TECHNICAL SEMINARS and **POSTER SESSIONS** will be held each day. Anybody wishing to present a poster should send a title and a brief synopsis.

NATURE VOL. 321 19 JUNE 1986

Sao Raimundo Nonato in north-east Brazil is famous for the richness of prehistoric art decorating the numerous rockshelters in the region. Carbon-14 dates from an excavation of one of these shelters, "Toca do Boqueirao do Sitio da Pedra Furada", establish human occupation beginning 32,000 years ago. This is the oldest site of Early Man presently known in America. The excavation is described on page 769 and discussed in *News and Views* on page 726.

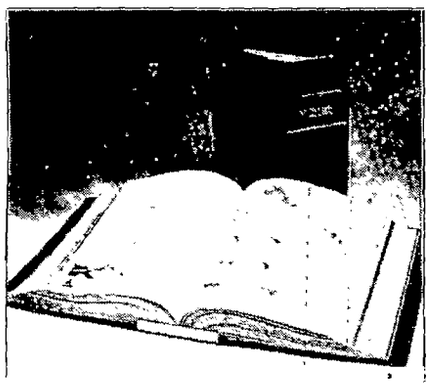
Something Special

Imagine the world's simplest operating ultracentrifuge. Add the most reliable drive ever designed—the Ultra-Smooth vacuum-encased induction system. Include automatic "Soft-Start," built-in diagnostics and the ability to run every Beckman high performance rotor. Top it off with a most attractive purchase price. And you have the new Model L7-55—the one you have been asking for.

With speeds to 55,000 rpm, forces to 408,000 *g*, integrated circuit logic and remarkably simple controls, the L7 is ideal for everyday applications. It's the perfect addition to the Beckman family of induction drive ultracentrifuges, joining the premier L8M models—the ultimate in centrifugal research tools—and the Benchtop TL-100 for rapid microvolume separations.

Use the L7 for the routine jobs. Save your L8M for investigations where microprocessor control and memory are an advantage, where delicate gradients call for acceleration/deceleration versatility, where computer interfacing is needed for remote control or record keeping. When you want to cut run times for these jobs by more than half, use the TL-100.



The workaday Model L7-55: it's something special—especially for you!

To get better acquainted, ask for Brochure SB-667. Beckman Instruments, Inc., Spinco Division, 1050 Page Mill Road, Palo Alto, CA 94304.

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc. should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc. should be identified on one copy of the manuscript at their first appearance.

References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts or proofs sent by air courier should be declared as "manuscripts" and "value $5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

Several hundred new products and services will be announced this year. But it's unlikely the press will give you all the facts – answer all your questions.

You need to talk to the people responsible.

The makers. The suppliers.

Because only then can you expect to get the information you want to make valued judgements.

NOT TO BE MISSED

Which is why Bio '86 at London's Olympia, September 23rd to 25th, is not to be missed.

Bio '86 is the new exhibition and conference for the biotechnology and genetic engineering industry.

And it has all the right credentials.

It was created with the active support of the AABB (Association for the Advancement of British Biotechnology) in collaboration with SIRA (Scientific Industries Research Association).

And it sensibly justifies the title "biggest and best."

With the largest, most comprehensive display of biotechnology products and services ever mounted in the UK.

And it's international.

Visitors and delegates to Bio '86 will be coming from all over the world. With strong representations from Europe and America.

Not just biotechnologists (although there will be a significant number), but research directors, department heads, biochemists, process engineers, chief technicians, lab technicians. Bio'86 is an allgrades event.

And it's part of the British Laboratory Week, this country's most successful scientific get-together – over 450 stands, nearly twice that number of exhibitors.

FREE TRANSPORT

Admission to Bio '86 is gratis. Free! Just return the coupon on this page.

Better than that, the Organisers will lay on free transport for you.

Make up a party of eight or more. We'll arrange for you to be collected from your lab or company Head Quarters and bussed to Olympia.

This is a terrific offer and should be taken up before our troglodyte accountant returns from holiday and reads us the Riot Act!

For this reason we suggest you use our:

CONFERENCE INFORMATION HOT LINE (0799) 25495

Leave your name and address on our answering service. Full details of Bio '86 plus tickets (you must say how many you want) will be sent by return post.

Another money-saving Bio '86 advantage is college accommodation. From as little as £17.00 + VAT per night.

Or, if you prefer to stay in a higher-priced hotel, we can arrange that too.

Use our Hot Line or tick the appropriate box on our coupon.

On registration at Olympia, you'll get a free exhibition catalogue. A handy item. It doubles as a guide and new product directory for the year ahead.

Bio '86.

You really should visit.

It's a thoroughbred event.

CUT AND MAIL FOR YOUR FREE TICKET!

The ELISA productivity machine.

Bio-Rad's new Model 2550 EIA reader packs fully automated capability into a compact, affordable system that doesn't sacrifice performance.

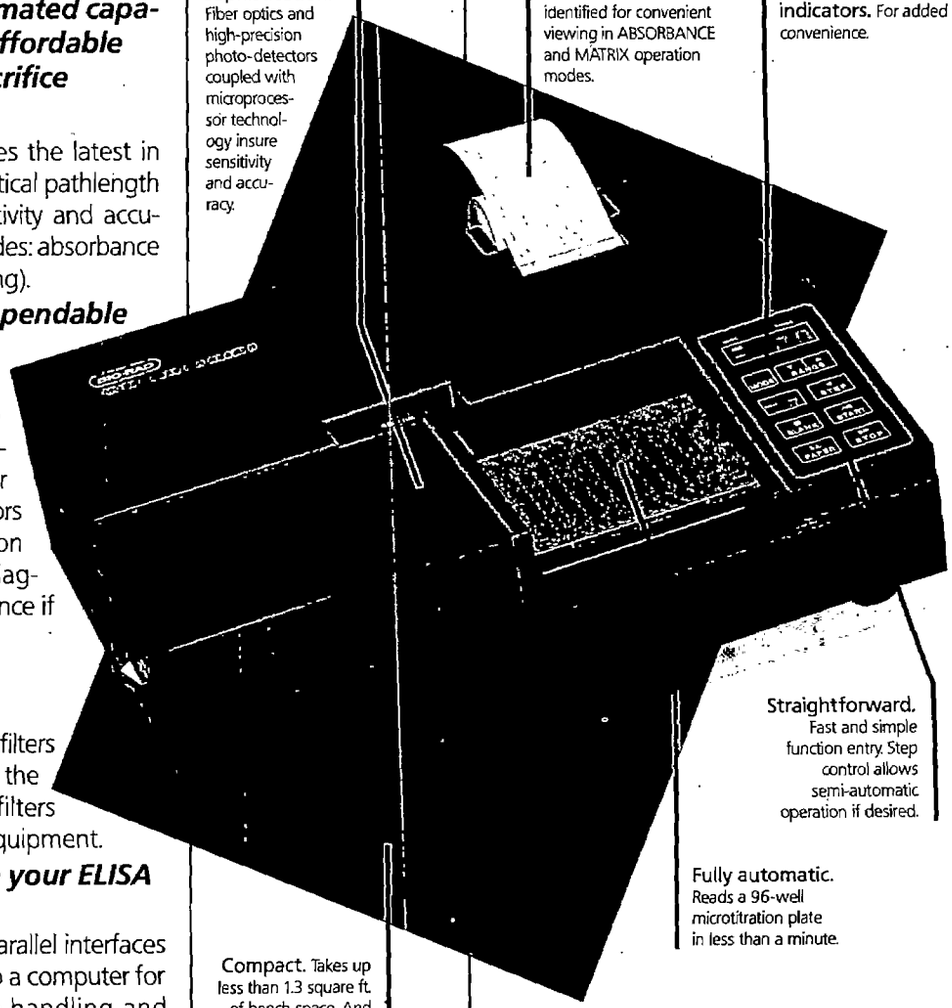
In fact, the 2550 combines the latest in fiber optics with a proven vertical pathlength design for exceptional sensitivity and accuracy in two measurement modes: absorbance and matrix (for rapid screening).

All this, plus simple, dependable operation.

All 2550 functions are entered on a touch-sensitive keypad with a minimum number of steps. Audible beeper and "ERROR" function indicators help to insure correct function entry. And on-board self-diagnostics let you know in advance if problems exist.

Multiple wavelength capability, too.

The 2550 is available with filters from 380 to 700 nm. Four of the more popular wavelength filters are provided as standard equipment.



More ways to increase your ELISA productivity.

With optional serial and parallel interfaces you can hook the 2550 up to a computer for high sample volume data handling and sophisticated data analysis.

For routine protein determinations, the 2550 and Bio-Rad's Protein Assay Kit combine for simple, accurate automated protein determinations—at rates up to 80 samples per minute!

And Bio-Rad also offers an extensive line of affinity purified antibodies, enzyme-antibody conjugates, pipets, tips, and plates for all ELISA applications.

In other words, the Model 2550 EIA reader is part of a comprehensive line of products developed for ELISA screening, protein determination, and related applications. It's a system that will save your time, money—and bench space.

Microprocessor sophistication. Fiber optics and high-precision photo-detectors coupled with microprocessor technology insure sensitivity and accuracy.

Easy-to-read data. Columns and rows are identified for convenient viewing in ABSORBANCE and MATRIX operation modes.

RANGE, ERROR, and OVERFLOW indicators. For added convenience.

Straightforward. Fast and simple function entry. Step control allows semi-automatic operation if desired.

Fully automatic. Reads a 96-well microtitration plate in less than a minute.

Compact. Takes up less than 1.3 square ft. of bench space. And that's not much!

Now linear to 2.0 absorbance units.

Put our ELISA expertise to work.

NATURE CLASSIFIED

Professional appointments — Research posts — Studentships — Fellowships — Conferences — Courses — Seminars — Symposia: Back Pages

GUIDE TO AUTHORS

Authors should be aware of the diversity of *Nature*'s readership and should strive to be as widely understood as possible.

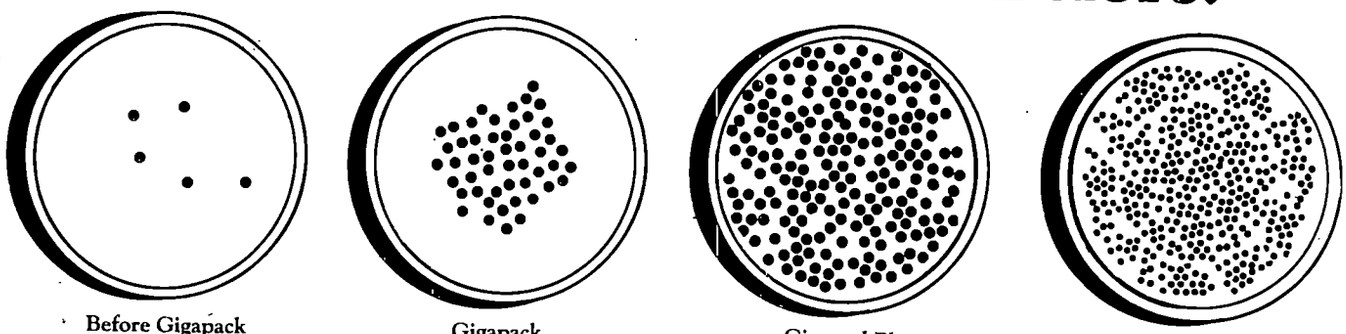
Review articles should be accessible to the whole readership. Most are commissioned, but unsolicited reviews are welcome (in which case prior consultation with the office is desirable).

Scientific articles are research reports whose conclusions are of general interest or which represent substantial advances of understanding. The text should not exceed 3,000 words and six displayed items (figures plus tables). The article should include an italic heading of about 50 words.

Letters to *Nature* are ordinarily 1,000 words long with no more than four displayed items. The first paragraph (not exceeding 150 words) should say what the letter is about, why the study it reports was undertaken and what the conclusions are.

Matters arising are brief comments (up to 500 words) on articles and letters recently published in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted.

Manuscripts may be submitted either to London or Washington. Manuscripts should be typed (double spacing) on one side of the paper only. Four copies are required, each accompanied by copies of lettered artwork. No title should exceed 80 characters in length. Reference lists, figure legends, etc, should be on separate sheets, all of which should be numbered. Abbreviations, symbols, units, etc, should be identified on one copy of the manuscript at their first appearance.



References should appear sequentially indicated by superscripts, in the text and should be abbreviated according to the *World List of Scientific Periodicals*, fourth edition (Butterworth 1963-65). The first and last page numbers of each reference should be cited. Reference to books should clearly indicate the publisher and the date and place of publication. Unpublished articles should not be formally referred to unless accepted or submitted for publication, but may be mentioned in the text.

Each piece of artwork should be clearly marked with the author's name and the figure number. Original artwork should be unlettered. Suggestions for cover illustrations are welcome. Original artwork (and one copy of the manuscript) will be returned when manuscripts cannot be published.

Important: Manuscripts of proofs sent by air courier should be declared as "manuscripts" and "value $5" to prevent the imposition of Customs duty and Value Added Tax in the United Kingdom.

Requests for permission to reproduce material from Nature *should be accompanied by a self-addressed (and, in the case of the United Kingdom and United States, stamped) envelope.*

Even More Efficient Than Before!

Before Gigapack | Gigapack | GigapackPlus | Gigapack Gold

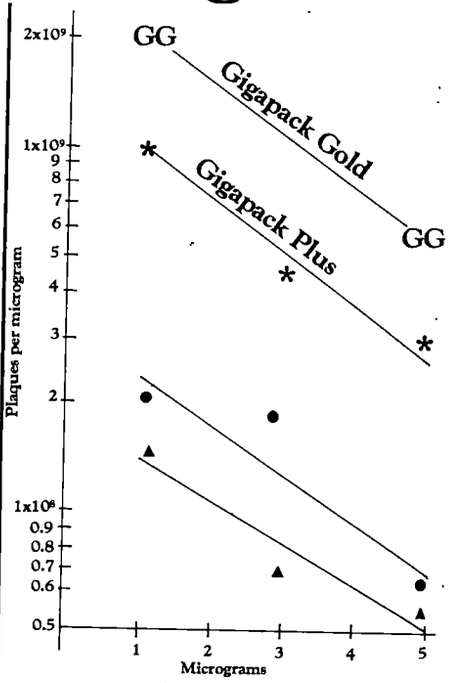
Gigapack Plus & Gigapack Gold

3 to 5 times better than the original!

Most in vitro lambda packaging extracts are made from Eco K12 derivatives, which express the Eco K restriction endonuclease system. Packaging extracts contain residual Eco K activity[1]. Thus genomic and cDNA inserts containing the sequences AACNNNNNNGTGC or GCACNNNNNNGTT are under-represented significantly in lambda and cosmid libraries. Eco K sites occur at a frequency of one in 8000 random nucleotides. Most 20 kb fragments will contain 2 or 3 Eco K sites; and approximately one in five cDNA inserts will have an Eco K site. Eco K sites can account for a 3 to 5 fold bias in DNA packaging efficiencies.

Gigapack Plus

Gigapack Plus is Gigapack without Eco K activity. It packages unmethylated DNA (such as eukaryotic DNA) 3 to 5 times more efficiently than the old Gigapack. The effect is most pronounced with large DNA inserts, and is striking with cosmids. But why take the 1 in 5 chance that your cDNA will have an Eco K site? In vitro methylation with Eco RI methylase does not protect against Eco K digestion.



The graph illustrates the superior efficiency of Gigapack Plus compared with two leading extracts. Note that Gigapack Plus outperformed the others 5 to 1, even when 5 micrograms were added to a single reaction. Gigapack Plus has the highest efficiency and highest total DNA *capacity* of any extract available. Even with these new improvements, price has remained stable. We even offer significant discounts for large purchases.

Gigapack Gold

For the connoisseur, we also offer Gigapack Gold. This is our highest quality extract, doubling the efficiency of Gigapack Plus. It too has no Eco K bias and offers the highest efficiencies available anywhere. For those really valuable libraries Gigapack Gold is worth the investment.

Figure Legend

Packaging efficiencies were compared using varying amounts of Eco K unmethylated (unprotected from Eco K cleavage — just like eukaryotic DNA) cI857 Sam7 DNA. The specified amount of DNA was added to a single packaging reaction according to manufacturer's instruction. All phage were plated on strain DP50 supF. Experiments were all performed in duplicate on the same day. *Gigapack Plus, GG Gigapack Gold, ● Popular single tube system, ▲Popular double tube system.

nature

NATURE VOL. 321 1 MAY 1986

What will emerge from Tokyo?

The economic summit meeting that opens in Tokyo on 4 May could be a chance to put the West's affairs in better order. But the precedents are discouraging.

THERE could be no better place than Tokyo for this year's meeting of the leaders of the seven large industrialized nations of the West. Although the city may not yet be the financial capital of the world, Japan as a whole has become the world's industrial pacemaker. Even as the participants are shuttled quickly from one event to another, they will not be able to avoid the question of how the most orderly of all the world's metropolitan conurbations can also be the source of repeated innovation which, elsewhere, is more usually marked by chaos. Those who can afford the time should stay on for a day or so after the two-day meeting; they will not be able in that time to come to grips with all the secrets of Japan's success, but they might be able to pick up a few tips that could help with the domestic problems awaiting their return and which will be waiting unchanged, as they have been for the past decade, unless this year's summit is markedly more successful than its predecessors.

Tokyo is planned as a largely economic meeting, and for good reason. These meetings became regular and annual only after the price of oil shot up in 1973; they were well established in the top politicians' calendar by the time of the 1979 meeting in Venice, when those present could do little but wring their hands about the second round of the price increase decreed by the Organisation of Petroleum Exporting Countries (OPEC). By that token, this year's meeting could have been an occasion for celebrating the demise of OPEC, at least temporarily, and for planning what should happen next. If the United States can avoid reading too many lessons to too many people about the horrors of terrorism, that could be a useful exercise.

Balance

What the Tokyo meeting might usefully do is to strike a better balance between the optimists and the pessimists about the likely course of events. The collapse of OPEC's policies has wonderfully increased the population of the optimists, who are especially thick on the ground where there are equity shares in industrial companies to buy and sell, and whose eagerness to buy has driven most of the world's stock exchanges to record price peaks (which means that shareholders forgo income now in the belief that there are capital gains to come). Nobody can conclusively quarrel with the view that the world stands on the threshold of a new period of economic growth from which everybody will benefit. The snag is that there is no evidence conclusively to support this cheerful view, nor sufficient evidence for the opposite conclusion that this may be the threshold of a time of honours. For the pessimists' case is not so much a case as a collection of gloomy speculations: what if countries such as Mexico should declare themselves bankrupt because selling oil at reduced prices will not allow them to service their debt? What if the US dollar, which now buys only two-thirds as many Japanese yen as at the beginning of 1985, should keep on falling? Or if the industrialized countries fearful of losing their place in the competition should seek to save themselves by trade protection, beggaring everybody in the process? A few years ago, when catastrophe theory in mathematics was fashionable, this would be recognized as a time of incipient bifurcation: events could go one way or the other.

World leaders may be no better able than the rest of us to tell which view is right, but what they decide in Tokyo could help to show which way the dice will fall. There are three groups of issues to be settled: money, trade and debt. The largest countries have been congratulating themselves in the past few months for having using their inner club (called the group of five) successfully to make the value of the US dollar decline. Central banks seem to have been able to trigger a substantial movement at very little cost, but may in the process have destroyed the source of the dollar's previous strength, the belief from which only a few sceptics dissented that it would always be a rock-solid currency. The problem now is whether bankers could as cheaply stop the continuing slide if they thought that necessary.

Usefulness

The devaluation will serve three useful purposes. By making imported goods and services more expensive in the United States, it will reduce the external deficit of the United States. Indirectly, it may help to simplify the funding of the US budget deficit, which means that interest rates will be given a further downward push. And it will mark a step towards realism, the recognition that industrial power has partly migrated from the United States, almost certainly for good. Even for the United States, this is a step towards enlightenment. The grounds for pessimism are different, and concern the capacity of the world's institutions, mostly financial institutions, to accommodate the rapid readjustments now under way. What can the summit-goers do to make the promise of prosperity less fragile?

Two things to begin with. The most urgent need is for a reaffirmation and an extension of the Western doctrine that trade protection is an abomination. The West free-traders echo closely St Augustine's plea to be made chaste, but "not just yet". The US government is rightly complaining about European agricultural protection through the Common Agricultural Policy of the European Communities, while protecting both its own farmers and a variety of other declining industries by quota arrangements that conflict with the spirit if not the letter of the General Agreement on Tariffs and Trade. In Europe as well as the United States, advanced industries and their sponsoring governments complain that Japan is selling unfairly in their mutual competition, whence another battery of quotas and "voluntary agreements" to limit imports. Japan is probably right to protest its injured innocence of these charges, but is equally guilty of what may be the most pernicious form of protection in modern circumstances, restraint on the free flow of capital. To ask that these and other restraints on trade should be promptly thrown out of the window would be to ask too much, but to ask that governments should plan eventually to practise what they preach is mere prudence.

The second urgent need is to face up to the reality of international debt. The lenders and the borrowers are at present playing chicken with each other, but everybody knows that the West will not, for example, let Mexico or the Philippines go bankrupt. Politically, these countries are too important, while the collapse of the commercial banks that would be carried with them would cause untold damage in the industrialized world. So

why wait until disaster stares these governments directly in the face? Why not find a way out of the mess before it actually exists? The US administration has shown signs of willing in this direction, although the Secretary of the US Treasury's plan for dealing with international debts (which would have the commercial banks lend more, but with an implicit government guarantee) will not be generally acceptable. A better and more durable plan is needed. That is what Tokyo should be for. □

What's in a name?

The latest name for the AIDS virus is in trouble before the christening is over.

EVERYTHING about Acquired Immune Deficiency Syndrome (AIDS) seems to be controversial. That will be many people's reaction to the report (see p.3) of the arguments that attend the launching this week (see p.10) of the proposed name for the causative virus. The Varmus committee which has laboured for more than a year on the design of a single name to replace the two now in common use will get none of the thanks it deserves for the trouble it has taken. The most serious danger now is that an important field of investigation already too much soured by contending passions will be further embittered by personal considerations. Everybody's interest is that a corrosive rivalry between research groups should be mollified.

The identification of the virus responsible for AIDS is in every sense a remarkable piece of modern history, the significance of which for the treatment of disease is not yet fully appreciated. AIDS as a recognizable disease is barely five years old. Its recognition as an infection, first on epidemiological grounds, is naturally more recent. The first published evidence that a virus is responsible is due to Dr Luc Montagnier, at the Institut Pasteur in Paris, and consists essentially of a number of clinical cases and an electron micrograph including virus-like particles. Soon afterwards, Dr Robert Gallo and his associates at the National Cancer Institute (NCI) of the US National Institutes of Health in Bethesda, Maryland, were able to publish evidence that virus-like particles isolated from patients with AIDS are indeed able to infect other lymphocytes in culture; with his then recent interest in human retroviruses infecting lymphocytes fresh in his mind, Gallo was naturally tempted to think of his virus as one of a series (of which there were then already two). This is how the Pasteur virus and the NCI virus are differently named; Montagnier's is called LAV (for lymphadenopathy-associated virus), Gallo's HTLV-III (for human T-cell lymphotropic virus). Further investigation, which has been breathtaking in its speed, shows the two viruses to be essentially identical, give or take the replacement of a sizeable percentage of the bases in the nucleotide sequence of the virus.

This would not be the first time the same organism has been discovered independently by two different routes. In the past, there has even been confusion of this kind about the naming of chemical elements. Ultimately, of course, there is usually a felt need to make sense of such confusion. What the Varmus committee has been doing, on behalf of the International Committee on the Taxonomy of Viruses, is to force the pace a little, to bring order to a field in which disorder appears rife. The snag is that this laudable attempt should have coincided with a serious dispute between the French and US groups. The two groups have been edgy about each other's proprietary interests in the discovery for some two years. Last year, after techniques for the diagnosis of AIDS antibodies were developed separately in Paris and Bethesda, the Pasteur Institute filed a claim against its US colleagues (or, strictly, against the US Department of Health and Human Services) on the grounds that US reagents were developed with the use of French material. The matter has been made to seem worse (but it may be only an appearance) by the discovery that one of the electron micrographs in Gallo's first paper about the virus was mistakenly an image of the French virus.

Trying to win agreement on a common name at a time like this is therefore a little like trying to win agreement on a national anthem in the middle of a civil war. It was courageous of the Varmus committee to attempt the task. (A letter from Gallo and his associates explaining how the mix-up happened, and remarking on some of the attendant issues, will appear in *Nature* next week.) Meanwhile, the committee's chances of winning acceptance for its proposals have been diminished by Montagnier's premature announcement of what the Varmus committee had decided. The issue has nothing to do with the recommended name but with the circumstances: bearers of important news are supposed to run on an inside track. It is understandable that Gallo should now be unwilling to use the recommended name for any but generic purposes; he was probably a reluctant member of the naming committee from an earlier stage.

There is nothing much that can be done about all this. It will not make sense to hope that there can be agreement on a common name for the virus that causes AIDS if one or other of the principal investigators in the field should decline to use it. Even if one should be compliant and the other should demur, enforcing commonality would be a disservice. That is why *Nature* will not attempt to lay down the law, but instead seek only to ensure that its readers are not confused. We shall (like our readers) wait and see. Meanwhile, the biomedical research community should do more than it has done so far to resolve the issue that has arisen. The Montagnier and Gallo groups stand out among several working in basic research laboratories that have thrown light on the way that AIDS infections work. Neither has yet cured a patient, but each has given hope to many. In passing, they have given everybody good cause to believe that the investigation of novel infections is now well within the competence of well-organized laboratories. It would be shabby, even disgraceful, if the contribution of these two men and their associates were not widely recognized, even by the principals. That is what the community owes its heroes, or near-heroes: for in this case, that of an infection for which there is still no therapy, the real heroes are the physicians who must deal with patients in ignorance of what may yet be possible. And, of course, the patients themselves. □

Cloud over Chernobyl

The first Soviet nuclear accident to be made public may bring unlikely comrades together.

LAST weekend's nuclear accident north of Kiev is a sobering reminder of the problems of running high-technology enterprises safely. The fact that the first sign of trouble was reported not from the Soviet Union, but more than 1,000 miles away, in Sweden, suggests that the Soviet managers of the plant that released the cloud of activity should have had a better telephone system at their disposal or that there should have been somebody able by other means to tell Sweden about the cloud of radioactivity on the way. Neighbourliness requires no less.

The important question, when the dust settles, is not so much how accidents like these can be prevented, but how we can learn to live with them safely. For, from time to time, even with nuclear plants (which go wrong less often than other kinds of machinery), accidents will happen. There is nothing particularly secret about the Chernobyl plant, whose general characteristics have been declared by the Soviet Union to the International Atomic Energy Agency at Vienna; it consists of six reactors, two still under construction, in which the neutron moderator is graphite and the coolant consists of steam (also a moderator). On paper, such a plant should have a degree of built-in safety. (Let coolant escape, and the chain reaction should be less efficient.) But something went wrong. The Soviet Union's neighbours have a right to know what it was, and also a right to some assurance that the same will not happen a second time. □

Virus nomenclature

Controversy over AIDS virus extends to name

Washington

MORE than a year of patient negotiations to choose a new name for the virus associated with acquired immune deficiency syndrome (AIDS) ended last week in a hectic torrent of letters, leaks and rearranged release dates. Two key members of the naming committee have refused to go along with human immunodeficiency virus (HIV) as a replacement for HTLV-III/LAV, but support for a new name is strong; HIV could well be the eventual choice.

The name change is proposed in a letter published elsewhere in this issue (see p. 10) and simultaneously in *Science*. The letter is the result of a year's deliberations by a specially empanelled subcommittee of the International Committee on the Taxonomy of Viruses (ICTV). Chaired by Harold Varmus of the University of California at San Francisco, the subcommittee consisted of the six members of the ICTV retrovirus study group (John Coffin, Natalie Teich, Kumao Toyoshima, Varmus, Robert Gallo and Max Essex), as well as seven members directly involved in AIDS research or familiar with the field (Ashley Haase, Jay Levy, Luc Montagnier, Steven Oroszlan, Howard Temin, Peter Vogt and Robin Weiss).

By February this year, the committee had tentatively agreed on HIV, and the name was proposed to ICTV's executive committee. David W. Kingsbury, who heads ICTV's human virus subcommittee, says that all 12 of the responses received so far from the 17 executive committee members are favourable to the new name.

But HIV never had unanimous support from Varmus's subcommittee. Nearly half of the members preferred the current compound name, HTLV-III/LAV. Others, including Gallo of the National Institutes of Health (NIH) in Bethesda, Essex of the Harvard School of Public Health and Temin of the University of Wisconsin, preferred human retrovirus (HRV), with numbers assigned sequentially for every new virus. But committee members were anxious to find a name that would eliminate disputes over priority of discovery; for that purpose, HRV was too nonspecific for most committee members.

Armed with a positive response from the ICTV executive committee, Varmus then sent to *Nature* and *Science* a letter proposing the new name, saying a full list of signatories would follow. But the announcement of new human retroviruses late in March dashed hopes for unanimity for HIV.

The new viruses, called LAV-2 by Montagnier of the Institut Pasteur and HTLV-IV by Essex, may turn out to be variations of the same virus. Montagnier announced his discovery at a meeting in Lisbon before it had been accepted for publication in any journal (see *Nature* **320**, 3; 1986). Montagnier's announcement

came slightly more than a week before publication (in *Science*) of Essex's discovery. Essex was incensed by Montagnier's action, and he informed Varmus that he would have nothing to do with the new name, already supported by Montagnier.

Essex says he had never been satisfied with HIV as a name for the AIDS virus. He feels that the name HTLV-III/LAV is so ingrained in the literature that it will not be possible to change it, and calls the committee's efforts "shortsighted". He is also concerned that the new nomenclature would not be appropriate for HTLV-IV, as it does not cause immune deficiency.

Shortly after Essex's decision, Gallo indicated that he would not go along with HIV either. Gallo's attitude hardened further when, two weeks ago, Montagnier delivered a lecture at NIH where he mentioned HIV. A reporter, alerted by Institut Pasteur's New York public relations company, attended the meeting, and a report that HIV would replace HTLV-III/LAV appeared in the *Washington Post* on 19 April.

Gallo was furious. Varmus had decreed that no subcommittee member should discuss the new name with the press before it appeared in a scientific journal. Outraged that Montagnier should have made his announcement "right under my nose", Gallo wrote to Varmus exhorting him to withdraw his letter to *Science* and *Nature*, and saying that he should reconsider the new name.

Varmus was also furious with Montagnier for leaking the new name prematurely, but felt that Essex and Gallo were being churlish not to go along. After consultation with editors John Maddox of *Nature* and Dan Koshland of *Science*, it was agreed that the letter proposing the new name would appear as soon as possible. A contentious sentence asking editors printing the letter to "urge" authors to use the new name was dropped in the final version.

As for the name itself, even Varmus concedes that HIV has problems, but he believes it represents a reasonable compromise. Several committee members conceded that HIV was not their first chose, but were willing to compromise and to accept it.

David Baltimore, who is heading a study of AIDS for the National Academy of Sciences Institute of Medicine, says the AIDS virus was "crying out" for a name change. Baltimore shares the opinion voiced by many that, because HTLV-III is too dissimilar from its numerical ancestors HTLV-I and II to share the name, a change is needed to eliminate confusion on that point. But supporters of the name HTLV, chosen originally by Gallo in the mistaken belief that it would be closely related to HTLV-I and II, argue that hepatitis A and B are even more dissimilar from each other than are the HTLV viruses, but that those two names coexist without controversy.

Gallo says that he used HTLV-III only after a protocol for naming new human retroviruses had been agreed by an international *ad hoc* committee formed at a Cold Spring Harbor symposium in September 1983. But it is precisely because controversy has arisen over the virus responsible for AIDS, says Kingsbury, that the committee has sought a new name

Steve Gillis of Immunex Corporation at Seattle, Washington, who is familiar with controversies over new names from his own experience with lymphokines, questions whether a name that is not supported by Gallo can win general support. In addition to Gallo and Essex, a prominent AIDS researcher who asked not to be identified indicated that he will not use the new name.

But support for HIV is already growing among people in the field. Baltimore has already begun to use the name, and Jerome Groopman of Harvard Medical School has included it in a draft of a paper he is preparing.

By the end of the week before publication of the Varmus letter, Gallo was insisting that he would never use HIV when referring to his original isolates, but he might consider using HIV to refer to a "generic" AIDS virus.

Formal endorsement from ICTV for HIV is expected to come in May. But, as ICTV chairman Fred Brown puts it, any name is acceptable "so long as people know what you are talking about".

Joseph Palca

British astronomy

Observatory move stirs passions

THE plan to move the Royal Greenwich Observatory (RGO) from its present location in Sussex to somewhere else in Britain has evoked mixed passions among British astronomers. If possible, feelings run even more strongly than in the high-energy physics community when British membership of the European Organisation for Nuclear Physics (CERN) was being examined more than a year ago. But British astronomers are divided between those who think RGO should stay where it is and those who wish it to be moved to one

or other of the three candidate locations.

The decision that RGO should be moved was taken by the Science and Engineering Research Council (SERC) in March (see *Nature*, **320**, 297; 1986). SERC is to decide at its meeting in June whether RGO should, while retaining its identity, go the Universities of Cambridge or Manchester or, alternatively, unite with the Royal Observatory, Edinburgh (ROE), on its Blackford Hill site.

SERC's announcement of these developments followed an invitation to seven British universities to offer hospitality to a transplanted RGO. Dr E.J.W. Mitchell, SERC's chairman, explained in March that the decision to move RGO had arisen in part from disappointment with the strength of its present relationship with university astronomers. Of the three future locations for RGO, the council said that Edinburgh was the most favoured.

Some of the fiercest reactions to this development have come from universities not now on the short-list of candidate locations. The University of Oxford, one of those invited to provide a site for RGO earlier in the year, is up in arms at what local astronomers consider to have been a change in the rules of SERC's competition when the finishing post was in sight. In a strongly worded protest to SERC, Oxford astronomers have complained that, when they had identified a building capable of providing the 2,000 m^2 of floor space required by SERC, they were told that the requirement of floor space had doubled.

According to a SERC spokesman this week, there is some confusion on this point. He acknowledged that there had been a change of specification, but said that the present requirement for 4,000 m^2 of space was intended to be a gross figure; usable floor space would be three-quarters of the total. This does not fully meet the Oxford contention that the hospitality the university offers includes a large workshop equipped for work in nuclear physics which will be under-used when SERC ceases to support the tandem electrostatic generator on the site.

The lobbying of the two universities on the short-list is, for Britain, unusually direct. The University of Manchester makes a great deal of its offer of rent-free accommodation, on the site of the Christie Hospital, for RGO. At Cambridge, on the other hand, it seems to be accepted that SERC would have to meet the cost of a building to house RGO, presumably out of the proceeds of the sale of the Herstmonceux buildings: SERC has said that the move will have to be self-financing. In the nature of things, the sale of the castle is at the speculative end of the real-estate spectrum.

Intellectually, Cambridge offers propinquity to the Institute of Astronomy and the Cavendish Laboratory, with RGO to be sited in the grounds of the university observatory adjoining the institute. Manchester, by contrast, emphasizes its own close academic links with other universities and polytechnics in the Midlands and northern England. In a letter addressed to all fellows of the Royal Astronomical Society, the Astronomer-Royal, Sir Francis Graham Smith, who is also director of the Jodrell Bank Observatory of the University of Manchester, argues first against the preferred move to Edinburgh on the grounds of geography, the tenuous academic link between the Edinburgh observatory and the university and by saying that the continued separate existence of RGO and the Edinburgh observatory offers the best scientific value. He then goes on, after declaring his interest, to put the case for Manchester on the grounds of geography and facilities.

Astronomers elsewhere appear mostly to wish that a decision could be avoided. All speak highly of the work done by the two public observatories in commissioning new telescopes on Hawaii (ROE) and La Palma (RGO); there is particularly high praise for the support offered by RGO to academic astronomers using the 2.5-m Isaac Newton telescope at La Palma.

This argument is lent support by the lack so far of an estimate of the savings that may result from the proposed move, which SERC says is being made on scientific grounds within the constraint that the cost of the move should be supported by the sale of assets. The staff at RGO has already shrunk from its peak of about 240 to a present complement of 190. By the time planned for the move in 1990, it is intended that the observatory's staff should consist of about 100 people in Britain with a further 30 at La Palma.

The opinions of the RGO staff are also divided, but favour Cambridge. A survey carried out last month (to which 55 per cent of the staff responded) showed that 80 per cent would be prepared to move somewhere, of whom 90 per cent gave Cambridge as their preference. Asked to identify the sites to which they would not move, only two per cent of the staff came out against Cambridge. In response to the same question, 60 per cent said they would not move to Edinburgh and 50 per cent dug in their heels against Manchester.

Meanwhile, a regional political lobby is forming to preserve RGO at its present site. The East Sussex County Council and the North Weald District Council, both of which have an interest in the tourists attracted by Herstmonceux, are seeking to influence official opinion, as are local members of parliament.

There is no precedent for political forces such as these influencing the autonomous decisions of research councils, yet SERC will need strong nerves if it is to stick to its timetable of a decision next month. Matters have not been much simplified by reports that Dr Harry Atkinson, the senior official of SERC in charge of astronomy spending (and also chairman of the European Space Research Organisation) had given the members of one committee the impression that there were political considerations in the decision not to vacate the Edinburgh site. Dr Atkinson explained on the telephone this week that he meant only that, in his opinion, SERC should pay attention to the regional distribution of its establishments, but even that may be enough for the Sussex lobby to keep the door ajar.

John Maddox

SDI in Japan

Growing interest in joint venture

Tokyo

AT the eleventh hour, two Japanese scientific groups have joined forces to organize a signature-gathering campaign across the country in protest against the US Strategic Defense Initiative (SDI). "Physicists and Mathematicians against SDI" claim to have gathered nearly 3,000 signatures from their colleagues at 145 universities and research institutes across the nation. But it looks as though their protest may be too late.

Last week, a report was submitted to the government from a fact-finding mission of government and business groups (see *Nature* **320**, 294; 1986). The 55-member mission had spent ten days in the United States visiting SDI-related research facilities and being briefed on the projects' technical aspects. The mission was the third to visit the United States but the first to include representatives from private companies, itself a pointer to the growing likelihood of participation.

Even before the mission left, business leaders had privately admitted that they had been approached by government and that a generally favourable attitude towards participation had developed. Their main worry, one said, is whether the United States would guarantee that SDI would be a long-term project and not susceptible to sudden cancellation. Without that guarantee, some of the smaller companies would find a commitment to SDI research too risky. Given these behind-the-scenes developments, it is no surprise that the fact-finding mission's eight-page report recommends that Japan take part in the "research phase of SDI".

The report describes SDI as being "non-nuclear" and aimed at abolishing nuclear arms, thus making it compatible with Japan's commitment to peace, enshrined in its constitution and in a Diet resolution never to permit nuclear weapons research. It also stresses that SDI is only a research programme and not a plan for deployment of a defence system. But the chief advantages it sees in participation are more practical.

The report says that progress has already been made in the SDI programme and raises the spectre of a "widening technology gap between the United States and Japan". It also asserts that there will be significant spin-offs for the civilian sector including new air-control radars and remote sensors from the surveillance, acquisition, track, kill and assessment (SATKA) section of SDI. The sensors used to detect heat from rocket exhausts will also find applications in medical sensors. Kinetic-energy weapons research will aid aircraft technology with development of new lightweight materials. And high-power lasers and particle beams can be used in the control of industrial chemical reactions. Altogether, participation will "greatly improve the level of related technologies in this country".

Further consultations will now take place and the final decision made by a group of five cabinet ministers — Defense, International Trade and Industry, Science and Technology, Foreign Affairs and the Cabinet Secretary — along with the Prime Minister. If the answer is positive, as is now expected, they will determine the form of Japanese participation. The decision is not expected to be in time for the Tokyo summit of the leaders of industrial nations next week.

With the SDI bandwagon already rolling, it is hard to see that a protest from scientists will have much impact. But many of those who have signed the petition opposing SDI are the very people – physicists, mathematicians and computer scientists — who might be expected to be involved in SDI research. They are concerned not only that science is being "increasingly militarized" but also that their research will be diverted into SDI and their publications become restricted "military secrets".

Alun Anderson

Animal protection

Critics assail West German law

Hamburg

THE Bundestag (the West German parliament) has now passed the amended form of the 1972 Animal Protection Act, introduced by the minister of agriculture, nutrition and forestry in the federal government, Ignaz Kiechle. But it seems unlikely that this development will silence the arguments about the use of animals in experiments that have become common in the past few years.

The new law is the first in a series of measures intended to cover several issues in the field of biological ethics. The dispute about animal experiments, involving industrial companies and scientists on one side and anti-vivisectionists on the other, has been especially fierce in recent months. Individual protesters continue to release experimental animals from institute laboratories, but the bombing of a Cologne laboratory last year has not yet been repeated.

On the face of things, the requirements of the new law are tough, and cover all experiments leading to "pain or injury of the animal", a definition that leaves the use of the organs of dead animals exempt from regulation. In future, investigators will have to justify the need for their use of experimental animals by reference to the investigation of the environmental impact of materials on human beings or the risk of new chemical substances used in medicine. The study of human and vertebrate physiology, like basic research in general, will be a valid justification of experiments.

The new law will require that laboratories where experiments with vertebrates are carried out must appoint animal protection officers (*Tierschutzbeauftragten*) who must be qualified physicians, veterinarians or zoologists, and who will be required to supervise the application of the new regulations, such as an interdiction of needless duplication of experiments.

The new law forbids the use of animals in the development and testing of weapons; animal tests are also forbidden in the testing of tobacco products, washing powders and cosmetics. While the immediate effect of the new law is to restrict animal experiments, there are provisions to encourage the use of alternative methods to the use of animals in research.

Authorization procedures are to be tightened, chiefly by the appointment of a network of commissions to supervise the authorization procedure. The animal protection organizations will have a powerful influence on the proceedings of these advisory commissions, having established the right to nominate up to a third of the members of the commissions.

The argument is certain to continue, if only because its philosophical and legal implications have not yet been talked out. Some jurists argue that the West German constitution (*grundgesetz*) is relevant in that a guarantee of human dignity on the principles laid down by Kant and Schopenhauer cannot also be used to justify the killing of countless animals so as to protect people from over-indulgence.

It is significant that there have been several recent decisions of the constitutional court to the effect that the "absolute" right of freedom of research can be in conflict with novel ethical principles, which may imply that guarantees such as this in the 1949 constitution may be mutable in changed circumstances.

Of the political implications of the new developments, there seems no question. The critics of the new law complain that "those to be controlled are the controllers", and their argument is consistent enough to continue at least until the next federal election in January 1987. The Social Democrats have said that they will amend the law if they win power; both they and the Greens also want the law to be extended to cover the extensive keeping of animals as pets. But scientists consistently oppose the new law as an impediment to research.

Jürgen Neffe

Japanese education

Further iteration towards reform

Tokyo

ATTEMPTS to reform Japan's educational system have taken another halting step forward with the publication last Thursday of Prime Minister Yasuhiro Nakasone's Special Educational Advisory Council's second full-length report.

The report met the barrage of criticism that has greeted every pronouncement of the special council (see *Nature* **319**, 347; 1986) and was preceded by the publication of counter-reports from women's groups, teachers groups and unions, proving, as other nations have found, that although it may be hard to effect educational reform, it is certainly not hard to whip up opposition to it. In the new report, for the first time, details begin to emerge of how universities might be reformed.

The central criticisms of the universities are that they are too inflexible, too homogeneous and do not make a contribution to the international research community commensurate with Japan's status as a world power. Furthermore, the universities are resistant to change and do not sufficiently influence educational policy.

The solution to this last problem is seen in the establishment of a "university council" which would have the right of direct access to the Minister of Education, Science and Culture. Its brief would be wide: as well as conducting surveys and collecting information, it would expect to proffer advice on the structure of the universites, their planning and construction, on what areas needed developing to provide trained manpower, the content of university education and the methods of teaching. There are at present a number of bodies representing the universities but none that can speak for all universities — including state and private universities and the junior (two-year) colleges.

To the problems of inflexibility and homogeneity come one familiar solution: the use of a credit system that would allow students to transfer between faculties, or even universities. If necessary, a special institution should be set up to grant degrees to those who have gained sufficient credits from several sources. Inputs to the universities could be made more diverse with quotas set for the enrolment of ordinary citizens and junior college graduates into the four-year universities.

Suggestions for the reform of university research begin with the surprising statistic that the ratio of graduate students to undergraduate students in Japan is the lowest of all the developed countries. In part, of course, this reflects the high number of engineering students who quickly enter industry. Less surprising is the recognition of the lack of technical back-up in the universities: the general rule is that if you want a piece of equipment you must build it yourself. To bring about reform, young people need better treatment.

The report gives the average age for completion of a PhD course as 27. To make things move faster, it is suggested that it should be made possible to complete a master's course in one year and a doctoral course in three years, with direct entry to a doctoral course after graduation possible for especially talented students.

Postdoctoral fellowships (of which there are still only a few hundred in Japan) should be made much more easily available. And thought should go to the establishment of an independent graduate university for research students. This is something those in the new research institutes for joint use by universities (like those at Okazaki) would particularly welcome, for without attachment to any particular university they have no ready source of graduate students. A graduate university could well find a home at Okazaki.

The role of "joshu", the lowly position of research assistant which is often the first rung on the ladder to professor but which is sometimes mistaken by professors as a post providing personal attendants, also needs to be looked at afresh, the report says. Low staff turnover is another problem: possible solutions are the usual early retirement, untenured short-term posts and contract research.

Reforms are,of course, expensive, particularly the provision of increased technical assistance, more fellowships, graduate universities and increased foreign exchange. The report points out that 330 thousand million yen will be spent on academic research this year. But estimates of how much reform of postgraduate education would cost suggest that the same amount again would need to be spent over the next ten years. This is unlikely to find favour with the Ministry of Finance, which is already complaining that spending on education is high enough. How high is high enough is hard to measure: the Japan Teachers Union claims that Japan's 1985 education budget accounted for 4.6 per cent of its gross national product compared with 9.1 per cent in Sweden, 8.1 per cent in The Netherlands, 7.2 per cent in the Soviet Union and 6.4 per cent in the United States. **Alun Anderson**

Soviet science

Lenin prizes return to basics

THIS year's Lenin Prizes for Science and Technology in the Soviet Union concentrate on fundamental research. Only two of the eight prizes awarded last week have any immediate relevance to the application of research results in production, hailed for the past two decades as the principal target for Soviet science.

Pravda's editorial preamble to the review of the prizes by Academician Anatolii Aleksandrov, president of the Soviet Academy of Sciences, still emphasizes the need to "accelerate scientific and technical progress", but the stress is now on the mobilization of "creative forces" in science rather than on the rapid implementation of results.

All but one of the awards are cumulative, for "cycles" of research and publications going back, in some cases, more than 20 years. The exception is the prize for Yurii Aleksandrov and his team from the Institute of Radio and Electronics of the Soviet Academy of Sciences and the Special Design Bureau of Moscow University, who won the prize for developing a special radar system for mapping the surface of Venus from the Venera-15 and Venera-16 probes. (This is the only prize-winning work for which Academician Aleksandrov mentions spin-off; the system, he says, has also been applied in the study of flooding, irrigation, salination, and soil and water studies in many parts of the Soviet Union.)

The longest "cycle" to be honoured is that of Academician Grigorii Devatykh, for his development of methods of obtaining high-purity volatile substances, which he began in 1959. Almost as early, and far more significant, is the starting date assigned to Dr Roman Khesin-Lur'e's work on "molecular principles of the functioning of the genome", which he apparently began to publish in 1960. Lysenkoism was then in full swing, and, according to the Soviet biological establishment, the gene was considered an "empty abstraction", accepted only by reactionaries. It would be interesting to know where Khesin-Lur'e published his work at that time, and what part, if any, he played in the overthrow of Lysenkoism.

Another interesting award is that for "inclusive processes in strong interactions of high-energy elementary particles and the discovery of scale invariance in these processes". Aleksandrov goes out of his way to stress that the new directions opened up by the work done at Serpukhov were afterwards confirmed at CERN and the Fermi National Accelerator Laboratory in the United States, and the team includes not only Soviet citizens but also Dr Nguyen Van Hue, president of the Vietnamese National Centre for Scientific Research. Lenin prizes are normally a purely Soviet affair, but this year there seems to have been a greater emphasis on their place in world science. **Vera Rich**

Biology at Berkeley

New order prompts fund-raising

Berkeley, California

THE University of California (UC) at Berkeley has started mailing thousands of glossy brochures to alumni and academic philanthropists in order to raise $50 million towards a planned $150 million refurbishment of its biology department. Spurred by the perception that Berkeley has lost pre-eminence in molecular biology and genetic engineering to other UC campuses, the scheme has snowballed into what must be one of the most ambitious reorganizations ever of an academic department.

Hundreds of reports and untold numbers of faculty meetings have resulted in a grand plan aimed at making the most of the new biology by merging and reshuffling most of the seventeen existing departments into three new super-departments based on affinities between research interests. The biggest problem at present is the condition of the life sciences building, completed in 1932 and by all accounts a continual frustration for its inhabitants. Researchers speak of overloaded power lines, frequent floods caused by faulty plumbing and insufficient storage space.

The grand plan calls for two new buildings (one for cell biology and molecular genetics, one for plant and molecular biology, microbiology and biochemistry) and the complete reconstruction of the existing life sciences building (for "integrative biology": organismic botany and zoology, ecology and some genetics, more or less). A special chancellor's advisory committee is making recommendations on all appointments.

Berkeley lacks the tradition of alumni support that private universities such as Stanford have relied upon. Undeterred, the Berkeley campus development office has compiled a table indicating how the required $50 million might be raised: one donation of $15 million, two of $5 million, and so on down to 40 gifts of $25,000. The state of California has agreed to pay two-thirds of the total cost of the project; overtures will also be made to foundations which have been traditional sources of support for private universities but which have been less generous elsewhere.

Not surprisingly, some professional feathers have been ruffled by the proposed reorganization, often of smaller departments fearful that they might be swallowed up, so disappearing without trace. Biophysics has yet to find a satisfactory home, and is pressing for joint departmental status with cell physiology, for example.

Another problem seems to be that biology at Berkeley is found in two largely autonomous units, the College of Natural Resources (which receives most of its funds from the state as an agricultural experiment station) and the College of Letters and Sciences. The College of Natural Resources, with its applied emphasis, has reservations about throwing in its lot with basic scientists, and some departments in the college (such as entomology) have indicated their desire to retain their independent status, although some of their staff might be affiliated with the new groupings.

Vice-chancellor Roderic Park sees the reorganization as an interim step towards a single new College of Biology (although no such decision has yet been approved) that would encompass both the existing colleges. Park believes that the device of the Experiment Station (which dates back to the last century) is an inefficient way of supporting research. In his view, California could buy better applied agricultural research if it were to put its grant money up for competitive bids from all comers instead of tying it to a permanent institution which is solely an administrative entity. But such a change would be resisted.

Although there is now general support for the planned changes, many details remain to be sorted out. Curriculum content, for example, has hardly been considered yet. Park says that one result of the reorganization that he would like to see is a better unification of theory and applied development. Wood replies that good researchers will continue to do good research, including collaborations, wherever they are. The debates on reorganization are far from over. **Tim Beardsley**

Engineered vaccines

Instant approval

Washington

THE US Department of Agriculture (USDA) has found a genetically engineered live-virus vaccine to be "pure, safe, potent and efficacious", and has enabled Biologics Corporation of Omaha, Nebraska, the manufacturer, to resume sales after a two-week voluntary suspension.

The suspension came about after charges appeared in the press that USDA had failed to follow proper procedures in approving the vaccine licence. USDA had not notified its own Agricultural Recombinant DNA Research Committee about the application (see *Nature*, **320**, 473; 1986). The vaccine, called Omnivac, protects swine from pseudorabies, a potentially fatal disease caused by a herpesvirus. Omnivac lacks a normally present gene for thymidine kinase that allows the virus to enter a latent state in an animal's nervous system, leading to future outbreaks of disease.

USDA's Animal and Plant Health Inspection Service conducted an "environmental assessment" of the vaccine based on available data, but critics of recombinant DNA research are not satisfied, calling instead for a full environmental impact statement. The Foundation on Economic Trends, headed by Jeremy Rifkin, has filed suit in federal court to suspend Omnivac's licence, and a congressional committee is also investigating USDA's procedures in this case.

Meanwhile, the Scientific Advisory Panel to the Environmental Protection Agency (EPA) has issued a favourable report on Monsanto's permit application to test a genetically engineered microbial pesticide in the field. Final EPA approval is expected later this month. **Joseph Palca**

Britain squeezed

THE proposed cuts in French research spending may have a knock-on effect elsewhere and, in particular, on British participation in the European Synchrotron Radiation Facility (ESRF) to be built at Grenoble. The British Science and Engineering Research Council (SERC), which has been keen to participate, has insisted that the principal members of the Grenoble consortium, France, Italy and West Germany, should in return join (and help pay for) Britain's Spallation Neutron Source (SNS) at the Rutherford Appleton Laboratory near Oxford. But now France, the least reluctant of the trio, seems less likely than ever to participate.

According to Pierre Papon, director-general of the Centre National de la Recherche Scientifique (CNRS), which with the Commissariat à l'Energie Atomique (CEA) would have been the leading French partner in SNS, the British have asked potential partners that the costs to Britain of participation at Grenoble should be matched, pound for pound, by European contributions to the planned second phase of SNS development.

"What advantage would there be in that for us?", Papon demanded last week. He is already conscious of the cuts that lie ahead, while CNRS and CEA apparently agree that French investigators already have "quite enough neutrons", and buying a share in SNS would entail an obligation for continuing operating costs.

Although the present ESRF partners would still like to see Britain contribute some 20 per cent of the Grenoble facility, Papon said last week that negotiations are also under way with a consortium of smaller European states, including Austria, Switzerland and Spain. If the negotiations succeed, Papon says, the remaining gap of 10 per cent may be closed without British participation. Robert Walgate

French budget cut

Chirac takes knife to fatted calf

AFTER five years of socialist expansion, French science is about to go into reverse under the new right-wing Chirac government. In the revised budget for 1986 announced last week, roughly half of all the budget cuts affect science and research. Under the new government, spending on civil research and development will fall by 9 per cent. Since the previous government had planned a 4 to 5 per cent increase in real terms, the result will be a real cut in resources for research and development, the first cut in spending since 1981.

In numbers, FF1,974 million (£84 million) is to be taken from research, most of it from the budgets set aside for the programmes in the gift of the old ministry of research and technology. Funds for the ministry's strategic research in support of new technology (*programmes mobilisateurs*), as well as for other research programmes independent of the research councils, are to be slashed by half, saving FF1,000 million.

Applied research will suffer most, although the chief French programmes in space and nuclear technology are to be protected. ANVAR (Agence National pour la Valorisation de la Recherche), intended to assist technology transfer to small businesses, will be cut by 40 per cent, and the French organization for alternative energy and conservation, AFME (Agence Française pour la Maîtrise de l'Energie), by a third.

The research councils are to lose 10 per cent of their operating budgets, but (with the exception of AFME) the large technology agencies such as the Commissariat à l'Energie Atomique (CEA) will be cut very little if at all. This means that the agencies transferred to the ministry of industry will be left intact but that the organizations left with the rump belonging to the ministry of research and higher education will have been cut.

One small mercy is that funds for the direct support of university research through the ministry of education will also be unchanged, although these are small compared with the sums awarded to universities by the research councils. As yet, the councils have not finally decided how to administer the budget cuts, but the medical council (INSERM) is likely to pass on a 10 per cent cut in laboratory operating costs according to a spokesman last week. The principal research council, the Centre National de la Recherche Scientifique (CNRS), which has to save FF230 million (£21 million), has yet to decide between the deletion of a "whole programme" of research and a general cut of 10 per cent in operating budgets.

The Chirac government is defending the cuts by saying that they are no greater than the amounts removed from the research budget by the Socialists in 1983, when the previous government was converted from Keynesian to conservative economics. But the government's critics point out that the cuts in mid-1983 were reductions of a budget which had been increased by 16 per cent over that for 1982. Then, there was a real increase of 4–5 per cent in science spending, not the reduction by that amount now in prospect.

M. Alain Devaquet, minister of research in the new government, says that he is "unhappy" with the cuts but that he "understands" the reasons for them. Speaking to journalists in Paris on Thursday last week, he insisted that research remains on the government's list of priorities.

At the same time, Devaquet disarmed fears that the French research councils CNRS and INSERM would be dismembered, as some members of Chirac's right-wing party were demanding during the election campaign. The minister now says that the research councils have some "small problems" which can be solved without radical change.

The new division of responsibility between the ministries of research and of industry has been partly clarified. Devaquet said last week that his ministry would be left with programmes (now halved in value) intended to encourage industrial research, while the industrial ministry would be responsible for the whole field of industrial development.

This seems to be a victory for those in the industry ministry who have always been suspicious of the upstart initiatives of the research ministry. By the same test, the development is a defeat for the influence of science on French industrial policy.

Robert Walgate

Military research

Campus protests at nuclear tests

Berkeley, California

THE University of California is yet again wracked by protests about military research on its campus at Berkeley. The university administration has now replied to campus petitions alleging failure to oversee the nuclear weapons laboratories it manages for the US government, saying it affirms that work at the laboratories must allow for progress towards nuclear disarmaments as well as design of nuclear weapons.

The issue arises in acute form at the University of California, which has had since the end of the Second World War contracts for the managements of the two principal weapons laboratories in the United States, as well as the Lawrence Berkeley physics laboratory.

The university's present position is spelled out in letters of reply sent to several groups of faculty petitioners who had written to university president David Gardner expressing concern over reports suggesting that nuclear bomb designers at the Los Alamos and Lawrence Livermore laboratories were designing unnecessarily sophisticated nuclear bombs that need constant testing. The charge was made most recently by Hugh DeWitt and Gerald Marsh, physicist at Livermore and at the IIT Research Institute, in the November 1985 issue of the journal *Bulletin of the Atomic Scientists*.

De Witt and Marsh argued that weapons laboratories are now operating under the assumption that continued testing of nuclear weapons will be possible, thus in practice making them necessary and making a comprehensive nuclear test ban impossible. This conflicts with declared US policy, at least until 1971, when weapons were designed on the assumption that there would eventually be a comprehensive test ban.

The current US administration is the first not to support the idea of a test ban in principle, arguing that continued testing is necessary to ensure the effectiveness and reliability of the weapons stockpile. One petition expressing concern was distributed on the Berkeley campus; its organizers say they believe several hundred faculty members wrote to Gardner on the topic.

The petition argued that any unnecessary testing represented a serious failure of oversight by the university, which manages the laboratories under contract. The university's management contract is voted on by the university every five years, and there have been enough close calls for the administration to be sensitive about allegations such as those of De Witt and Marsh.

Although nobody expects there to be any immediate changes at the weapons laboratories as a result of the university statement, faculty members opposed to the university's role regard it as a step in the right direction. William Frazer, the vice-president for academic affairs at the University of California, says the university is confident that weapons are not being designed deliberately to require nuclear testing and says there are no grounds for thinking the conduct of Livermore improper.

Nevertheless, Gardner is to ask a standing academic review committee to "delve deeper" into the matter, according to Frazer.

Tim Beardsley

Lawrence Berkeley laboratory

SDI brings back old problem

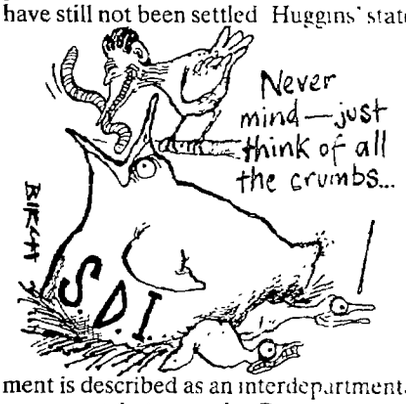
Berkeley, California

THE steep decline in federal support for magnetic fusion research and the concurrent growth in the Strategic Defense Initiative (SDI) budget are posing hard questions at Lawrence Berkeley Laboratory (LBL). Administrators and staff are having to confront again a question many thought had been settled in the early 1970s, when the laboratory's remaining classified research projects were either wound down or transferred to Lawrence Livermore Laboratory, 40 miles away.

Should LBL pursue weapons-related research for the Department of Defense that might, if successful, end up being classified? Recent hard-fought negotiations over publication restrictions on strategic defence research at LBL have now thrown the issue into new relief.

The ability of the national laboratories to set their own policies on classified research was challenged last summer, when the Department of Energy proposed (*Federal Register*, 26 August, p.34662) that they should agree to accept defence work, whether classified or not. That proposal was withdrawn after strong opposition from virtually all quarters, and led LBL director David Shirley to issue a clarifying statement last November to the effect that research at LBL could be "freely communicated to the scientific and technical community". Occasional use of laboratory facilities for classified work by investigators from other institutions would need case-by-case approval in advance by the director.

Similar questions have now been raised by research, supported by the SDI organization, into neutral-particle beam accelerators and high-current beam instability. The "very objectionable" restrictions on publication originally proposed by the SDI organization have been "fought very hard", according to LBL's general counsel Aleetha Owens. But the fighting is apparently not yet over.



The neutral beam research includes theoretical and experimental work on the development of hydrogen-ion accelerators, and was until recently supported by the Department of Energy's magnetic fusion programme; neutral beams formed by neutralizing hydrogen ions might be a means of heating plasmas to achieve conditions required for fusion. But the magnetic fusion budget at LBL has fallen from around $6 million to $2 million in the past two years, and substantial layoffs were likely without an alternative source of funds.

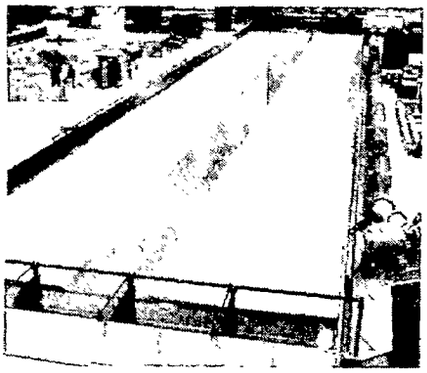
After what sounds like much heart-searching, investigators in LBL's accelerator and fusion research division decided last year to make two applications for SDI funds. A third proposal, for a radio frequency quadrupole accelerator to operate at extremely low temperatures in outer space, was vetoed by the division on the grounds that it had no feasible non-military justification. The result of the applications submitted was a contract for the work on neutral particle beams worth $2.2 million in the current year, with another $600,000 for theoretical studies of instabilities in high current beams. SDI also supports work at LBL on infrared sensors.

Laboratory staff say they have been left in no doubt that SDI research results must now be submitted for pre-publication review to ensure that classified information is not disclosed, although the research itself will not be secret. This apparently represents a change of policy by the SDI organization, which insisted last year that there should be no such restrictions on earlier particle beam work. A statement dated 14 February 1986 and signed by James Huggins of the the US Army's Strategic Defense Command now circulating among LBL staff says that, following pre-publication review, "any information deemed classified shall not be published".

Staff see Huggins' declaration as drawing a "mighty fine line" between classified and unclassified research. Huggins also states that new interviews and press releases on neutral particle beam work will require advance review for classification and that information that is "non-releasable based on the Militarily Critical Technologies List" shall be revised in consultations with the author.

Owens says she doubts that pre-publication review would be used to classify LBL research retroactively, but sceptics point to the free electron laser as an example of LBL research that was classified and moved to Livermore when it became militarily important. Although the SDI money at LBL is already flowing for the neutral beam and beam instability research, the official LBL line is that the publication conditions of the contract have still not been settled. Huggins' statement is described as an interdepartmental agreement between the Departments of Defense and Energy which has still not been agreed by the director of LBL.

A further complication is that the University of California, which manages LBL, has endorsed the "no classified research" policy and would take a keen interest in any erosion of that position.



Another concern, according to Jay Marx, assistant director of the accelerator and fusion research division, is the feeling in the division that SDI funds should not exceed 10 per cent of the division's budget because "frankly we're worried about the volatility of the funding". Director Shirley adds that if the laboratory is to undertake a multi-million dollar project, it should have confidence that support will continue for a substantial period, say ten years. But SDI is hoping to achieve breakthroughs by the early 1990s and "that is not research".

There is a conspicuous absence of security controls at LBL; all buildings are open, and visitors can enter the site without so much as a name check by hopping on a shuttle bus at the University of California's Berkeley campus, just a mile down Cyclotron Road. Researchers say they value the unrestricted exchange of ideas with university faculty and others, and are wary of the change in atmosphere that security restrictions would bring about.

Thus James Symons, head of LBL's nuclear chemistry division, says "most people much prefer the present system and hope we can keep it that way". Symons is clearly speaking for the majority in saying that he would react "very strongly and very negatively" to the imposition of restrictions on what he could publish. But the alternative, at least for some researchers, seems to be no research at all. Some might say the objectors had better decide whether they want to have their cake or eat it.

UK flood channel

THE UK Science and Engineering Research Council has this week opened a new flood channel facility built at a cost of £0.75 million at Hydraulics Research Limited, Wallingford. The facility is designed to investigate the interaction between flow in a river channel and over a flood plain; it is 56 m long and 10 m wide, with a discharge capacity of up to 1.1m^{3}s^{-1}. □

What to call the AIDS virus?

SIR—The undersigned are members of a subcommittee empowered by the International Committee on the Taxonomy of Viruses to propose an appropriate name for the retrovirus isolates recently implicated as the causative agents of the acquired immune deficiency syndrome (AIDS). Adoption of an internationally acceptable name for this group of viruses has become an important issue because of the widespread interest in AIDS and its origins and because of the multiplicity of names currently in use. Thus the several isolates of what are now evidently closely related members of the same virus group have been called lymphadenopathy-associated virus (LAV), human T-lymphotropic lymphotropic virus type III (HTLV-III), immunodeficiency-associated virus (IDAV), and AIDS-associated retrovirus (ARV). At present, two compound names (HTLV-III/LAV and LAV/HTLV-III) are also used in publications, while the colloquial name, the AIDS virus, is often used by the general press.

We propose that the AIDS retroviruses be officially designated as the human immunodeficiency viruses, to be known in abbreviated form as HIV.

We have considered several issues bearing on this proposal.

(1) The name should conform to common nomenclature for retroviruses, beginning with the host species ("human"), ending with "virus", and containing a word that denotes a major (though not the only) pathogenetic property of the prototypic members of the group ("immunodeficiency"). ("Feline leukaemia virus" and "mouse mammary tumour virus" are two well-known examples of such names for retrovirus species.)

(2) Though the name should clearly link the viruses to the disease with which they are associated, it should not incorporate the term "AIDS", which many clinicians urged us to avoid.

(3) The name should be readily distinguished from all existing names for this group of viruses and has been chosen without regard to priority of discovery.

(4) The name should be sufficiently distinct from the names of other retroviruses to imply an independent virus species, a group of isolates that can presumably exchange genetic information readily with each other but not with members of other known retrovirus species. These other species include the human T-cell leukaemia viruses (for example, HTLV-1 and HTLV-2), which will continue to be named according to a convention adopted by several leading investigators in September 1983. (Though roman numerals are often used to indicate the type of HTLV, arabic numbers were originally prescribed in the agreement and are thus used here.)

(5) Retroviruses isolated from subhuman primates and found to be genetically related and biologically similar to HIVs should be designated as immunodeficiency viruses of the appropriate host species (for example, simian immunodeficiency virus [SIV] or African green monkey immunodeficiency virus [AGMIV]).

(6) Because HIV isolates are numerous and display considerable genetic heterogeneity, particularly in the *env* gene, it will be necessary for each laboratory to assign subspecies designations to their isolates. We recommend that each laboratory adopt a code with geographically informative letters and sequential numbers to identify their isolates (for example, the 42nd isolate at the University of Chicago could be described as HIV [CHI-42]). Initially, the existing, well-characterized isolates, such as LAV-1, HTLV-IIIB or ARV-2, should be identified as such in publications to ease the transition to a unified nomenclature.

(7) Any future isolates of human retroviruses with clear but limited relationship to isolates of HIV (for example, more than 20 per cent but less than 50 per cent nucleic acid sequence identity) should not be called HIV unless there are compelling biological and structural similarities to existing members of the group.

We hope that this proposal will be adopted rapidly by the research community working with viruses.

JOHN COFFIN (Tufts University, Medford, Massachusetts, USA), ASHLEY HAASE (University of Minnesota, Minneapolis, Minnesota, USA), JAY A. LEVY (University of California, San Francisco, California, USA), LUC MONTAGNIER (Institut Pasteur, Paris, France), STEVEN OROSZLAN (Frederick Cancer Research Center, Frederick, Maryland, USA), NATALIE TEICH (Imperial Cancer Research Fund, London WC2, UK), HOWARD TEMIN (University of Wisconsin, Madison, Wisconsin, USA), KUMAO TOYOSHIMA (University of Tokyo, Tokyo, Japan), HAROLD VARMUS, chairman (University of California, San Francisco, California, USA), PETER VOGT (University of Southern California, Los Angeles, California, USA), ROBIN WEISS (Institute of Cancer Research, Chester Beatty Laboratories, London SW3, UK)

• An earlier version of this letter asked that journals publishing it should make use of the name HIV a condition for the publication of research articles. There is much to be said for the general use of a common name, while the present proposal seems to have much to commend it (except for the possibility of misreading the last two initials as a roman "four"). Nevertheless, *Nature* will continue its present practice of allowing its contributors to use whatever nomenclature seems to them appropriate, while reserving the right to add a clarifying note if this should seem necessary to avoid confusion. Editor, *Nature*.

Disposal of British civil plutonium

SIR—The stated position of the Central Electricity Generating Board (CEGB) on British civil plutonium (*Nature* **318**, 406; 1985) has for its keystone an apparent material inaccuracy of very considerable magnitude, namely, the claim that "no plutonium produced in CEGB reactors has been... exported for use in weapons". Three apparent facts indicate that the claim is false.

First, CEGB is party to a statement that "... approximately four tonnes..." of such plutonium has been exported to the United States under the provisions of the 1958 Mutual Defence Agreement and its 1959 Amendment, Cmnd 859 (*The Electrical Power Engineer*, p.163, August/September 1984).

Second, Paragraph C of Article V of Cmnd 859 specifies an *exclusive* use of this plutonium: "the preparation or implementation of defence plans". (Colloquially, this appears to mean bomb tests and bombs.)

Third, and setting the issue beyond reasonable doubt, a spokesman for the US government has recently stated that "...the Mutual Defence Agreement actually requires the United States to use *all* plutonium obtained from the United Kingdom under the Agreement for military purposes..." (*The Electrical Power Engineer*, February 1985, p38; my italics).

The apparent material inaccuracy is very considerable. Approximately 4,000 kg of plutonium is enough for a thousand bombs, perhaps two thousand if the design is sophisticated, more than enough to devastate the whole of Europe, or the whole of the Soviet Union, or both. Thus, the apparent involvement of the UK "civil" nuclear power programme in weapons production is on a very large scale indeed.

A similar, apparently false statement occurs in a written Parliamentary Answer published in the first weeks of the Sizewell Inquiry: "...no plutonium from the CEGB nuclear programme has ever been exported for use in weapons..." (*Hansard*, Commons, 4 February 1983, col. 206).

Is there inanimate memory?

It is too easy to forget that pre-Victorian physics ascribed memory to lumps of iron. Now this still surprising phenomenon has a mathematical basis to call its own.

EVERYBODY knows what is meant by hysteresis, chiefly from what school physics teachers have had to say. Take a piece of magnetic material such as iron, put it in a magnetic field whose strength can be varied and, starting with unmagnetized iron, let the strength of the magnetic field increase steadily. To begin with, the magnetization of the iron increases less quickly than the field; anthropomorphically, the iron hankers after its unmagnetized condition. But then the rate of increase becomes greater; magnetization grows on what the economists call an S-shaped curve, the kind of thing that might be represented by a factor such as $[1 - \exp(-x)]$.

The surprise is that the same happens on the way down. Decreasing the external magnetic field gives the impression that the lump of iron hankers after its magnetized condition. Plotting the values for magnetization and external magnetic field on a piece of graph paper, there is a gap between the two S-shaped curves. Many young people are asked to record the difference, but are rarely asked to think what it means. But these days, when school administrators are so concerned with technology, young people may be expected to know that the area of the hysteresis curve is a measure of the energy loss of a transformer using iron as a magnetic inductor.

The more interesting question is that of the physics of the process. How is it that a lump of iron can remember its past history in such a reproducible fashion that its hysteresis curve can be counted as a function of its constitution? To be sure, the area within the hysteresis curve is a function of the frequency with which the cycle is traversed (the faster, the greater the area), which implies that lumps of iron have not merely a memory, but a time-dependent capacity to forget. I.D. Mayergoyz from the University of Maryland has now provided a framework in which to ask how such odd behaviour may arise (*Phys. Rev. Lett.* **56**,1518; 1986).

Mayergoyz's starting point is in 1935, and the work of the German physicist Preisach who is said (a little disdainfully) to have constructed a model of hysteresis on "some hypotheses concerning the physical mechanisms of magnetization. Abstractly, of course, magnetization followed by demagnetization must entail some kind of energy expenditure. A magnetized state is ordered, and so has lesser entropy than that from which it was formed. Simple thermodynamics proclaims that achieving such a state in a finite time requires that some work should be done (which will eventually appear as heat). But that is no more illuminating about the underlying mechanism than the calculations economists make to show that a trade surplus (deficit) must always be balanced by an export (import) of capital, whence (in physics) concepts such as magnetostrictive friction, fashionable enough in the 1930s.

That is why the mathematical framework of the discussion may be helpful in its own right. Mayergoyz borrows heavily from the Soviet mathematician Kasnoselski, whom he describes as having distilled from earlier work a way of describing hysteresis. The problem is this. A hysteresis curve is a function in some appropriate space. An input, in the simplest case the changing strength of the external field as a function of time, yields an output characteristic of itself. If the speed of the transition from the unmagnetized to the magnetized condition is immaterial, or is ignored, there remains a problem in that the shape is a function of the initial and final values of the external field. More generally, at any point of the planar graph in which magnetization is represented as a function of external field, there is an infinity of curves that may represent the future behaviour of a lump of iron, each one dependent on a particular past history.

What emerges from this argument is a description very similar to what the statisticians would call a Markov system. The future behaviour (magnetization) of a lump of iron may be determined from a knowledge of its state at some instant and from a knowledge of the magnetic field then and at subsequent times. How could it be otherwise, when causality applies? So there must be something about the initial state that embodies the memory of recent past history. In dynamical systems, it may be the rate at which the system is changing on a microscopic scale (the velocity field); in the relatively static context of magnetization, the pattern of magnetization is the clue to the past.

The important part of Mayergoyz's result is his demonstration that it should be possible to calculate the properties of the operator that transforms the input function of the system (the external magnetic field) by means of a simple series of experiments in which the output (magnetization) is recorded. The demonstration is mathematical, and in a novel way, but the result is to suggest what the history of mathematical physics has consistently shown to be significant, the forging of relationships between functions of one kind and functions of another. The fact that, in the simplest case of hysteresis, that of magnetism, the results must accord with the thermodynamics of entropy and the explanation may lie in microscopic physics is, for the time being, irrelevant.

One practical implication of the argument stands out. Although a system showing hysteresis will behave in a particular way determined by its starting condition and the external influences upon it, there are general rules that determine the behaviour of systems exposed to extreme conditions that appear to be unaffected by the details of the case This is mirrored, in Mayergoyz's treatment, by the way in which the local microscopic conditions (say, local magnetic domains), which are the local repositories of memories of the past, will be smeared out or extinguished by extreme conditions.

What may this mean for the concept of memory? The simple and oversimple answer is that there can be no connection between inanimate physical systems such as lumps of iron and biological systems, some even blessed with what is called consciousness, in which memory must be an infinitely more subtle business. But can that in reality be the case? Nobody seriously suggests that human beings, who can remember the past, are on that account exceptions to causality.

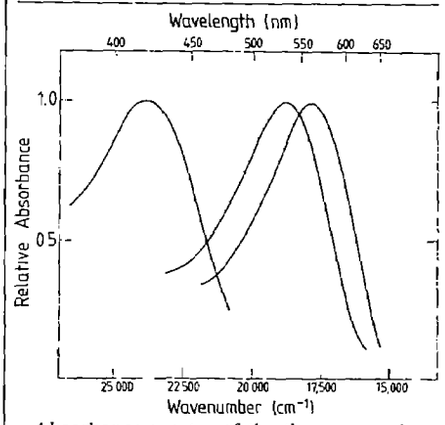
On the contrary, it is simplest to suppose that the state of the nervous system at any instant somehow mirrors past experience in such a way as to be able to regenerate images of the past that people call memories. What Mayergoyz has done is merely to show that such a model can represent what happens with inorganic materials that appear to have a memory of the past. That is not surprising in itself. The fun will come if it turns out that the equations explain some of the properties of memory as people know it. And if the physical analogy of magnetization shows that exceptional local patterns tend to be smeared out, what can explain in the human case the enhancement of especially vivid memories? It will be interesting if the tricks that people play on themselves can be derived from theorems of some kind. **John Maddox**

Molecular genetics

Understanding colour vision

from J.D. Mollon

THOSE with deficient or anomalous colour vision live in different subjective worlds from the rest of us. Psychologists have been slow to take an interest in molecular genetics, but two recent papers by Jeremy Nathans and collaborators[1,2] allow us to trace one detailed mechanism by which specific variations in DNA lead to individual differences in perceptual ability and in subjective experience.



We already know that normal colour vision depends on the presence in the retina of three classes of cone cell, each containing a different photopigment[3] (see figure). A fourth pigment, contained in the rod cells, underlies our colourless vision at twilight. Each of these pigments consists of a protein molecule to which is bound a derivative of vitamin A_1, 11-*cis*-retinal. The 11-*cis*-retinal is common to all the pigments, but the pigment absorbs maximally at different wavelengths according to the protein component. We know in some detail how the photopigment, embedded in the infolded membranes of receptor cells, initiates electrical signals when light is absorbed. To work out the wavelengths falling on a local region of the retina, the nervous system must then find the ratio of the quantum catches in different classes of cone. We have a good idea of how this is done[4,5]. And we know something of how the local ratio is compared with those measured elsewhere in the visual field, so as to give us accurate colour perception despite changes in the spectral composition of the illumination[6].

A major addition to our knowledge is provided by the new reports of Nathans *et al.*, who isolated and sequenced the genes that specify the three proteins underlying normal vision[1] and show how the genes are altered in cases of colour deficiency[2]. Nathans *et al.* began with a radioactively labelled fragment of DNA derived from the gene that specifies the rod pigment of cattle. With this probe they were able to identify in human DNA not only the rather similar gene specifying the human rod pigment, but also — by manipulating the experimental temperature and thus the readiness of DNA to 'hybridize' with a partially mismatching probe — they were able to identify other, rather less similar, genes that were likely to be those that specify the cone pigments.

To localize genes on particular chromosomes, probes were prepared from each of the genes and were hybridized with DNA from a panel of mouse–human hybrid cells that retain various subsets of the human chromosomes. From the pattern of results, the gene for the rod pigment is localized on chromosome 3 and one of the putative cone genes is localized on chromosome 7; the latter gene was taken to be that for the short-wave pigment because disorders of this pigment are known not to be sex-linked. The other genes lie on the q-arm of the X-chromosome. To distinguish genes for the middle- and long-wave pigments, Nathans *et al.* examined 25 colour-deficient men, collating subjective measurements of colour vision with the pattern of hybridization to probes derived from the X-chromosome genes. One curious finding was that more than one middle-wave gene might be present on the X-chromosome of a colour-normal man. But there was never evidence for more than one long-wave gene.

Evolution of colour vision

Why are inherited anomalies of the short-wave cones very rare whereas anomalies of the middle- and long-wave receptors are so very common? Why are the absorbance curves of our photopigments (see figure) so unequally spaced in the spectrum? Why is our visual resolution in space and time so poor when it depends only on signals originating in the short-wave cones of the retina? These and other features of human vision can be explained by an evolutionary scheme that has recently been suggested by various lines of evidence and is now supported by the work of Nathans *et al.*

Absorbance spectra of the three cone pigments of human vision. These curves are plotted from Table 2 of ref. 3 and are based on microspectrophotometric measurements of cone cells from human retinas. Peak sensitivities lie in the violet (short-wave), green (middle-wave) and yellow–green (long-wave) regions of the spectrum.

Widespread among mammals is an ancient, dichromatic form of colour vision that depends on a comparison of the quantum catches in a short-wave class of cones with peak sensitivity near 430 nm; and in a second class of cones with peak sensitivity varying between species but usually in the range 510 to 570 nm (ref. 7). The short-wave cones are sparse[3,8,9] and are probably used only for colour vision, whereas all the other business of daytime vision (such as spatial discrimination and the detection of movement or flicker) depends on the second, more numerous, class of cones. The explicitly chromatic information — provided by the ratio of quantum catches in the two kinds of cone — is carried within the visual system by a sub-channel that seems to be electrophysiologically and morphologically distinct[10,11].

No doubt a trichromatic, or three-variable, system of colour vision has more than once appeared in the mammals. But our own form of trichromacy seems to be shared only with the Old World monkeys and the apes[12]. We, and these primate relatives, enjoy a second dimension of colour vision, provided by a comparison of the quantum catches of the 530- and 560-nm cones. This comparison allows us to make fine discriminations in the red–green part of the spectrum. A distinct retinal channel may not yet have evolved to handle this second type of chromatic information. It is carried by a class of retinal ganglion cells that also extract spatial contrast[4].

The very recent differentiation of the middle- and long-wave photopigments has probably been achieved by duplication of a single gene on the X chromosome. Nathans *et al.*[1,2] confirm that the genes for the middle- and long-wave pigments lie in the same region of the X chromosome and they show that 96 per cent of the inferred amino-acid sequence is identical for the two. By contrast, the short-wave pigment shows only a 43 per cent identity with the middle- and long-wave pigments. This is comparable with the degree of identity between the latter pigments and the human rod pigment.

Colour blindness

About 8 per cent of males in Caucasian populations inherit some form of colour deficiency or anomaly. About 2 per cent are dichromats, requiring only two primary wavelengths to match all colours. From reflection densitometry of the living fovea[12], and from microspectrophotometry of individual receptors[13], there is direct evidence that dichromats lack one of the three cone pigments. Six per cent of Caucasian males are anomalous trichromats, who, like normal observers, require three variables in a colour-matching experiment but who make matches that are different from the normal[14]. The most favoured explanation of anomalous trichromacy is that one of the three photopigments is shifted in its spectral position.

What are the genetic abnormalities that

underline dichromacy and anomalous trichromacy? Visual scientists have probably entertained rather simple notions of these disorders, assuming that local mutations of the gene lead to local substitutions in the sequence of amino acids. Nathans *et al.* show that such point mutations are unlikely to be a common source of colour deficiency. Rather, they suggest, the trouble lies in the juxtaposition and the similarity of the genes for the middle- and long-wave pigments. During the formation of ova and sperm cells, when crossing-over occurs between members of a pair of chromosomes, misalignments of the DNA may occur in the region that encodes the middle- and long-wave pigments. Because the sequences are so similar, the long-wave gene on one chromosome might get itself apposed to a middle-wave gene on the other chromosome. If now crossing-over occurs and if the breakpoint lies in the duplicated spacers between genes, then one chromosome might lose its middle-wave gene and the other chromosome end up with two. If, on the other hand, the breakpoint occurs within a gene, a hybrid gene might be formed that consists of part of the long-wave gene and part of the middle-wave gene.

A man who inherits an X chromosome that lacks the middle-wave gene will be a dichromat, but if the X chromosome carries a hybrid gene, then the outcome will depend on where the breakpoint occurred at the time of crossing-over. There is one sub-region of the gene that seems to determine the actual spectral sensitivity of the resulting photopigment. If this sub-region is drawn from the long-wave gene, then the hybrid gene may produce a photopigment very similar to the normal long-wave pigment; the owner of this chromosome will again be a dichromat. But there may be a whole range of possible breakpoints and some of these may produce hybrid genes that encode photopigments with spectral sensitivities intermediate between those of the normal long- and middle-wave pigments; a man who inherits such a hybrid gene will be an anomalous trichromat. □

Taxonomy

Taxonomic tangles from Australia

from Tony Thulborn

IN THE next few years, many of the world's biologists may find themselves beset by taxonomic problems originating from Australia, where a pair of taxonomists is engaged in upsetting the stability of zoological nomenclature. So far, the pair have confined their attention to the Australian herpetofauna, which has been augmented by no fewer than 577 questionable taxa in the past 18 months. As a result, the comparatively stable nomenclature of Australia's reptiles has threatened to collapse into near chaos. Readers will be alarmed to know that the perpetrators now plan to turn their attention to the rest of the world's reptiles.

The saga began in 1981, when R.W. Wells undertook to edit a new periodical, *Australian Journal of Herpetology*, on behalf of the Australian Herpetologists League. Manuscripts were solicited on the understanding that they would undergo rigorous review by an editorial board comprising three renowned herpetologists. The first two issues of *Aust. J. Herp.* appeared on schedule, and the journal began to draw subscriptions from individuals and libraries throughout Australia and overseas. Things started to go wrong after Wells left his undergraduate studies at the University of New England (Armidale, New South Wales) and moved to Sydney. *Aust. J. Herp.* failed to appear for the next two years, although Wells maintained an address at New England and continued to receive manuscripts.

In 1984 Wells unveiled the third issue of *Aust. J. Herp.* It contained only one paper — a 56-page 'Synopsis of the Class Reptilia in Australia', by Wells and his co-author C.R. Wellington. Manuscripts that had been refereed and accepted for publication in order of receipt had been pushed aside for the Wells and Wellington paper; in fact none of the manuscripts processed by the editorial board has yet been published, although information from at least one of them was transplanted into the Wells and Wellington 'Synopsis'. Authors requesting the return of their manuscripts have so far met with no success. The third issue of *Aust. J. Herp.* revealed another surprise: its copyright had been transferred to an organization called 'Australian Biological Services', with Wells as 'Managing Editor' and Wellington as 'Advertising Sales Manager'.

The 'Synopsis' itself can only be described as shoddy work — there are no illustrations, and the diagnoses of taxa are so perfunctory as to be useless. Nevertheless, Wells and Wellington designated 33 new genera and 14 new species and elevated 208 synonyms or sub-specific names to the rank of species. The reactions of professional herpetologists ranged from disbelief to outrage. Most dismayed of all were those who found that their casual remarks about their research findings had been published as definitions for new taxa. At its annual general meeting in 1984 the Australian Society of Herpetologists discussed the possibility of suppressing the Wells and Wellington nomenclature, and several individual workers expressed their opinions in letters to *Herpetological Review* (**16**, 4; 1985).

Wells and Wellington were not deterred. In a 98-page publication dated 1 March 1985, identified as *Aust. J. Herp. Supplementary Series* No. 1, and titled 'A Classification of the Amphibia and Reptilia of Australia' they update their previous synopsis of the reptiles and proceed to treat the frogs in similar fashion. The document enumerates 66 new genera (9 of them resurrected from synonymy) and 256 new species (119 of them as resurrected synonyms). It also claims to designate lectotypes for 108 species.

In the bibliography to this second paper there is a list of more than 500 papers said to have been published by Wells in *Australian Herpetologist* since 1983. The existence of those papers is questionable: *Australian Herpetologist* is a 'phantom' publication that cannot be located by librarians, and Wells has not responded to requests for copies of his papers. Also mentioned in the bibliography is a 10-volume work on 'The Herpetology of Australia' by Wells and M. Peterson; this is stated to be 'in press' under the imprint of Australian Biological Services.

Wells and Wellington have created much confusion. Thanks to the convenience of modern word-processing equipment they have been able to exploit existing databases (for example, *The Zoological Catalogue of Australia* Vol. 1, Reptilia and Amphibia) and to re-shuffle them into chaos. The resulting taxonomic work is hopelessly inadequate. Names have been coined for animals on the grounds that they were mentioned by previous authors as local variants. Other taxa are based on nothing more than a reference to a photograph published elsewhere. Type specimens are not identified (unless their registration numbers appear in existing

publications). In several instances there is an attempt to designate a lectotype from an unseen series of syntypes by the ploy of nominating the 'large specimen'. More than 300 names have been elevated to species rank without any explanation or definition beyond "We herein resurrect from synonymy . . .".

The choice of formal names is odd, to say the least. For example, Wells and Wellington introduce the genus names *Licentia* (meaning 'freedom to do as one pleases'), *Phthanodon* ('to anticipate' or 'to do first'), *Contundo* ('to crush') and *Solvonemesis* ('to set free the goddess of retributive justice'). Then there are names that can only be regarded as frivolous: the bestowal of a patronymic species on the Australian Prime Minister, the naming of a species for Telecom Australia, and *Vaderscincus* ('named for Mr Darth Vader'). The name *Eroticoscincus* needs no comment.

While the taxonomic practices of Wells and Wellington would not be tolerated in conventional publications, it is not absolutely clear that they contravene the rules and recommendations of the International Code of Zoological Nomenclature. Unfortunately, it seems certain that some of their name-games will amount to technically valid combinations.

What is to be done? First of all, biologists outside Australia should be alerted to the situation. Wells and Wellington have placed themselves beyond the pale of legitimate science, and their publications and taxonomic revisions should be treated with extreme scepticism. The Australian Society of Herpetologists plans to approach the International Commission on Zoological Nomenclature with a view to seeking formal suppression of the Wells and Wellington nomenclature. However, such a procedure could be expensive, protracted and somewhat uncertain in its outcome — especially if the Commission refuses 'blanket' suppression and examines each of the 577 cases on their individual merits. Meanwhile, it may suffice that taxonomists are aware of what has been happening to the nomenclature of Australian herpetology. □

Ocean Drilling Program

Mid-Atlantic bare-rock drilling and hydrothermal vents

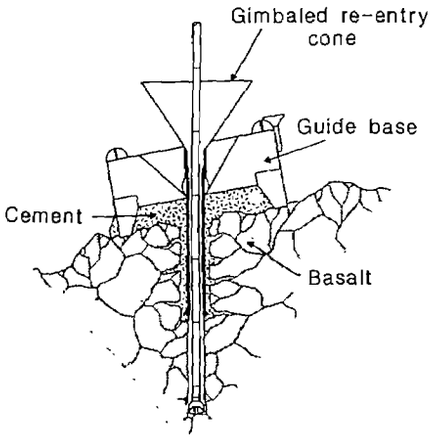
*from the Leg 106 shipboard scientific party**

LEG 106 of the Ocean Drilling Program (ODP) has taken two significant steps in the study of geological processes at mid-ocean ridges. The first essentially 'zero-age' crustal hole was drilled on the plateau at the summit of a small axial volcano in the Mid-Atlantic Ridge Rift Valley 2,200 km south-east of Bermuda; and engineers demonstrated the feasibility of 'bare-rock', spud-in drilling and coring. The survey of a hydrothermal area in the rift valley also led to the discovery of an active vent field with large sulphide chimneys, hot 'black smoker' vents and a unique biological community. Several drill holes in this area, the first ever drilled in an active, submarine hydrothermal system, recovered massive sulphides (Fe and Cu) and unconsolidated hydrothermal deposits of Zn, Cu and Fe sulphides. Despite the need for technical developments to improve drilling rates and core recovery in these difficult conditions, Leg 106 opens up exciting possibilities for crustal drilling at oceanic spreading centres.

In submarine volcanic areas, cold seawater circulates close to hot, intrusive rocks deep within the crust where it is heated to very high temperatures and upwells as hot springs on the sea floor. Although at least six active hydrothermal vent areas have been identified along medium- and fast-spreading ridges in the eastern Pacific, until recently no direct evidence for such activity was known along the slow-spreading Mid-Atlantic Ridge. During a pre-drilling site survey in May 1985, W.B.F. Ryan (Lamont-Doherty Geological Observatory) and L. Mayer (Dalhousie University) took photographs of pockets of greenish-white, mottled hydrothermal sediment, crabs and small, spindly worms indicative of recent hydrothermal activity in an area about 25 km south of the Kane Fracture Zone. The new hydrothermal vent field was discovered during a 36-hour video survey of this area on ODP Leg 106. The sulphide chimneys range up to several metres in diameter and more than 11 m in height, and display the spectacular dendritic, tubular structures and elaborate ornamentation previously seen on the East Pacific Rise and Juan de Fuca Ridge.

Ten shallow holes were drilled at this site to sample the hydrothermal deposits and the underlying basement rocks, two of which are located at the foot of a large black smoker. The hydrothermal deposits are surprisingly thick — more than 13 m at the foot of the black smoker and at least 3–6 m more than 17 m away from the vent. Recovery of the sand-sized sulphide deposits was generally poor, but our analyses indicate that they are composed mainly of chalcopyrite ($CuFeS_2$), sphalerite (ZnS), pyrite (FeS), marcasite (FeS_2) and pyrrhotite (Fe_{1-x}) in varying proportions. Lenses of massive (Fe + Cu) sulphide were also drilled and recovered from a hole at the base of the black smoker. Where recovered, the underlying basalts were fresh.

The vent field is also associated with a diverse biological community that is surprisingly different from that observed in the Pacific. We did not observe any clams, mussels or large, sessile tube worms near the vents. The most common forms of life are large swimming crustacea, small shrimp-like organisms and long (30–60 cm), flat, snake-like swimmers (possibly eels) that give the area the name of the Snake Pit. The shrimp-like organisms seem to congregate on rock surfaces near the vent orifices while sessile little white balls (possibly some type of anemone) litter the sea floor around the vents. In general, the community appears to consist of smaller, more mobile organisms than those previously found at submarine hydrothermal vents.



Previous attempts to drill to significant depths in young oceanic crust have been unsuccessful because of difficult drilling conditions in the fresh, abrasive and highly fractured basaltic rocks found at

Co-chief scientists: Robert S. Detrick (Univ. Rhode Island, Kingston) and Jose Honnorez (Univ. Louis Pasteur, Strasbourg, France and Univ. Miami). ODP Staff scientist, Andrew C. Adamson (Texas A & M Univ.). Also Garret W. Brass (NSF), Kathryn M. Gillis (Dalhousie Univ.) Susan E. Humphris (Woods Hole Oceanographic Inst.), Catherine Mevel (Univ. Pierre et Marie Curie), Peter S. Meyer (Woods Hole Oceanographic Inst.), Nikolai Petersen (Univ. Muenchen) Martina Rautenschlein (Max-Plank-Inst. fur Chemie), Tsugio Shibata (Okayama Univ.), Hubert Staudigel (Scripps Inst. Oceanography), Anita Wooldridge (Univ. Miami) and Kiyohiko Yamamoto (Tohoku Univ.).

THE three-man deep-sea submersible *Alvin* is going to take a close look at some hydrothermal vents, but this time in the waters of the Atlantic rather than the Pacific Ocean, where all the vents have so far been found. These sites where hot brines emerge from the sea floor, together with their characteristic 'black smokers', sulphide chimneys and peculiar ecology, have now been found on the Mid-Atlantic Ridge by two groups. On page 33 of this issue, Rona *et al.* describe vents found by dredging and video cameras during a cruise in July–August 1985, and on this page, the ODP Leg 106 scientists reveal similar finds made quite close by in December of last year. The level of excitement generated by these discoveries can be judged by the fact that Rona has managed to get time to use *Alvin* in the early summer of 1986. Normally he would have had to wait until at least 1988 to stand a chance of getting a slot on a cruise. But the *Alvin* team just happened to be planning a visit to the mid-Atlantic, and a few extra days have been found to look more closely at the hydrothermal vents. Peter Gambles

mid-ocean ridges. The requirement for significant thicknesses of sediment (>100 m) on the basement to spud-in to the crust also precluded any drilling within the narrow, zero-age crust of the accretionary zone itself.

The main objective of ODP Leg 106 was to test and evaluate new bare-rock drilling techniques at the site in the Mid-Atlantic Ridge Rift Valley and to establish a zero-age crustal hole that could be re-occupied and deepened on subsequent legs. Among the new engineering systems tested were a hard-rock guide base to confine the drill bit during initial spud-in on sediment-free rock (see figure); a low-light television camera system for imaging the sea floor and monitoring drilling operations; and

The hard rock guide base used on Leg 106, designed to provide the lateral support necessary for the drill bit to spud-in to hard, volcanic rock on slopes up to 20 degrees and water depths of up to 6,000 m. The 20-ton guide base stands on four legs and is 5.7 m square and 2.3 m high. It is lowered to the sea floor and cemented in place with 56 m^3 of cement. A cone 5.3 m in diameter and 2 m deep is built into the base and serves as a temporary re-entry cone. Once the hole is started and cased, a permanent, gimbaled re-entry cone is positioned in the base.

new downhole drilling and coring motors to facilitate bare-rock spud-in.

The site chosen for the first bare-rock drill hole is about 70 km south of the Kane Fracture Zone on the flat summit plateau of a small axial volcano. This site is characterized by bulbous and tubular pillow lavas up to 1–2 m in diameter with a light dusting of pelagic sediment. The hard-rock guide base was successfully lowered 3,344 m to the sea floor, released and cemented without incident. A positive-displacement, downhole drilling motor was used to spud-in to the basaltic crust. The drilling motor and conventional rotary drilling advanced the hole to a total depth of 33.3 m below the sea floor before drilling was terminated after 25 days.

The average recovery for the 26.7 m of cored hole was 23 per cent, comparable with that experienced during previous drilling in young volcanic rocks. All the recovered rocks are very fresh, plagioclase–olivine, sparsely phyric basalt. The texture of the groundmass ranges from glassy to subvariolitic to intersertal to intergranular, indicating that most samples are probably derived from parts of pillow lavas. The presence of plagioclase and olivine glomerocrysts and the absence of chromian spinel suggest that the basalts are typical, moderately evolved mid-ocean ridge basalts. The drill hole was left cased and open so that it can be deepened when the ship returns later this year. □

Adrenergic receptors

Some similarities and surprises

from Peter Newmark

Two particularly striking results have emerged from the sequence, reported by Richard Dixon *et al.* on page 75 of this issue, of the gene for one of the most studied of all receptors, the β-adrenergic receptor through which adrenaline and other catecholamines exert their physiological effects. The first is that there are some structural resemblances between the receptor and rhodopsin, the protein at the front end of the machinery in rod cells of the retina that converts light into the visual response. The second surprise is that the protein-coding sequence of the gene that encodes the hamster β-adrenergic receptor is not interrupted by non-coding sequences (introns).

Adrenergic receptors have been subject to the relentless prying of endless ranks of scientists. Physiologists have established the responses to catecholamines mediated by them. Pharmacologists have categorized them into types (α_1, α_2, β_1 and β_2) and established their behaviour (for example, desensitization and down-regulation, to use the operational terms beloved of pharmacologists) in response to various types of exposure to catecholamines. And biochemists have elucidated the initial events that follow the binding of catecholamine to the receptor.

What biochemists (biochemical pharmacologists?) have established is that catecholamine binding to β-adrenergic receptors induces their coupling to so-called G (or N) proteins (which come in several types, each of which has three subunits, α,β and γ). The coupling is followed by the binding of GTP to the α-subunit of the G protein, which then dissociates from its partners to activate adenylate cyclase, and thus the synthesis of cyclic AMP. This is a transient event, lasting only until the α-subunit has hydrolysed the GTP that is bound to it. The cyclic AMP produced during that time mediates the eventual physiological responses to the catecholamine.

Dixon *et al.* report two ways in which the structure of the β-adrenergic receptor protein, whose amino-acid sequence they deduce from the DNA sequence, resembles rhodopsin. First, there are three peptides within the receptor sequence that have a considerable number of amino acids in common with peptides in roughly equivalent positions within rhodopsin; and second, rhodopsin and the receptor have "remarkably similar" hydropathicity profiles (providing some measure of which parts of a protein lie within the cell membrane and thus how the protein is threaded through the membrane).

These structural resemblances make sense in the context of biochemical parallels between the two systems. When rhodopsin is stimulated by light, it couples to transducin, a G protein whose α-subunit binds GTP and, until the bound GTP is hydrolysed, activates a phosphodiesterase that in turn hydrolyses cyclic GMP. The resulting closure of ion channels on the rod cell membrane produces the visual response (see Altman, J. *Nature News and Views* **313**, 264; 1985).

It is because of the structural resemblances between the two proteins that it comes as a particular surprise to find that the gene for the β-adrenergic receptor contains no introns. In any case, it joins a very select band: histone and interferon genes are the only other mammalian genes to lack introns; and introns have so far turned up in each of the genes for cell-surface receptors. In the particular case of the rhodopsin gene and its relatives, there are four introns in the mammalian gene, four or five in the genes that encode the three human colour pigments (Nathans, J., Thompson, D. & Hogness, D.S. *Science* **232**, 193; 1986) and three or four in two different opsin genes of the fruitfly (see Cowman, A.F., Zucker, C.S. & Rubin, G.M. *Cell* **44**, 705; 1986). Dixon *et al.* are confident that they have sequenced the real gene for the receptor rather than a pseudogene, so their discovery will be interesting grist for the mill of those who try and explain the evolutionary goings (and comings?) of introns.

And for those with an interest in β-adrenergic receptors either as a prime example of a receptor or as a target for drugs that modify the physiological responses to catecholamines, the structure of the receptor itself, quite apart from its resemblance to rhodopsin, should prove immensely valuable. □

Astrophysics

The most reliable black hole yet

from M.G. Watson

BLACK holes are frequently invoked by astronomers to explain the vast amount of energy radiated from the nuclei of many galaxies. The energy is produced, in this picture, as material surrounding the black hole falls down its extremely steep gravitational potential well. The same phenomenon is believed to occur on a much smaller scale in a few X-ray-emitting binary stars in or near our Galaxy, providing the best available evidence that these theoretically predicted objects exist at all. In these X-ray binaries the infalling matter eventually accreted by the black hole is supplied by the companion star. A recent investigation of a system of this type — an X-ray transient — has produced results which arguably place the existence of black holes on considerably firmer ground (McClintock, J.E. & Remillard, R.A. *Astrophys. J.* in the press).

X-ray transients are a small but important subclass of X-ray binaries. Most are believed to be systems containing a faint red star and an accreting compact object (a neutron star or black hole). As such they are closely similar to the persistent low-mass X-ray binaries (White, N.E. & Mason, K.O. *Space Sci. Rev.* **40**, 167; 1985), the principal difference being that X-ray transients are only luminous X-ray emitters during their relatively short (of the order of months) outbursts which recur on timescales of years, a pattern of behaviour which presumably reflects a highly variable mass transfer rate onto the compact object. The X-ray transient A0620−00 is perhaps the most famous member of its class as it was, for a few months in 1975, the brightest celestial X-ray source ever recorded (Elvis, M *et al. Nature* **257**, 656; 1975). Despite the enormous observational attention that it attracted then, little was learnt about the properties of the underlying binary system. A decade later, the new detailed optical study of the A0620−00 system (now in its quiescent state) by McClintock and Remillard provides compelling evidence that the binary system contains a black hole.

McClintock and Remillard's result is based on several years of photometric observation of A0620−00 in quiescence that provide a unique orbital period of 7.75, together with just one night's spectroscopy which allowed them to determine the radial velocity curve of the faint red companion to the compact object by measuring the periodic Doppler shifts of its absorption lines. The amplitude of the radial velocity curve, 457 ± 8 km s^{-1}, is very large for a binary with such a short period, and this measurement alone sets a firm lower limit to the mass of the compact object of 3.2 solar masses. This is significantly above the maximum mass for a neutron star for the stiffest equation of state of neutron matter considered realistic, leading inexorably to the conclusion that the compact object must be a black hole. A more realistic estimate of the compact object mass can be made by assuming a reasonable mass for the red companion star, and using the constraints on the orbital inclination placed by the lack of X-ray eclipses and the modelling of the photometric light curve. On this basis McClintock and Remillard conclude that the mass of the compact object is likely to be greater than 7 solar masses.

The X-ray transient A0620−00 thus joins CygX−1 and two systems in the Large Magellanic Cloud, LMC X−1 and LMC X−3, as the fourth system which is a good candidate for a black-hole binary on the basis of dynamical measurements of the compact object mass. In contrast to the other three black-hole binaries which have hot, luminous, massive companions, the companion in A0620−00 is clearly a faint, low-mass red star. The presence of a massive black hole in this system may pose a fresh set of evolutionary questions. In particular it is difficult to understand how the black hole could have formed in this system without the binary being totally disrupted. The mass of the progenitor star would have had to be at least 20 solar masses (probably more), hence it seems very likely that the formation of the black hole would have involved the loss of more than half the system mass, leading to the binary becoming unbound. The present short binary period is also difficult to reconcile with the size of the original binary system required to accommodate the large, massive progenitor of the present black hole. The difficulties associated with understanding the evolutionary history of A0620−00 suggest that it is a rather rare system. It is too early to say whether this is indeed the case, because the binary system parameters of a large fraction of all X-ray binaries, transient or otherwise, have yet to be measured, but it is interesting to note that the empirical X-ray spectral classification scheme proposed by White and F.E. Marshall (*Astrophys. J.* **281**, 354; 1984) suggested several new black-hole candidates, one of which was A0620−00.

In the case of A0620−00 there can be little doubt about either the correctness of the radial velocity measurements or their interpretation. One of the standard sceptical responses to any unlikely dynamical measurement has been to suggest that the system is a triple, rather than a binary. This argument cannot be applied to A0620−00, given the small size of the system implied by the 8-hour period. Thus, A0620−00 is arguably the most reliable (or the least unreliable) black-hole candidate yet discovered. Because of this, and because it is a nearby galactic system, it may be that the impact of this result will be mainly psychological in making the possibility, if not the reality, of black holes of stellar mass seem more appealing to many astronomers. □

100 years ago

New System of Earthquake Observations in Japan

OWING to the invention of new seismographs by the members of the Seismological Society of Japan, there has been of late a complete change in the system of earthquake observations in this country. The Meteorological Bureau now employs the horizontal pendulum and vertical-motion seismographs of Profs. J. Milne and T. Gray, and of Prof. J.A. Ewing for systematic observation, while the Imperial University of Tokio publishes from time to time detailed accounts of particular and more interesting shocks by the use of similar instruments. These seismographs register on a revolving glass plate or drum automatically started by the earthquake motion, components of horizontal and vertical motions of the earth on a magnified scale, thus producing continuous diagrams, and indicating successive displacement of the ground in conjuction with the time. The account of the earthquake of December 28, 1885, the largest shock during the last three months, is here given as a sample of seismic record now issued in this country. The motion is slowly commenced, not accompanied by quick tremors, as is usually the case. At the 14th second from the commencement a considerable E.–W. motion occurred; in another second the maximum movement appeared in the same direction, which was followed by smaller shocks during about one minute; and from thence the oscillations, gradually subsided. As usual, the particles of the ground did not move to and fro, but traced a curvilinear path, although the E.–W. components always remained greater than the S.–N. components. In all, over 130 shocks or complete waves were registered. I may add in respect to the above earthquake, and in general, that the vertical motions are always — in our experience — smaller than horizontal ones, and the maxima and minima of these two kinds of motions are not synchronous. I shall have occasion before long to communicate to you the general results of all observations made during past years.

Mathematics

Hermann Grassmann was right

from Ian Stewart

THE late nineteenth century witnessed many attempts to develop an algebra of n-dimensional space, by analogy with the representation of the plane by complex numbers. Prominent among them was Hermann Grassmann's *Die lineale Ausdehnungslehre* (*The Calculus of Extension*), published in 1844. Grassmann had the misfortune to write in a discursive, philosophical and obscure style at the time when axiomatic presentation was becoming *de rigeur* in the mathematical world. Further, he was a high-school teacher with no formal training in mathematics. Not surprisingly, his ideas were at first not taken very seriously — but later, Élie Cartan used Grassmann's 'exterior algebra' as the basis of his theory of differential forms. This work proved highly influential and established the importance of Grassmann's work. But, as Marielena Barnabei, Andrea Brini and Gian-Carlo Rota write in a recent paper (*J. Algebra* **96**, 120; 1985) "In the process Cartan paid a price of omission from which we are yet to recover." They argue that mathematicians have still not fully understood what Grassmann was trying to say, and propose a formulation of his ideas in modern terms which provides a natural language for the study of invariants.

In Grassmann's original work the same notation was used to denote two different operations performed on vectors, called the progressive and regressive products. This was not an oversight, but a deliberate choice. Every mathematician knows that what Bourbaki calls "abuse of notation" can, when wielded with care, greatly illuminate what would otherwise be a confusing situation. Unfortunately Grassmann managed to confuse greatly what might otherwise have been an illuminating situation. The tale has two main threads: differential forms and invariants.

Cartan's theory of differential forms attempts to make sense of the idea that expressions such as dx and dy in calculus can have a perfectly sensible meaning. The intuitive idea of 'a very tiny bit of x' runs into severe difficulties, and is not very helpful; but the basic idea that the derivative dy/dx satisfies an equation $dy=(dy/dx)dx$ is crucial. So is the idea that an integral $\int dx$ can be thought of as an operation $\int$ applied to a differential form dx. The fundamental observation is that products of differential forms, such as $dx.dy$, do not obey the usual laws of algebra. This is because the double integral $\iint dx.dy$ represents a signed area, positive or negative; and interchanging x and y turns a left-handed coordinate system into a right-handed one, multiplying all areas by -1. In other words, one must set up the formation to make $dx.dy=-dy.dx$. Grassmann's progressive product obeys the same kind of law. Cartan found that the regressive product added nothing to his theory, and he quietly abandoned it. Until now, its demise has gone unmourned.

The new work of Barnabei *et al.* is part of an extensive programme of research that Rota has carried out for more than a decade, applying combinatorial methods to invariant theory. Classical invariant theory is the study of expressions that remain unchanged when their variables are transformed in particular ways. A simple example arises in connection with quadratic equations $ax^2+bx+c=0$, for which there is a well-known formula involving square roots of b^2-4ac. This quantity is called the discriminant, because it vanishes precisely when the two roots of the equation are equal. Suppose the variable is changed from x to $x+h$. Then the quadratic becomes $(x+h)^2+b(x+h)+c$, or $ax^2+(2ah+b)x+(ah^2+bh+c)$. Write this as Ax^2+Bx+C. Now compute the new discriminant: $B^2-4AC=(2ah+b)^2-4a(ah^2+bh+c)=b^2-4ac$. Thus the formula for the discriminant does not change, although the variable x does. It is called an invariant of the transformation.

Invariant theory was invented around 1850 by Arthur Cayley and James Joseph Sylvester. It considers more complicated expressions than only quadratics, and more complicated transformations than $x \to x+h$. The fundamental problem in the theory is to prove that, in any particular case, the full system of invariants can be expressed in the terms of a finite subsystem, called a basis. The main classical method is to describe explicitly all invariants and to exhibit such a basis. By such methods Paul Gordan, the 'king of the invariants', proved in 1868 that for any expression in two variables, a finite basis exists. Limited extensions were proved by Gordan and others, but progress became painfully slow as ideas were overwhelmed by a swelling mountain of calculation.

In 1888 David Hilbert created a tremendous stir by proving that a finite basis always exists — and he did it without calculating any invariants at all. He used only very general abstract properties of systems of polynomials. "This is not mathematics", Gordan complained, "it is theology". But theology won the day, and explicit computation of invariants went out of fashion, being replaced by a much more abstract, higher level approach that gave conceptual ideas pride of place. But history tends to run in spirals, and in recent decades there has been something of a classical revival, inspired in part by the needs of other branches of mathematics, and by applications. Explicit formulas, rather than existence results, are often desirable. Rota, an expert in combinatorics, has developed a powerful approach to such problems: his methods manage to be both conceptual and computational at once. How does one achieve such a balancing act? By making the notation reflect the concepts. As a result Rota has become the Edgar Allen Poe of mathematics, exhuming Grassmann's regressive product from its premature burial.

Barnabei *et al.* motivate their ideas in terms of three important types of transformation: orthogonal transformations are essentially rotations in a multidimensional space; symplectic transformations arise from mechanics; and a general linear transformation is, as its name implies, the most general transformation that keeps straight lines straight. Barnabei *et al* summarize the standard results in the first two cases as follows: (1) a Hilbert space is a vector space having a symmetric form (x,y). That is, $(x,y)=(y,x)$. A transformation T is orthogonal if it preserves this form, that is, $(Tx,Ty)=(x,y)$. Invariants under orthogonal transformations are polynomials in the symmetric form. Computations in Hilbert space are carried out in a naturally associated algebra, the Clifford algebra; (2) a symplectic space is a vector space having an antisymmetric (or symplectic) form $[x,y]$, that is, one such that $[y,x]=-[x,y]$. A transformation is symplectic if it preserves this form. Invariants under symplectic transformations are polynomials in the symplectic form. Computations occur in a naturally associated algebra, the Weyl algebra.

The parallel between these two theories is striking, and it suggests a fruitful question: is there an analogous setting for the general linear group? Barnabei *et al.* show that the answer is yes. They define a Peano space to be a vector space having a bracket $[x,y,z,\ldots]$. Invariants under the general linear group are polynomials in the bracket. Computations are carried out in a naturally associated algebra, the double algebra. It is so called because it has two operations (rather than the usual one). They are, of course, modern versions of Grassmann's regressive and progressive product. *Plus ça change...*

Ideas that are ahead of their time do not always find immediate favour, and those that are not appreciated tend to be forgotten. But it is hard to keep a really good idea down. It was Grassmann's tragedy to be ahead of his time, but it is a mark of his genius that his ideas are now coming to full flower. □

Cell biology

Origins of the cytoskeleton

from Carl M. Cohen

A REPORT by Catherine Woods and Elias Lazarides on page 85 of this issue[1] shows that our understanding of membrane skeletal biogenesis shares at least one characteristic with the cells in which it has most recently been studied — both are embryonic. Lazarides and co-workers have recently provided us with fascinating insights into membrane skeletal biogenesis in chick embryo erythroid cells. Although these cells are nucleated, they nonetheless contain a membrane skeleton composed of the protein complex spectrin–actin–band 4.1 as well as the spectrin-binding protein ankyrin (goblin) which links spectrin to the integral membrane protein band 3. Lazarides' group has interpreted their observations in terms of a 'receptor-driven' membrane skeletal assembly, that is, that the amount of band 3 (the 'ultimate' membrane skeletal receptor) limits the amount of newly synthesized ankyrin that gets incorporated into the skeleton. Ankyrin is then thought to limit the amount of spectrin β chain (containing the ankyrin-binding site) which in turn limits spectrin α-chain incorporation[2]. According to this scheme, spectrin chains that are not incorporated into the skeleton as α/β heterodimers, α_2/β_2 heterotetramers or higher hetero-oligomers are degraded[3,4].

A major question raised by this model is how the unassembled chains are targeted for destruction. Woods and Lazarides' new work[1] suggests that α and β chains not incorporated into the skeleton pass their brief existence as homo-oligomers, either α_2 or β_4. These oligomers are largely incapable of forming stable functional associations within the membrane skeleton and the cytosol, and are somehow marked for destruction.

The possible existence of spectrin homo-oligomers runs counter to a small body of literature suggesting that such complexes do not form, or are rare, in solutions of purified α or β chains[5–8]. But these studies were done on mammalian erythrocyte or brain spectrins, and there may be important differences between chicken and mammalian spectrins. Although chicken non-erythroid and human erythroid spectrin chains have much in common, these two forms are probably the most widely divergent among the spectrin-chain family[9–11]. (Because chickens apparently possess only a single spectrin gene, the same must hold for chicken erythroid spectrin.) More to the point, recent unpublished studies by M. Mooseker, J. Coleman and J. Morrow at Yale University show that purified chicken erythroid β-spectrin chains have a remarkable propensity to self-aggregate. This is apparently true of fodrin chains as well[12]. Taken together, these studies suggest that for most spectrins, self-oligomerization of spectrin chains, particularly the β chain, may be the rule rather than the exception.

Intriguingly, the chains making up homo-oligomers in the chick cytosol seem to be perfectly capable of forming heterodimers if the homo-oligomers are first denatured and then mixed with their partners under appropriate renaturing conditions. Thus, there is nothing inherently different about those chains that end up as homo-oligomers. What, then determines the proportion of spectrin chains that end up as heterodimers? Is the proportion regulated by membrane-bound ankyrin? If not, what happens to the heterodimers that are synthesized in excess of ankyrin? Woods and Lazarides find no evidence for unassembled heterodimers in the cytosol of chick erythroid cells after translation *in vivo*. Are unassembled heterodimers also somehow targeted for destruction?

It seems likely that heterodimerization would take place in the cytosol during or soon after synthesis in order for the chains to be protected from self-oligomerization. In fact, the proposition that the α/β heterodimer (or α_2/β_2 heterotetramer) may form before its incorporation in the skeleton makes sense in the context of the known functional capabilities of spectrin chains. Several groups have shown that the high affinity association of spectrin in the spectrin–actin–band 4.1 complex requires an α/β heterodimer (or α_2/β_4 heterotetramer) even though isolated α and β chains bind to band 4.1 quite well[5,8]. Even fodrin, which can apparently bind to actin filaments without the need for band 4.1, must be heterodimeric for the association to occur[7]. Thus, it is more appealing to envision a fully competent heterodimer or heterotetramer forming a stable link in the nascent membrane skeleton than a single β chain arriving and waiting for its α mate.

If the homo-oligomer degradation route is operative in mammalian cells it may be less stringent, but the same principles may still apply. For example, in mice with any one of several genetic defects at the *sph* locus there is no α spectrin synthesized, whereas β spectrin is synthesized at a nearly normal rate. Almost normal amounts of β spectrin are bound to the reticulocyte membrane skeleton, and about 20 per cent of normal

is retained in red cell membranes at steady state[13]. This suggests that whatever form the β chain is in, most of it makes it to the reticulocyte membrane skeleton without being degraded. Subsequently, 80 per cent of the β chains are degraded, presumably because they fall off the membrane (as oligomers?). These and other instances documented in mice[13] show that the mere presence of single chains (be they monomers or homo-oligomers) does not dictate immediate destruction. Possibly, if the chains make it to the membrane soon enough they are spared. In cases where there are no heterodimers to compete for membrane binding, the β chains may have a higher probability of associating with the membrane and escaping degradation, if only transiently.

Interesting as these studies are for those in the membrane skeleton field, there are also paradigms emerging which may be more general. The notion that post-translational folding, and hence the fate of a protein, may depend as much on the presence or availability of other protein subunits as on primary structure clearly has wide implications (see ref. 2 for review). Also, the rather unorthodox characteristics of the degradation of excess α and β chains (the former ATP dependent and lysosome-like, and the latter ATP independent) suggests that more surprises are in store the deeper we probe membrane skeletal beginnings. □

Information technology

New flow of ideas in networks

from Alistair Mees

FLOWS in networks are a common feature of today's world — they may involve physical quantities such as traffic in a city, or information in a telephone or computer network. Many problems that do not at first sight directly concern network flows can easily be converted to that form: railway scheduling and project management are well-known examples. Until recently only simple versions of such problems have been easy to solve. But now a new mathematical approach opens the way for greatly improving the efficiency of the solution of common, hard problems.

With the advent of ever more complicated networks, particularly in telecommunications, rapidly increasing amounts of computer time are needed to answer questions such as: what is the capacity of a particular network and how should the flows be arranged to attain it; and what is the cheapest way to expand a network to have a particular capacity?

For the simplest sort of network flow, in which there is only one commodity flowing (for example a network of pipes carrying water, or an electricity grid), many problems can be solved by existing methods (Ford, L.K. & Fulkerson, D.K. *Flows in Networks* Princeton University Press, 1962). The methods are good both because they are intuitively 'right' — a feature which is more important in mathematics than is often admitted — and because they are efficient for use on computers. For instance, think of a network with capacity limits on the arcs (the lines), where there is a single source and a single destination, and we want to find the maximum traffic capacity. The famous Ford–Fulkerson method finds a route from source to destination; looks for the bottleneck on it which determines the maximum capacity of that route; and pushes through that amount of traffic. That particular route is now blocked because the bottleneck is operating at maximum capacity. The method now finds another route and does the same, continuing until all routes are blocked by previous traffic. We now have the maximum flow that the network is capable of carrying.

More sophisticated problems, for example those in which there are costs associated with different routes, can be solved by related methods. The 'out-of-kilter' algorithm is one, in which certain conditions are checked for each arc, which it is said to be out of kilter if they do not hold: the algorithm uses a route-search-and-block method successively to put arcs into kilter. (This is the only time I have ever heard the expression 'in kilter'.)

The most important mathematical feature of these methods is that they are based on results from duality theory. Duality refers to the fact that for every optimization problem there is a related problem which (under some convexity conditions that hold in the cases under discussion) has the same solution. For example, the basic Ford–Fulkerson result is actually a duality theorem which states that maximum flow equals minimum cut, meaning that if the network is cut so that the source is in one part and the destination in the other, the sum of the capacities of the broken arcs is always at least as big as any allowed flow, and for certain cuts it will equal the biggest possible flow. Duality theory pervades the mathematical theory of optimization and often has a price or a game-theoretic interpretation: if we let the capacity of an arc be the cost of breaking it, the Ford–Fulkerson result could be expressed in terms of an attacker who tries to isolate the source from the destination, and a defender who tries to make the attack as expensive as possible. The conditions for an arc to be in kilter in the more general problem come directly from duality theory.

Things get harder when we talk about multicommodity flows, in which there may be distinct kinds of traffic, with different sources and destinations, all sharing the same capacitated network. This is a lot closer to many real-world problems, but the ideas that were good for single-commodity flows do not work well: if one kind of traffic is maximized, another kind may be blocked, although some different arrangement would allow both flows to coexist. Trying out different arrangements from scratch quickly leads to a combinatorial explosion in which the number of options to try grows exponentially fast with the size of the network or with the number of commodities. Exponential growth of the time taken to solve a problem means that beyond a certain size of problem (in this case probably rather a small size) it becomes impossible to find solutions with present technology, and any future improvements in computing power will only marginally increase the size that can be managed. There is nothing for it but to look for better algorithms.

Multicommodity problems have been solved by linear programming methods (Assad, A.A. *Networks* **8**, 37; 1978), but because they transform to very special and degenerate linear programs this is an inefficient way to proceed: only problems of a rather modest size can be solved.

Recent work by Soviet mathematicians shows promise in solving multicommodity problems in the same sort of nice way that single-commodity problems are solved. An entire issue of the journal *Discrete Applied Mathematics* (**11**; 1985) is devoted to a paper by M.V. Lomonosov describing combinatorial approaches to multicommodity flow problems. There are many theoretical and algorithmic ideas in this long paper, some of them new and some of them summarizing recent work by the author and his colleagues, particularly A.V. Karzanov, most of which has not previously been published outside the Soviet Union. Duality theory is as central as ever, with Ford and Fulkerson's max-flow min-cut theorem being extended, but perhaps the most practically useful ideas are switching techniques that give systematic ways to unlock a multicommodity network and allow different flow patterns. Switching and draining transformations are introduced to allow flows to be rearranged without reducing the traffic amounts. Providing systematic transformations between different flow patterns is an important step towards overcoming the combinatorial explosion: the

fact that these transformations do not reduce flow may mean that, as with the simplex algorithm for linear programming, rather a small number of different arrangements can be stepped through to reach the optimum.

It is too early to say whether these new ideas will lead to significantly greater efficiency in solving multicommodity problems. The paper deals only with certain specialized flow problems, so it is roughly analogous to the situation with the Ford–Fulkerson approach before the out-of-kilter algorithm was developed. Lomonosov does not discuss algorithmic efficiency directly, nor does he give explicit examples, but it is likely that his methods will prove good for some kinds of problems. If this turns out to be the case, we may hope for extensions to more practically realistic problems and perhaps a large increase in the size of multicommodity problems that can be solved. □

Molecular biology

Self-incompatibility in plants

from John Fincham

In many families of flowering plants, exemplified by the Solanaceae (which includes the genera *Nicotiana* and *Lycopersicon*), self-pollination is prevented by a genetic system based on multiple alleles at what appears to be a single locus which is given the symbol *S*. Impressive progress towards the goal of discovering what the products of the *S* allele are and how they relate to each other in molecular terms has recently been made by two groups, first by J. B. Nasrallah *et al.* from Cornell University (*Nature* **318**, 263; 1985) and now by Anderson *et al.* of Melbourne University and reported elsewhere in this issue (*Nature* **321**, 38; 1986).

It is known that pollination is blocked only when the same allele is present in the germinating pollen grain and the style down which it is trying to grow. Because wild populations of outbreeding species usually have tens or even hundreds of *S* alleles, this system ensures that the great majority of random cross-pollinations are fertile. In some plant families, including the Cruciferae and its best-known genus *Brassica*, there is a variant system in which pollen expresses one or both of the *S* alleles present in the diploid plant which bore it, even though each pollen grain, as a haploid product of meiosis, retains only one allele. The difference between the two systems is presumably one of timing of *S*-locus expression — post-meiotic in the Solanaceae and pre-meiotic in the Cruciferae — and does not necessarily imply any fundamental difference in the functions of the products of the respective *S* loci. In each case, incompatibility evidently results from some kind of interaction between products of identical *S* alleles.

What is the mechanism of this self-recognition by *S* alleles? There are two possibilities. If one supposes that the *S* locus is really a single gene, encoding the same protein in pollen and style, one can think in terms of dimerization of similar protein monomers, located respectively on the cell surface of the pollen tube and in the cell sap of the style. The alternative is to postulate that the *S* locus is a complex of at least two genes expressed respectively in pollen and style, with each *S* allele encoding a stylar product and a different but complementary pollen product. The second model does not require the products of any particular *S* allele (more accurately termed a haplotype) to bear any specific structural relationship to those of any other — each haplotype could evolve independently, subject to selection only for self-recognition. A bipartite structure of the *S* locus has, in fact, long been postulated as an explanation of *S* mutations, which tend to affect pollen and style reactivities independently.

The breakthrough by the Cornell group was the molecular cloning of a complementary (c)DNA sequence representing an abundant style-specific messenger (m)RNA in *Brassica oleracea* of genotype S_6S_6 (obtained by forced self-pollination). When used to probe restriction-endonuclease digests of DNA from plants carrying other *S* alleles, this cDNA clone revealed a restriction fragment size polymorphism that was closely and perhaps inseparably linked to the *S* locus; each *S* allele was associated with its own specific array of restriction sites within the region covered by the probe. Moreover the cDNA, when cloned into an expression vector, was translated in *Escherichia coli* into a protein product that reacted with an antiserum made against a glycoprotein of relative molecular mass (M_r) ~ 85,000 that had been found specifically in styles of plants bearing allele S_6. Only a partial sequence of the cDNA clone has been published so far.

The starting point for the Australian group was the finding of an abundant glycoprotein of M_r ~ 32,000 in styles of *Nicotiana alata* (tobacco) plants carrying allele S_2. Somewhat surprisingly, no glycoprotein of comparable abundance was isolated by the same method from plants carrying other *S* alleles, which raises the possibility that different *S* alleles have very different stylar products. Determination of part of the N-terminal amino-acid sequence of the M_r 32,000 protein permitted the synthesis of a mixed DNA probe for the encoding gene, and the gene was indeed recovered by this means from a cDNA library made from mRNA of styles carrying S_2. Sequencing of the cDNA clone revealed an open reading frame encoding a 204-residue polypeptide chain with a 22-residue N-terminal hydrophobic portion (presumed signal sequence) leading into the sequence already found at the N-terminus of the mature glycoprotein. The cDNA hybridized strongly to DNA of plants carrying S_2 and much more weakly to DNA of plants with other *S* alleles, suggesting again that the different *S* alleles have very subtantially different coding sequences and only remotely related stylar products. There is as yet no direct evidence about the extent and nature of the inter-allele differences within *N. alata*, but Anderson *et al.* do present some preliminary information from another Solanaceous species, the wild tomato *Lycopersicon peruvianum*. A part of the N-terminal sequence has been obtained from two different stylar glycoproteins associated with different *Lycopersicon S* alleles; these are clearly homologous with each other (although there are also several differences) and also with the N-terminal sequence of the *N. alata* S_6 protein. Disappointingly, but not surprisingly, no similarity is visible as yet between the *Nicotiana* or *Lycopersicon* sequences and the limited amount of sequence available from the *Brassica* S_2 protein.

Clearly we are at the beginning of what is bound to be a period of intense activity as these highly promising observations are carried further. Several questions are now readily answerable. We should soon see some full-length comparisons between the DNA sequences of different *S* alleles (or at least those parts of them governing the stylar products); it should soon become apparent if there is any homology between the *Nicotiana*/*Lycopersicon* and *Brassica S* loci. More difficult, but probably not long delayed, will be the identification of *S*-allele products in the pollen tube and the cloning of the corresponding DNA sequences. If the *S* locus really does have separate pollen- and style-specific products with seperate coding sequences, much may depend on how close together these sequences are in the genomic DNA. If they are separated by only tens of kilobases, walking from one to the other should not be difficult; but if they are hundreds of kilobases apart, as they could be and still be almost inseparably linked, there will be more of a problem. □

Keeping supercomputers under control

SIR—The Purdue Water Resources Reseach Center in conjunction with the Office of Health and Environmental Research of the US Department of Energy recently co-sponsored a meeting on the current uses of, and future needs for, supercomputers in hydrology. 'Supercomputers in Hydrology: Future Directions', the first meeting of its kind, aimed to evaluate the need for large-scale vector and parallel processing machines and their peripherals in the hydrologic sciences, especially in subsurface hydraulics. While the charge of the seminar was to specifically deal with hydrologic applications of supercomputers, the conclusions drawn at the meeting apply equally well to many other fields of science and technology.

Almost all technical issues involving the use of supercomputers were presented either by a computer scientist, a programmer or an applied mathematician. Because the architecture of most supercomputers is radically different from scalar processing machines, this is no surprise. The real importance of this observation is the implied increase in need for multidisciplinary research teams to solve major ecological problems. Unfortunately, in the United States, many of the larger supercomputer funding initiatives do not address this issue at all.

This defect in the supercomputer initiatives leads to two major problems: scientists not doing 'science' and the inefficient use of supercomputers. If funds were available to support programmers with expertise on a machine of a certain architecture, the scientist would only need to communicate effectively with the programmer. The projected changes in architecture affect the programmer and not the scientist; hence the scientist is free to do science.

An alternative to long-run funding of programmer-consultants is for the initiatives to increase their effort in the development of very high level languages. Rice of Purdue's Computer Science Department gave a talk on projected advances in hardware and software over the next 10 years. From 1975 to 1985 computing speed increased by a factor of 25. Between 1985 and 1995 the speed is projected to increase by a factor of 2,000. On the other hand, from 1975 to 1985, computer languages have been improved by a factor of only 1.4. Unless more funding is made available for the development of high-level languages, improvement in ease of coding is not expected to increase nearly as fast as machine computational power. In fact, because of radical changes in architecture, programming may well become more difficult.

Another important point brought out at the seminar is that advances in science should not be overpowered by advances in computational capability. Do we really improve our fundamental understanding of science by looking at larger and larger computational problems? Many would argue that the understanding of complex chemical and physical interactions in the subsurface and the ability to estimate parameters is so poor that the large supercomputer models may in fact be totally incorrect. In this instance, supercomputer modelling efforts may turn out to be a greater obstacle to real progress than no model at all.

So there is clearly a role for supercomputers, but the extent of this role will depend on the availability of high level languages, expert programmer consultants working closely with multidisciplinary teams, exposure to different computational systems, and a judicious choice of problems with the aim of advancing our understanding of science.

The real hazards of nuclear fallout

SIR—In his article "On minimizing the consequences of nuclear war"[1], Carl Sagan is misleading in his discussion of the dangers of radioactive fallout. Our remarks on this question are made in the spirit that the goal of scientists is to be as accurate and unbiased as possible in assessing the potential or alleged impacts of an event such as nuclear war, and that either minimizing or maximizing these consequences is a disservice to the general public and to decision makers who seek guidance. If scientists are not accurate, credibility is lost and messages from the scientific community will eventually be ignored.

To our knowledge, the serious consequences of local (or early) fallout, that which is deposited during the first 24 hours, have been accepted by the scientific community for over three decades. Projections of the intensity and extent of local fallout are highly sensitive to a number of variables, which helps explain why different assessments have produced widely different results. Uncertainties in these projections can be divided into three categories, those due to (1) the targeting scenario, (2) the fallout calculation model and (3) the selected meteorological conditions.

The targeting scenario contains variables such as numbers of weapons, the yield mix, fission fraction, height of burst and precise target locations. The height of burst (HOB) is of particular significance because air bursts do not produce significant local fallout, except for the possible rainout of debris from tactical yield weapons. Only when the fireball interacts with the ground (a ground level or near ground burst) does significant local fallout ensue. A reasonable assumption often made is that hardened military targets are targeted with ground bursts. For the 'softer' industrial and other military targets, maximum damage is accomplished by air bursts where the HOB can be optimized. The primary fires hypothesized in urban areas in 'nuclear winter' studies are assumed to be initiated by airbursts, because ground bursts have shorter range for initiating fires. Hence, maximizing smoke production implies minimizing local fallout. (2) Uncertainties in dose calculations in the best fallout models originate from several sources. These uncertainties are due to limited experimental calibration data, whether the modelled radioactivity is rigorously conserved, and whether time of arrival is properly accounted for. (3) Assumptions about selected meteorology — such as wind velocities, shears, precipitation patterns — affect the results. Hence local fallout assessments can vary greatly depending on these many assumptions.

In assessing the human impact of local fallout, additional factors must be considered. By far the most sensitive of these is the protection factor afforded by structures, such as homes, buildings, basements, and shelters. These structures can dramatically mitigate the unprotected dose assessments normally cited. An additional important consideration is the assummed lethal acute external whole body dose levels. Finally, for radiation exposure that is protracted in time, biological repair of the resulting damage is important in mitigating the effects'. This is especially important with regard to global fallout, where the dose is received slowly over many years. Dose effectiveness factors from 0.1 to 0.5 for chronic exposures have been suggested[2]. This means that a large chronic dose will have an effect equivalent to a much smaller acute dose. Any presentation that implies that our planet would be a radioactive desert of certain demise is not including these important factors in a balanced sense; hence, inaccurate and biased estimates can be created. Calculations of total fatalities produced by large-scale attacks on the continental United States undertaken by our group have produced estimates of fallout fatalities (after subtracting those already killed by blast and thermal effects) that range over almost two orders of mag-

R439

nitude. This large variation in fallout fatalities is well understood in terms of variations in the parameters discussed above.

As part of our contribution to the recent International Council of Scientific Unions (ICSU) SCOPE-ENUWAR study of the environmental effects of nuclear war[3], we undertook calculations of local fallout using the computer model KDFOC2[4], using single burst fallout patterns and a semi-empirical approach for multiple explosions. Calculations were done for a 6,000-megaton multi-phase counterforce-countervalue nuclear exchange. Results indicated that about 7 per cent of the land areas of the United States, Soviet Union and Europe would receive a minimum of 450 rads within 48 hours. This assumed no shielding and would apply to a population unprotected by structures. The SCOPE-ENUWAR study[3] was primarily concerned with direct effects on unprotected plants and animals and excluded direct effects on humans. In considering the direct effects on humans, protection factors and population distribution should be added into the picture, with the result that land area envelopes are reduced below 7 per cent by factors of several (land area envelopes scale very roughly as the inverse of the protection factor). As an example, a recent study[5] used protection factors of 3 for rural areas and 10 for urban areas. The figure of 30 per cent of all northern-midlatitude land areas receiving an acute mean lethal dose to humans obtained by TTAPS and quoted by Sagan[1] is clearly much higher than our SCOPE result, and we believe inaccurate and misleading.

There is a hint of *On the Beach* in Sagan's discussions of global fallout; the spectre of a cloud of lethal levels of radioactivity spreading around the globe. Our group first reported in 1983 that long-term total doses of 100 rem or larger in global fallout hot spots are possible[6]. Sagan refers to this, and then interjects the possible effects of a 100 rem acute dose on the immune system (a speculative new result). This may mislead the reader as there is an immense difference in the effects of an acute compared with a long-term (lifetime or 50-year) dose.

The calculations at Livermore on global fallout reported in 1983[6] were supplemented by additional work in 1984[7]. The original results using the GLODEP2 code[8] assumed an atmosphere unperturbed by smoke. These were supplemented by new work utilizing GRANTOUR[9], a fully interactive microphysical, three-dimensional global circulation model code developed at LLNL. Doses were calculated with and without smoke in the atmosphere to assess the impact of a perturbed climate on global fallout.

Our GLODEP2 calculations for strategic nuclear exchanges of 5,000 to 6,000 megatons predict that the 50-year unsheltered unweathered average external total body gamma dose levels in the Northern Hemisphere would be about 15 rads, and about 0.5 rad in the Southern Hemisphere. The maximum of 30 to 40 rads appears in the 30° to 50° north latitude band. Values predicted for the global population (chronic) dose are typically about 6×10^{10} person-rads. The dose in hot spots, obtained using an area grid of 10° latitude by 10° longitude, are a factor of 6 to 8 higher than the Northern Hemisphere averages. These results have an estimated confidence level of about a factor of 2. Some 50–75 per cent of the global fallout dose is due to the tropospheric injections of radionuclides that are deposited in the first month.

The additional calculations, utilizing GRANTOUR involving a perturbed nuclear winter atmosphere indicate that the above dose assessments would be about 15 per cent lower in the Northern Hemisphere and marginally higher (approximately 1 rad) in the Southern Hemisphere compared to the unperturbed atmosphere predictions. These results are consistent with the projection that smoke injections can increase vertical stability, inhibit precipitation, and increase interhemispheric transport. We note that the GRANTOUR calculations utilizing a fully interactive microphysical approach with a three dimensional global circulation model produced results that were in good general agreement with the GLODEP2 results that depended on empirical observations from past atmospheric tests.

These calculations have been presented at a number of scientific meetings, including the ICSU-SCOPE workshop on radiation held in Paris in October 1984. There, an international array of radiation experts reviewed this work in detail, and it then became a basis of the chapter of radioactivity in the SCOPE-ENUWAR report[3] and underwent additional external review by dozens of international experts. The effects of these levels of global fallout were summarized in the Report of the Paris Commission on Radiological Dose Assessments and Biological Effects[10]. It concluded "The long-term increase in genetic and carcinogenic effects on humans from global fallout is of the order of 1 per cent of the natural incidence and should be considered a second order effect." No mention is made of pro-dromal effects on humans because at these lifetime dose levels and considering biological repair, pro-dromal effects from global fallout would not be observed. This does not sound anything like the *On the Beach* scenario or the impression transmitted to the audience at the Washington Sheraton Hotel briefing held by Sagan and others on Halloween, October 1983.

It is true that our original calculations have not been published in a refereed journal, nevertheless they have undergone extensive external review. Sagan should perhaps heed the Biblical injunction "let he who has not sinned cast the first stone". Reference 2 in his paper[1] (EOS, **63**, 1018; 1982) is a 250-word unreviewed abstract of a paper that was to be given at the San Francisco meeting of the American Geophysical Union but was cancelled before presentation. Authored by the "TTAPS team", this unpublished paper was cited in Sagan's recent *Nature* article 10 times!

This work was performed under the auspices of the US Department of Energy by the Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48.

ANNOUNCING Volumes 10 & 11 in the internationally acclaimed series

PRACTICAL METHODS IN ELECTRON MICROSCOPY

edited by Audrey M. Glauert

"This is the standard manual that could hardly be improved, a must in any electron microscopical laboratory, and equally important to the beginner and the experienced investigator."
Bjoïn Afzelius Science Tools

Volume 11

Thin foil Preparation for Electron Microscopy

by **P. J. Goodhew**

This comprehensive volume covers all the commonly-used techniques for preparing thin specimens for transmission electron microscopy in material science. Full descriptions are given of both simple laboratory techniques and sophisticated commercial thinning equipment for electropolishing, ion beam milling and replica making.
All the stages involved in the production of a thin foil from a large piece of metal, ceramic, polymer or semi-conductor are described.

CONTENTS: Chapters. 1. Introduction. 2. Initial preparation of bulk specimens. 3. Final thinning: chemical and electropolishing. 4. Final thinning: ion beam thinning and mechanical techniques. 5. Preparation of specimens with difficult geometry. 6. Replica techniques. 7. Mounting and storing specimens. Appendix. List of suppliers. Subject index.

1985: xiv + 216 pages
Price: US $ 64.75/Dfl. 175.00
ISBN 0-444-80701-2
Hardback
Price: US $ 24.00/Dfl. 65.00

Volume 10

Low Temperature Methods in Biological Electron Microscopy

by **A. W. Robards** *and* **U. B. Sleytr**

This volume gives a comprehensive description of the state of the art of low temperature methods for ultrastructural studies on biological specimens. The theory behind each technique is described to form a scientific basis upon which to build.
Methods given in each chapter are complete and self-explanatory. Clear flow diagrams and schematic drawings allow a fast access to each technique and possible combination of procedures.
The chapter on freezing is essential introductory reading for the other chapters. It gives an unique survey and analysis of the theoretical and practical aspects of the freezing of water and of biological tissues.
Although written for biologists, this book is highly recommended to materials scientists studying hydrated specimens by electron microscopy.

CONTENTS: Chapters. 1. Introduction. 2. Freezing. 3. Direct viewing and analysis of cold specimens. 4. Freeze-sectioning. 5. Freeze-drying. 6. Freeze-fracture replication. 7. Freeze-substitution and low temperature embedding. 8. Future Outlook. Appendix 1. Safety. Appendix 2. List of suppliers. Subject index.

Group selection revisited

Eric Charnov

Evolution Through Group Selection. By V.C. Wynne-Edwards. *Blackwell Scientific:1986. Pp.386. Hbk £29.50, $58; pbk £14.95, $29.*

NEARLY 25 years ago, V.C. Wynne-Edwards published a provocative and important book about the evolution of social behaviour. It was entitled *Animal Dispersion in Relation to Social Behaviour,* and in it Wynne-Edwards proposed that most features of vertebrate reproductive and social behaviour are adaptations whereby populations regulate their numbers and so avoid over-exploitation of their food resources. Most of the book was a discussion of biological examples of this process at work. Thus, clutch size, territoriality, dispersal, male display and competition for females, as well as other aspects of social interaction, were assigned functions in terms of population regulation — individuals practised reproductive restraint when necessary for the good of the group's resource management. Of course, such group-level adaptations would seem to require that natural selection acts mainly on the group, and not through individual reproductive success.

Animal Dispersion had an immediate impact. It drew an enormous following, and during the 1960s various ideas based on "group selection" became popular among many biologists and social scientists. The book's appeal may have stemmed from the intellectual climate of the time, combined with the facts that the main thesis was both morally satisfying and a *tour de force* of radical thinking: to explain so much with one simple principle!

Wynne-Edwards himself realized that *some* form of group selection was required by his theory; he clearly said so. And his main critics (D. Lack, W.D. Hamilton, J. Maynard Smith and G.C. Williams) immediately fired back. To them it seemed unlikely that natural selection at a group (or population) level could overcome selection at the level of individuals. Furthermore, most of the biological examples he discussed, and which he saw as beneficial in regulating a population, could, they considered, be more easily explained in terms of individual reproductive success. This latter criticism was even more important than those of the notion of group selection; alternative hypotheses, not considered by Wynne-Edwards, did a better job with the data, and his vision of individual reproductive restraint was illusory. So said the critics. However, by taking such a strong stand on the "why's" of social evolution, his book focused attention on the subject: ideas that were developed over the past two decades in opposition to his theory are prominent in much of the current thinking in sociobiology and behavioural ecology.

This new book is an up-date of *Animal Dispersion.* The first half includes a restatement of the hypothesis that populations manage their resources; again, most social interaction (at least in vertebrates) is seen as operating to regulate the population concerned. Following this is an account of the population and social dynamics of red grouse, the fruit of a superb long-term field study. In the second half of the book Wynne-Edwards discusses group selection as a process, both in theory and as seen against the data. He introduces one major new "population level benefit" hypothesis, describes a few case histories and ends with a good summarizing chapter. His new hypothesis, to which I shall come in more detail at the end of this review, is that populations benefit from managing their genetic structure; somehow, natural selection has favoured populations which control their mating system (for example monogamy versus polygamy), dispersal and other genetic characteristics which may be involved in the working of group selection. Simply, these controls exist and they function to facilitate the evolution of group benefits. They both facilitate group selection, and are themselves examples of it.

Subject of study — the red grouse, well-camouflaged in its natural habitat.

This new book is bound to be widely read and discussed. In my opinion, however, it suffers from many of the same problems as its predecessor. At issue here is not the *possibility* of group selection, but whether it has produced all (or many of) the behaviours and reproductive phenomena that Wynne-Edwards considers.

To develop this point, let us first consider the "resource management" hypothesis. Here I will pose three questions. Is it needed (in theory)? Is it supported by the evidence? Is it a likely outcome of a group selection process? This critique applies equally to the conceptual development of the author's theory and his case history of red grouse.

Wynne-Edwards claims that predator populations *must* regulate their numbers socially or they would typically decimate their prey populations; this applies also to herbivores and their food plants. But I know of nothing in population dynamics theory which generally supports this proposition. Numerous equations describing predator–prey interaction have stable or cyclical solutions. Predators may often be limited by their own predators, by parasites or by the availability of food of adequate quality. Density-dependent birth and death effects may operate in many ways, and may often stabilize the population at numbers far short of those required for resource destruction. The fact that individuals use social interaction to compete for food, space or mates does not necessarily support any hypothesis of population regulation; indeed, even if social interaction *does* sometimes regulate population size, such a density-dependent effect may simply be viewed as a by-product of individual reproductive competition. Wynne-Edwards's blanket claim — that we need social regulation or else . . . — is much too strong. (While I accept his key observation that predators do not usually decimate their prey, I doubt that anyone has studied how often this does or does not occur.) Of course, that "resource management" may not be needed *generally* does not mean it does not or cannot ever happen.

In the past 20 years we have greatly increased our knowledge of social evolution and natural selection, including group selection. Wynne-Edwards discusses a fair bit of this newer work on group selection, but he mentions none of the rest of sociobiological thought. Modern ideas on mating systems, sexual selection, sex allocation, territoriality and group structure, game theory and evolutionarily stable strategies — almost the entire contents of books such as *Behavioural Ecology*, edited by J. Krebs and N. Davies (Blackwell Scientific, 1984) or M. Daly and M. Wilson's *Sex, Evolution and Behavior* (Duxbury, 1983) — are virtually ignored. This is perhaps the book's greatest failing. At the very least, the author ought to have attempted to convince us by a fair contest of various ideas set against the evidence, especially when many workable alternatives were put forth in response to his

previous book. Although plenty of data are discussed, critical tests of hypotheses are not. We are, then, left with a work of advocacy.

Professor Wynne-Edwards appears to have adopted the position that the criticisms of *Animal Dispersion* simply mandated his finding, demanding only that he should demonstrate a mechanism of group selection which he has now found in the works of M.J. Wade and D.S. Wilson.

"Group selection is *not* different from natural selection. ..."

The concept of group selection has had a chequered history, and here I can give only a necessarily simplistic account of the arguments. Readers who wish to follow things up should refer to the review articles by M.J. Wade (*Q. Rev. Biol.* **53**, 101–114; 1978) and D.S. Wilson (*A. Rev. Ecol. Syst.* **14**, 159–187; 1983).

Group selection is *not* different from natural selection. Suppose a population is split into groups where the members within a group interact mostly with each other. As a result of social interaction, feeding, predator escape and so on, individuals produce offspring. Clearly, natural selection will favour attributes (genes building phenotypes) which confer higher reproductive success. But a phenotype's reproductive success or fitness may be thought to consist of two parts: the first is an individual's contribution of genes, relative to other members of its group; the second is the group's contribution of genes to the overall population. These are the within-group and between-group components of fitness. While not all theorists agree with this distinction, it is useful in showing that attributes may sometimes be selected for if they increase group productivity, even if their bearers do worse at reproducing relative to other members of their own group.

Of course, some attributes may increase *both* group productivity *and* an individual's fitness relative to other group members; these two components of fitness need not conflict. The strength of each component depends upon factors such as group size and stability, how groups are formed, dispersal patterns and so forth. Using a fairly extreme form of differential group productivity (extinction), Wade has demonstrated in laboratory experiments with *Tribolium* that the between-group component of fitness is sufficient to produce a fair amount of phenotypic change. A group-selection effect has also been shown in the field for the evolution of sex ratio in group-structured populations of parasitoid wasps and mites. Briefly, a sex ratio of 1:1 is favoured within each group, but the migrants or dispersers are all females and so the group productivity component of fitness favours a female-biased sex ratio. It is the within-group component of fitness that favours an equal sex ratio. The resulting sex ratio *is* often female biased, reflecting a balance of the between- and within-group components of fitness. This group-selection interpretation for the female-biased sex ratio is not accepted by everyone, and other explanations are possible. Yet I think it is a reasonable interpretation. So, the between-group component of fitness can influence evolution; it can sometimes affect the value of characters. In his 1983 review, Wilson suggested that the evolution of traits containing a strong component of self-sacrifice would probably require small groups with one or a few founders (or kin selection, see below), and he made the sensible suggestion that the traits most likely to be favoured with more diffuse groups would be those with high social (group) benefit and little personal costs. Altogether, biologists would do well to pay closer attention to the thoughts of Wilson and Wade.

Wynne-Edwards is doing much more, however, than arguing that selection can sometimes favour traits which benefit the group. He is claiming that such traits will *usually* evolve and will include traits for population regulation for resource management. He further asserts that such traits will often not be opposed by the within-group component of fitness; what benefits the group will usually benefit the individual within the group. Although this latter assumption supports his hypothesis, I can think of no compelling reason why we would find it to be true for the multitude of examples that Wynne-Edwards discusses. Furthermore, nothing in the literature particularly suggests population regulation as the typical or expected outcome; the example of sex ratio in wasps and mites was not at all related to potential over-exploitation of food resources.

"Wynne-Edwards is doing much more, however, than arguing that selection can sometimes favour traits which benefit the group. ..."

Another response to *Animal Dispersion* was the development of the theory of kin selection, mainly by W.D. Hamilton. There are several approaches to this question, one of which shows kin selection to be a special case of group selection, as discussed above. In the new book, Wynne-Edwards shows a curious love–hate relationship with kin selection. Early on he claims that it is a form of group selection; then, in the final two chapters, he totally rejects it in favour of group selection. Scattered throughout the book are various discussions of the inadequacy of kin selection to explain this or that; these are invariably followed by a glib claim that group selection will do the trick. I really do not know what to make of such statements.

I will end this review with a brief discussion of Wynne-Edwards's new proposal: that is, populations genetically structure themselves to foster beneficial processes such as group selection. I find this notion difficult to understand in terms of population-level adaptation. Let us consider an example. In Chapter 16, Wynne-Edwards uses the idea to explain a long-standing puzzle in the reproductive biology of Atlantic salmon. Immature fish (called parr) first spend a few years in fresh water, and then go to the sea to feed, grow and mature, before returning as adults to spawn in fresh water. The puzzle is that some parr (young males, who have not yet gone to sea) become reproductive, spawn and then turn off sperm production to join the usual out-migration to the sea. Some of these parr will undoubtedly return to spawn as adults. Wynne-Edwards's answer to this puzzle (why do parr become reproductive?) is that these fish are assigned the role of keeping genes in the group. Field data suggest that many adult fish do not return to their home stream to spawn; thus, the parr are the main bearers of in-group genes to the local group and this role is a form of genetic structuring favoured by group selection.

Three observations are in order. First, the population structure (with lots of mixing of fish from different groups during reproduction) is just that where group selection would not really work. Second, the population-level benefits of this "in-breeding" are not really specified (and totally escape me). Third, small breeding males are common in fish species and have now been studied in salmonids. The idea of the frequency-dependent fitness advantage of small males, in reproductive competition with larger males, has proved a very powerful tool in the analysis of these systems; this involves no postulated group benefit whatsoever. Readers of Wynne-Edwards's present book should compare carefully his explanation for the existence of these small breeding males with the evidence and interpretation of the same phenomenon by M. Gross (*Nature* **313**, 47–48; 1985). A fair contest of ideas would seem to be in order.

Animal Dispersion, or rather the responses to the extreme position adopted by Wynne-Edwards in that book, did much to discredit notions of group selection. For many people, the pendulum has swung from uncritical acceptance to equally uncritical rejection of the idea. I hope that the similarly extreme tone of *Evolution Through Group Selection* does not add further to that process. Natural selection, operating in a group-structured population, can sometimes produce the unexpected. And we still have so much to learn. □

Coming in to the cold

Daniel Branton

Low Temperature Methods in Biological Electron Microscopy. By A.W. Robards and U.B. Sleytr. *Elsevier:1985. Pp.551. Hbk $111, Dfl. 300; pbk $48.25, Dfl. 130.*

GREATER USE of low-temperature methods and frozen specimens in biological electron microscopy has resulted from recent advances in a variety of morphological and analytical applications, especially freeze-etching, immunocytochemistry and the direct examination of hydrated frozen specimens. While all of these applications depend upon the use of frozen specimens, workers experienced in one particular area will, upon reading Robards and Sleytr's book, discover well-developed traditions and critical manipulations that have simply not crossed the boundary between, for example, those laboratories engaged in freeze-etching and those doing cytochemistry of frozen sections. For the expert, this book is the equivalent of an informative tour of distant laboratories. Here they will learn of the latest "tricks" in freezing biological materials, direct viewing of frozen specimens, freeze-sectioning, freeze-drying, freeze-substitution, low-temperature embedding and freeze-fracturing.

The book will also be very helpful for the non-expert. It is a clear and accurate survey of a large number of methods, almost all of which are illustrated and wisely accompanied by detailed description and discussion. Although the amount of detail may appear excessive, success with low-temperature methods often hinges on apparently minute points. Freezing and freeze-etching methods are particularly well covered, and attention is given to tissue differences and important principles of sampling and interpretation that are often overlooked in "methods" books. Throughout, the authors provide critical comparisons and sufficient background and theory so that readers can decide for themselves what they can hope to gain by using low-temperature methods, and which method should be selected from the many available.

The book is abundantly illustrated but the graphics are often disappointing. The authors' attempt to be comprehensive is admirable, but the introductory diagrams are sometimes so cluttered with details of alternative pathways that many readers will have the impression of being given an unabridged chart of intermediary metabolic pathways before even having been introduced to the tricarboxylic acid cycle. An appendix listing suppliers of commercially available equipment is included, but it is not as useful as it could have been: there are too few listings under specific categories and little attention has been given to suppliers outside Europe.

A breakthrough in low-temperature electron microscopy has been the demonstration that biological specimens can be vitrified. Although some of the techniques for the preparation and direct viewing of vitrified specimens at high resolution are included, the coverage here is neither as well organized nor as complete as this promising area deserves. To be fair, these methods are very recent; but it is regrettable that Robards and Sletyr did not have more of an opportunity to comment on these advances, for they have otherwise produced a discerning and up-to-date reference work. □

Graded grains

Peter D. Moore

Numerical Methods in Quaternary Pollen Analysis. By H.J.B. Birks and A.D. Gordon. *Academic:1985. Pp.317. $59, £45.*

Pollen Records of Late-Quaternary North American Sediments. Edited by Vaughn M. Bryant Jr and Richard G. Holloway. *American Association of Stratigraphic Palynologists Foundation, PO Box 819047, Dallas, Texas 75381, USA:1985. Pp.426. $35.*

ONE of the most valuable features of pollen grains as palaeoecological material is their sheer abundance. Combine this with their capacity to survive well in peats and lake sediments, and we have in fossil pollen assemblages a splendid opportunity to use numerical methods for their analysis. This was immediately apparent to von Post when he first came upon pollen in peat and it has been exploited by all subsequent research workers in the area. Until the 1960s numerical analysis was restricted to the expression of pollen counts in terms of percentage values, but since then there has been rapid growth in ways of treating data in order to improve their value to the palaeoecologist. Among those who have led this field of enquiry, few have contributed more to its development than the authors of *Numerical Methods in Quaternary Pollen Analysis*.

In their book, Birks and Gordon present a critical review of the current state of each aspect of Quaternary palynology to which numerical techniques have been applied, commencing with the most obvious, the presentation of pollen data. The use of binomial and multinomial models, as originally described by Mosimann, is explained in some detail, though, as a basis for establishing homogeneity within a section of the stratigraphic profile, ordination methods are preferred. This involves the classification of samples, using spatial models, on the basis of dissimilarity indices.

This approach provides a number of opportunities to the palynologist, one of which is the establishment of objectively determined zones. These are subdivisions of the pollen profile into relatively homogeneous subunits for the sake of simplicity. In the early days a subjective approach to this process was considered perfectly adequate, since zones are simply aids to description of pollen proportions in time (that is, vertical space in the sediments) Recently many research workers have questioned the need for such zones at all, because they have led to a great deal of confusion in the past, while others feel that each of the main pollen taxa should be zoned independently. One wonders, therefore, whether sophisticated methods of zonation based on tests of homogeneity are necessary, but the practice is unlikely to do any harm and it may give confidence in the location of lines of maximum change.

Much more useful, in my opinion, is the application of the same group of techniques to follow the course of development of pollen assemblages through time, to compare one sequence with another and to set a fossil sequence in the context of modern pollen studies. Here the numerical approach comes into its own and many of those who doubted the value of these methods in the past, myself among them, have now become regular users.

Several variants of ordination methods are currently available for this type of work and they are well known to phytosociologists. These techniques are well explained by Birks and Gordon, and their application to palaeoecology is set out with clarity and enthusiasm. Many waverers have already been converted to their use and this book will be a means of initiating yet more palynologists into an increasingly fruitful type of analysis. Altogether, no palynological laboratory can afford to be without this compendium.

The second book under review, a manual of results rather than methods, is a long overdue synthesis of the vegetation history of North America through the late Pleistocene and Holocene. It is divided into geographical regions, ranging from Mexico to Alaska and Texas to Quebec, each dealt with by a different author. In each chapter representative pollen diagrams are reproduced and the variation in vegetation history is described, together, where appropriate, with assessments of climatic variations and human impact.

The emphasis is naturally upon vegeta-

tion change rather than methodology, but there are some helpful discussions of techniques such as the interpretation of alluvial pollen data in the drier regions, as in New Mexico, and the development of the isopoll vegetation maps in the north-east. The bibliographies supplied with each chapter are extensive and are a splendid point of entry to the relevant literature.

The timing of this volume is somewhat surprising, coming as it does on the heels of the two-volume *Late Quaternary Environments of the United States* (University of Minnesota Press/Longman, 1984). There is obviously a fair degree of overlap with that work, but the book reviewed here is confined to pollen data and is thus more detailed in vegetation descriptions and in its attention to regional variation.

Bringing so much information into one volume must have been a formidable undertaking and it has been brought off successfully only by careful planning and editing. Apart from finding a wide audience in North America, the book will be welcomed by palynologists on this side of the Atlantic who, perhaps, may be inspired to perform a similar service for Europe. □

Done with a will

Richard Passingham

The Brain Machine: The Development of Neurophysiological Thought. By Marc Jeannerod. Translated by David Urion. *Harvard University Press:1985. Pp.171. $16.95, £14.50.*

THE subtitle of *The Brain Machine* says that it deals with *The Development of Neurophysiological Thought.* It doesn't. In the original French the subtitle is *Physiologie de la Volonte,* and indeed the book turns out to be about the history of neurophysiological speculation about willed movement.

In Descartes' time people were credited with a will but animals were not. Descartes correctly conceived of the brain as a machine, although his conception of its workings was quaint. However, he also believed that by some mysterious process the machine was controlled by an indwelling soul.

Later physiologists, such as Hughlings Jackson, suggested a class division within the brain: based on the observation that damage to the motor cortex interfered with willed movements while leaving many automatic movements intact, the idea was that the lower centres catered for our animal needs, while the higher neocortical centres supervised our voluntary activities. Certainly, it is true that patients with such damage report that it is their subjective impression that moving the affected limb requires them to summon up an effort of will.

Jeannerod argues that "the elucidation of the term 'will', and the multiple concepts it covered, without doubt constitutes the central problem in comprehending the physiologic bases of the different aspects of movement" (p. 20), and in the various chapters of his book he covers some of these concepts. One issue is how a movement is triggered. We carry out some movements in response to external prompts, but there are others that we perform at our own direction and at our own pace. In accounting for spontaneous movement, the author mentions the spontaneous rhythms of the electroencephalogram and the oscillators proposed by von Holst. He also describes studies in which slow potentials are recorded from the cortical motor areas while subjects make simple movements. These potentials differ in their pattern and timing when it is the subject rather than the experimenter who decides when the movements are to be made.

A second idea is that of intention. Jeannerod argues that if a movement is intended the brain knows "what will happen as a result of its own action" (p. 97); that is, the brain is aware of its own commands and can therefore compare what happens with what was intended. A copy of the command to the motor system is sent to other centres, but if a movement occurs which is not intended there will be no such copy.

There is, too, a third notion: "Human action, when it is voluntary, intentional, or propositional, has the distinction of being dominated by language, in the sense that language precedes the action and is an integral part of the representation" (p. 121). More generally there must be a plan; people can try out possible actions in their heads before performing them. Recent technology has allowed us to detect evidence of such planning. When brain regions increase their activity they increase their metabolic requirements, and we can use the flow of blood to an area as a measure of its metabolic activity. It is now possible to take these measurements from the outside of the skull and thus to investigate the activity of brain regions in human subjects while they carry out mental work. If subjects are asked to rehearse mentally a set of finger movements without actually performing them, activity can be detected in the supplementary motor area.

Jeannerod's book gives the history of these and other ideas. He includes chapters on such topics as the natural history of the soul; hierarchy and integration of movements; the motor cortex; the physiology of spontaneity; representation, plan, programme; and action, the force of self-organization. He ranges widely, his theme taking him from animal spirits to electrical conduction, and from spinal reflexes in frogs to apraxia in the hospital clinic, and also into the realms of European philosophers such as Schopenhauer, Cassirer and Merleau-Ponty. Because the thrust of the book is primarily historical, Jeannerod says little of modern experiments in modern physiology. But the history of ideas on this subject is intriguing, and makes an altogether fascinating story.

The book is illustrated with line drawings, some of which are delightful: for example, the author reprints Descartes' splendid drawing of the mechanism for muscular contraction, a naive diagram by an alchemist of mental function and a beautiful drawing of a brain dissection done in 1827. The text has been well translated by David Urion, and it is to his particular credit that if the book were handed to someone who did not know they might fail to guess the language of the original. □

The mean mass density of the Universe

P. J. E. Peebles

Joseph Henry Laboratories, Princeton University, Princeton, New Jersey 08544, USA

Observations of galaxy clustering indicate that the mean mass density is only about one-third of that predicted by the popular Einstein–de Sitter cosmological model. Theory and observation can be reconciled if there has been large-scale segregation of galaxies from mass, but the gravitational instability of the expanding universe would tend to destroy such a segregation. Thus either conventional ideas about galaxy formation are wrong, or the Einstein–de Sitter model is not a useful approximation.

THE mass distribution of the universe is approximately uniform on a large scale, and can be described by two parameters: the mean mass density ρ and the expansion rate H. Conventional general relativity gravity theory indicates that if ρ is large enough the expansion eventually stops and the universe collapses to a singularity, while for small ρ the universe continues to expand forever. This conventional theory has two defects: it fails to explain why the large-scale mass distribution should be so close to uniform and its requires that the expansion can be extrapolated back to a singularity at a definite time in the past. As will be indicated below, Guth's[1] inflation model offers a partial solution to both problems. In the usual interpretation, inflation requires that the mean mass density ρ be equal to the critical value that separates universes that eventually collapse from those that expand forever, so that ρ has a definite value fixed by the expansion rate, H. However, as will be described, estimates of ρ based on derived masses of clusters of galaxies and counts of these objects are lower than the critical value by a factor of ~3. It is impressive that the observed density is so close to the expected critical value, but it is also apparent that the discrepancy is real. We can avoid the problem by recalling that the gravitational acceleration of a hollow spherical mass is zero inside the sphere. Thus estimates of the mass of a cluster of galaxies based on the accelerations of the galaxies in the cluster would miss any mass on the outskirts beyond the observed galaxies. The 'biased galaxy formation' model, in which galaxies form in islands surrounded by a sea of dark mass, can thus reconcile the observed mass density with the larger theoretically expected value. However, there is yet another consideration. The universe is gravitationally unstable, which means that gravity is drawing galaxies together to form an ever larger hierarchy of clusters. Because different forms of mass fall at the same gravitational acceleration, the gravitational instability draws mass together with galaxies. Thus if galaxies formed in tight islands, then the collections of islands formed later by gravity would be expected to yield a higher apparent mean mass density. The fact that this is not observed suggests that either galaxies formed in a different way from the standard picture, in islands large enough that all available observations miss the sea, or else that ρ really is smaller than the critical value.

The idea that the mean mass density might be expected to equal the critical value predates the inflation model. The historical development of this idea is reviewed in the next section, in order to show why the value of ρ has received so much attention and has so strongly influenced the direction of research in cosmology. There follows a review of observational estimates of ρ, which shows that the measurements are now sufficiently detailed to merit serious attention. Possible ways to reconcile the observations with the higher critical mass density are discussed next. Finally, I indicate how we might most simply adapt our ideas on cosmology if a low value of ρ is accepted.

Historical remarks

Cosmological models. In the general relativity cosmological model the rate of expansion, measured by the Hubble constant, H, and the mean mass density, ρ, are related by the equation

$$H^2=\frac{8}{3}\pi G\rho\pm\frac{c^2}{(aR)^2}+\frac{\Lambda}{3} \qquad (1)$$

The radius of curvature of space (measured at a fixed cosmic time, t) is $a(t)R$ (where R is the cosmic scale factor). Λ is Einstein's cosmological constant, and the dimensionless expansion parameter $a(t)$ is proportional to the mean proper distance between conserved particles (such as galaxies). G is the universal gravitational constant, and c is the speed of light. The mass density term is often written as $\frac{8}{3}\pi G\rho = H^2\rho/\rho_c = \Omega H^2$, where $\rho_c = 1.88\times10^{-29}h^2\,\mathrm{g\,cm^{-3}}$ and $H = 100\,h\,\mathrm{km\,sec^{-1}\,Mpc^{-1}}$. The length unit is 1 Mpc (megaparsec) = $3.1\times10^{24}\,\mathrm{cm}\simeq3\times10^6$ light yr. The dimensionless parameter h reflects the uncertainty in the Hubble constant; it is thought to be in the range $0.5\leq h\leq1$. The critical density is ρ_c. If $\Lambda=0$, as is usually assumed, then if $\rho<\rho_c$ the universe continues expanding indefinitely, and if $\rho>\rho_c$ the universe eventually collapses. The density parameter is the ratio $\Omega=\rho/\rho_c$ of the mean mass density to the critical value.

Arguments for $\rho=\rho_c$. The value of Ω is of course an observational question, but one gets a useful guide to its significance by reviewing the theoretical arguments which have been advanced in support of $\Omega=1$.

The cosmological model with $\Lambda=0$ and $\Omega=1$ is named after Einstein and de Sitter[2,3], who argued as follows: in the original static Einstein cosmological model the presence of a non-zero mean mass density ρ (with a reasonable pressure) requires that Λ and space curvature both assume specific non-zero values. By 1932 it was recognized that the static model is a special case; a positive mean mass density generally requires evolution in time (expansion or contraction of the universe). Einstein and de Sitter noted that in evolving models with non-zero mass density there is no requirement that Λ or space curvature be non-zero, and suggested that these terms might be dropped. De Sitter recognized that if $\Lambda=0$ and $R^{-2}=0$ it would require a rather large mean mass density, but he argued that this is not inconsistent with the observations. However, his estimates of the number density of galaxies and the mean mass per galaxy exceed the values found by Hubble[4], and in the more recent work summarized below.

In a second argument, one observes that the mass density term in equation (1) $\frac{8}{3}\pi G\rho$, varies at least as rapidly as $(a(t))^{-3}$,

the curvature term varies as $(aR)^{-2} \propto (a(t))^{-2}$ and the last term is $\Lambda/3 =$ constant. The three terms thus vary with time in three different ways. The values of these terms were presumably set as initial conditions in the very early universe when classical general relativity theory became a useful approximation and when the expansion parameter $a(t)$ was very much smaller than it is now. If $\Omega \neq 1$, at least two of the terms on the right-hand side of equation (1), density and one other, make an appreciable contribution to the present expansion rate, H. But because these terms vary with $a(t)$ in different ways, in the very early universe the two terms that are comparable now would have been vastly different, but by the highly special factor needed to make the terms comparable just now. This is an unlikely arrangement. The advantage of the Einstein–de Sitter model is that the one term we know is present, the mass density, always dominates. This attractive argument based on the undesirability of coincidences is not easy to find in the literature before the introduction of the inflation model, although Dicke[5,6] has advanced it for 25 years.

Wheeler[7] has long argued that Mach's principle, which states that inertial motion is defined by the mean motion of mass in the universe, sets boundary conditions for general relativity, requiring that space be closed, like the surface of a sphere. This eliminates Minkowski space (which is the limit to which an open expanding universe with $\Lambda = 0$ tends as $t \to \infty$), in which test particles have inertia but there is no background matter to define inertial motion. If $\Lambda = 0$ a spatially closed universe requires $\Omega > 1$, which means the density is high.

In Guth's[1] inflation model, the expansion of the universe can be traced back to a phase transition before which the energy density of space would have had a large, nearly constant term (which behaves like a large Λ-term) that would have caused space to expand as an exponential function of time (instead of the power-law expansion of the usual models). If this exponential 'inflationary' phase lasted long enough it could have stretched all characteristic lengths, in whatever chaos the inflation started from, to values larger than the maximum distance we can see, $cH^{-1} \simeq 3{,}000\ h^{-1}$ Mpc. That would account for the fact that we see such very small density gradients around the sky at depths $\simeq cH^{-1}$. But then it would have to follow that the radius of curvature $|aR|$, is also much larger than cH^{-1}, so the curvature term would have to be negligibly small in equation (1). The coincidence argument mentioned above says that Λ ought to be negligible. Particle physicists observe that Λ has the units of mass to the fourth power (with suitable factors of G, c and Planck's constant). A reasonable mass from particle physics yields a value of Λ suitable for the inflationary phase but more than 100 orders of magnitude larger than is now observationally acceptable[1]. The only other 'reasonable' value is $\Lambda = 0$, which brings us to $\Omega = 1$.

Finally, galaxy formation seems to be easier to understand if $\Omega \simeq 1$ because if $\Omega \ll 1$ the kinetic energy of expansion dominates the gravitational potential energy, thus suppressing the growth of mass concentrations by gravity[8], so that to get the observed degree of small-scale clustering of mass in galaxies and clusters of galaxies we would have to postulate larger initial mass-density fluctuations in the early universe, which would cause fluctuations in the microwave background that are uncomfortably large compared with the observational limits[9].

Exotic matter. Evidence for a low mean mass density in baryons comes from the computed production of elements in the hot Big Bang. It is difficult to see how the abundance of deuterium in our stellar neighbourhood could have been produced in stars. If an appreciable part of the deuterium were to have been produced in the early universe in the conventional hot Big Bang cosmology it would require a mass density of baryonic matter that (with a value of H in the standard range) would imply $\Omega \lesssim 0.1$ (ref. 10). However, as noted by Chapline[11] and Gott *et al.*[10], that constraint would be lifted if the mass of the universe were dominated by non-baryonic matter such as small black holes or massive neutrinos; the list of such possible exotic forms of dark matter is now quite long[12]. Thus it appears that if $\Omega = 1$ the mass of the universe must be dominated by exotic matter other than the material out of which we and stars and the bright parts of galaxies are made. There are some prospects for the experimental detection of exotic matter if it is present in our neighbourhood of the Galaxy[13].

Segregation of galaxies from mass. It was well established by the early 1970s that the 'seen' mass in the dense central parts of galaxies is well below what is required in the Einstein–de Sitter model, but there were already indications that there is considerably more mass in 'massive faint extended haloes' of galaxies[14]. Gott *et al.*[10], arguing partly from the nucleosynthesis constraint on the baryon density, concluded that $\Omega \simeq 0.06 \pm 0.02$. Ostriker *et al.*[15] and Einasto *et al.*[16] argued that there is in fact a lot of mass outside the bright parts of galaxies, the observations suggesting that the mass of a galaxy increases almost linearly with radius to at least ~1 Mpc, which would bring the density parameter to $\Omega \simeq 0.2$. If the trend of mass with radius extrapolated to the mean separation between galaxies, $\sim 4\ h^{-1}$ Mpc, it would bring Ω quite close to unity[17]; however, there has recently been considerable improvement in the dynamical estimates of masses on scales larger than that of a single galaxy and, as described below, it appears that the trend does not continue. If the mean mass per galaxy derived from the dynamics of groups and clusters were assigned to all galaxies it would yield $\Omega \simeq 0.3$, quite close to the estimates of a decade ago.

Although dynamical estimates of Ω use whole-galaxy masses (because they consider systems of galaxies) they could nonetheless underestimate Ω if there were a smoothly distributed mass component that has little effect on clustering dynamics. In the now standard version of this idea it is argued that galaxy formation would be expected to be biased toward regions of higher than average mass density, where galaxies could more readily form and survive. The current interest in this idea largely developed out of a series of papers that appeared in published or preprint form in 1984. Kaiser's[18] argument that clusters of galaxies may cluster more strongly than do galaxies themselves, because clusters are unusually dense spots that tend to have dense surroundings, was soon generalized to the suggestion that galaxies cluster more strongly than mass because galaxies form at unusually dense spots[19,20]. Rees[21] emphasized that it is easy to think of ways in which the formation of a galaxy could influence the formation of neighbours; and Davis *et al.*[22] found that N-body model simulations of the motion of pressureless matter in an Einstein–de Sitter model would give reasonable results if galaxies were located at the high (2.5 standard deviations) mass density peaks. Biased galaxy formation is the framework for most recent papers on galaxy formation[22–28].

Estimates of Ω

Three methods have yielded useful measures of Ω from galaxy clustering dynamics. We are in a small collection of galaxies, the Local Group, on the edge of a large cloud, the Local Supercluster (LSC), which is roughly centred on the Virgo cluster of galaxies. The mass concentration in the LSC produces an inward peculiar velocity field, v_v. We can hope to measure v_v and so derive the local peculiar gravitational field and hence the mass excess, δM, in the LSC. If this is a fair sample then the mean mass per galaxy in the LSC multiplied by the global mean number density of galaxies yields the global mean mass density[29,30]. Recent estimates[31,32] of v_v are in the range $150 \lesssim v_v \lesssim 450\ \mathrm{km\ s^{-1}}$. The concentration of bright galaxies within our radius in the LSC is $\delta N/N = 2.2 \pm 0.3$, where N is the expected mean number of galaxies for a homogeneous distribution and δN the observed number minus N. The recession velocity of the Local Group from the Virgo cluster is $cz = HR_v - v_v = 980 \pm 50\ \mathrm{km\ s^{-1}}$, where R_v is our distance from the centre of the mass concentration. (z is the redshift corresponding to this recession velocity.) If the material in the LSC is a fair sample,

so that the mass concentration is $\delta M/M = \delta N/N$, then these numbers yield[31-33]

$$0.05 < \Omega_{LSC} < 0.45 \quad (2)$$

The large spread results mainly from the uncertainty in v_v. To obtain $\Omega = 1$, v_v would have to be $\simeq 900$ km sec^{-1}, but it is unlikely that the observations could have missed such a large value. With the numbers given above, $\Omega = 1$ requires that the mass constrast in the LSC be $\delta M/M = 0.5$-1, which is a factor of 2-4 less than $\delta N/N$, and it is difficult to believe that the counts could be that far off. The connection between v_v and $\delta M/M$ assumes either linear perturbation theory or spherical symmetry. In an interesting cautionary example, Bushouse *et al.*[34] find that in N-body models the value of Ω derived from the mean v_v may be wrong by 30-50% (after correction for nonlinearity; A. Melott, personal communication). However, what such N-body models mainly show is a model velocity field considerably rougher than observed, indicating that the real mass distribution somehow stays a good deal smoother than in the models. One can estimate the possible effect of departure from spherical symmetry another way, by asking what transverse velocity, v_t, of our Galaxy (and its neighbours) relative to the LSC would be needed if the present gravitational acceleration of the LSC were balanced by the present centrifugal acceleration due to v_t. If $\Omega = 1$ the result is

$$v_t^2 = \frac{1}{2}\frac{\delta M}{M}(HR)^2 \quad (3)$$

With $\delta M/M = \delta N/N$ and the above numbers this yields $v_t \simeq$ 1,200 km sec^{-1}, which is about three times bigger than could be allowed, so it is difficult to see how the estimate could be spoilt by departures from radial motion. Thus the evidence is that if $\Omega = 1$, the mass concentration $\delta M/M$ in the LSC is less than about half the galaxy concentration $\delta N/N$.

For the discussion of biased galaxy formation it will be useful to have an estimate of what the LSC would have been like when galaxies formed. The numbers here assume the Einstein-de Sitter model, with $\Omega = 1$, and assume pressure may be neglected in estimating the growth of clustering. As quasars are seen at redshifts z (where $1+z$ is the ratio of observed to emitted wavelength) $\simeq 4$, it is reasonable to assume that the sites of galaxy formation were fixed at a redshift z_i no less than about 5. The mass concentration in the LSC can be extrapolated back from its present value, $\delta M/M \simeq 0.5$-1, to $(\delta M/M)_i \leqslant 0.10$ at $z_i = 5$, and $(\delta M/M)_i$ scales as $(1+z_i)^{-1}$. The galaxy concentration extrapolates back to $(\delta N/N)_i \simeq 1$, very nearly independent of z_i. The mean number density of bright galaxies is $\langle n\rangle \simeq 0.02\, h^3$ Mpc^{-3} (ref. 35). (The bright galaxies are those that contribute 75% of the net mean luminosity per unit volume.) The number of bright galaxies N_{is} within our radius in the LSC is the product of $\langle n\rangle$ with the volume and $(1+\delta N/N)$: $N_{is} \simeq 600$. Thus in the biased galaxy formation model the Local Supercluster would have originated as a moderately prominent island of ~600 bright galaxies, with $(\delta N/N)_i \simeq 1$, but with a modest mean-mass-density enhancement, $(\delta M/M)_i \leqslant 0.1$.

The second method of estimating Ω is based on the mean mass distribution around pairs of galaxies. If galaxy redshifts are used to derive distances assuming pure Hubble flow (that is, distance $= cz/H$), then random relative motions make the galaxy clustering pattern appear elongated along the line of sight. The size of the effect is a measure of the relative velocity of pairs of galaxies[36,37]. This measure has been applied to three moderately deep samples of galaxies selected by apparent magnitude and to two samples of more or less isolated pairs of galaxies[37-40]. The root-mean-square (r.m.s.) relative line-of-sight velocity dispersion, σ, of pairs of galaxies as a function of the projected separation, r_p, is found to increase slowly with increasing separation at 5 kpc $\leqslant r_p \leqslant$ 1 Mpc; typical values are $\sigma = 200 \pm 20$ km sec^{-1}, $hr_p = 10$ kpc; $\sigma = 300 \pm 75$ km sec^{-1}, $hr_p =$ 1 Mpc. The first number agrees with what is expected from observed velocities within galaxies at $hr \simeq 10$ kpc (where r is the radial distance from the galaxy centre). The flatness of $\sigma(r_p)$ is an extension of the nearly flat rotation or velocity dispersion curves observed in spiral and some elliptical galaxies[41,42].

The relative motions of close galaxy pairs must be balanced on average by gravity, because otherwise the clustering pattern observed at $hr \leqslant 1$ Mpc would dissolve within a Hubble time (H^{-1}). If we model the mass distribution as the linear sum of spherical haloes with mass (within r) $\delta M(<r)$ centred on each galaxy, then the condition for statistical support of the clustering pattern at small r, where typically two galaxies are involved, is $\delta M(<r) \simeq \sigma^2 r/G$. (This assumes isotropic velocites. If orbits tended to be radial then, as discussed below, this would reduce δM and Ω.) We can compare δM with the known mean number of galaxies in excess of random within a distance r of a galaxy:

$$\delta N(<r) = \langle n\rangle \int \xi_{gg}(r)\, d^3r \simeq r^{3-\gamma} \quad (4)$$

where $\xi_{gg} = (r_0/r)^\gamma$, $\gamma = 1.77$ and $hr_0 = 5.4 \pm 0.3$ Mpc. $\xi_{gg}(r)$ is a two-point correlation function measured from galaxy counts, and $\langle n\rangle$ is the global mean galaxy number density. The power-law model is a good approximation at $hr \leqslant 10$ Mpc[38,43,44]. We see that because σ varies roughly as $r^{0.1}$, δM and δN scale with r in about the same way, as $r^{1.2}$. This invites us to consider the assumption that whatever gathered galaxies together to make the present clustering pattern gathered mass in the same proportion, so that $\xi_{g\rho} = \xi_{gg}$ and therefore $\delta M(<r)/\delta N(<r) = \langle\rho\rangle/\langle n\rangle$, where $\langle\rho\rangle$ is the global mean mass density. The result of solving the above equations for $\Omega = \langle\rho\rangle/\rho_c$ is

$$0.3 \leqslant \Omega_{gg} \leqslant 0.6 \quad (5a)$$

This applies at $hr \leqslant 100$ kpc, where the galaxy pair typically has no bright close neighbours.

At $hr \simeq 1$ Mpc, where a galaxy pair typically has many ($N_{is} \simeq$ 10) bright neighbours that can contribute to the mean relative gravitational acceleration, we assume that each galaxy has mass m and then use the known statistics of the galaxy distribution to compute the mean relative acceleration. This yields[38,39]

$$0.1 \leqslant \Omega_{gg} \leqslant 0.3 \quad (5b)$$

The third dynamical estimate is based on the mean distribution of galaxies and mass around the rich compact clusters of galaxies catalogued by Abell[45]. Let $n(r)$ and $\rho(r)$ be the mean values of the galaxy number density and the mass density at distance r from an Abell cluster and averaged across a fair sample of clusters, and write $n(r) = \langle n\rangle[1+\xi_{cg}(r)]$ and $\rho(r) = \langle\rho\rangle[1+\xi_{c\rho}(r)]$, where $\langle n\rangle$ and $\langle\rho\rangle$ are the large-scale mean values, and ξ_{cg} and $\xi_{c\rho}$ are analogous to ξ_{gg} and $\xi_{g\rho}$, but for clusters. The Lick[46] galaxy counts around the positions of Abell richness class 1 clusters yield[47]

$$\xi_{cg} = \left(\frac{7.0\ \text{Mpc}}{hr}\right)^{2.5} + \left(\frac{12\ \text{Mpc}}{hr}\right)^{1.7} \quad (6)$$

at $0.5 \leqslant hr \leqslant 40$ Mpc. Gravity will have caused $n(r)$ and $\rho(r)$ to have grown considerably since galaxies formed. If gravity pulled in mass and galaxies alike, then at large enough r, $\xi_{c\rho}$ must approach ξ_{cg}, in which case the known ξ_{cg} fixes $\rho(r)/\langle\rho\rangle$. If we can estimate $\rho(r$ from dynamics we have an estimate of $\langle\rho\rangle$[47].

The following assumes $\xi_{cg} = \xi_{c\rho}$ at $r \simeq 2\, h^{-1}$ Mpc. This avoids the dense central parts of the cluster (where the galaxies are gas-poor so the mean mass per galaxy might be anomalous) but is still close enough to the centre to permit a reasonable estimate of $\rho(r)$. The Struble-Rood catalogue (M. F. Struble & H. J. Rood, unpublished) lists 17 Abell clusters of richness class 1 in which enough redshifts are known to permit estimates of the line-of-sight galaxy velocity dispersion σ_0; the r.m.s. value is $\langle\sigma_0^2\rangle^{1/2} = 830 \pm 80$ km sec^{-1}. The measurements of σ_0 are concentrated well within the Abell radius ($hr_A = 1.5$ Mpc). For the

four clusters in which the variation of velocity dispersion with radius has been fairly well measured (the Coma, Perseus, Hydra I and Virgo clusters), the $\sigma(r)$ estimates decrease with increasing r outside a possible slight central minimum[48–51]. These results suggest that $\sigma(r)$ at $hr \simeq 2$ Mpc is down from the central value by a factor of 1.3 to 1.5.

If the galaxy orbits in the cluster are isotropic, with velocity dispersion $\sigma(r)$ varying only slowly with radius, the mass density needed for statistical equilibrium is $\rho(r) = \sigma(r)^2/(2\pi G r^2)$. This implies $\rho \simeq r^{-2}$, consistent with the above estimate of $\xi_{cg}(r)$. The above numbers at $hr = 2$ Mpc give

$$0.2 < \Omega_{cg} < 0.35 \tag{7}$$

This assumes an isotropic velocity distribution. A spherical system is described by two components of dispersion, σ_r in the radial direction and σ_t in one transverse direction. Following White[52], we assume that at $hr \simeq 2$ Mpc, σ_r and σ_t have reached constant values and the galaxy number density scales as a power law, $n \propto r^{-\varepsilon}$. Then the equilibrium gravitational acceleration, g is

$$g = \frac{GM(<r)}{r^2} = \frac{2\sigma_t^2 + (\varepsilon - 2)\sigma_r^2}{r} \tag{8}$$

and the line-of-sight velocity dispersion is $\sigma^2 = \sigma_r^2/\varepsilon + \sigma_t^2(1 - 1/\varepsilon)$. It is a reasonable approximation to take $\varepsilon = 2$; this simplifies the equations to

$$\frac{GM}{r\sigma^2} = \frac{4\sigma_t^2}{\sigma_t^2 + \sigma_r^2} \tag{9}$$

Equation (7) assumes σ_t. If orbits were purely circular, with $\sigma_t \gg \sigma_r$, this would double M and Ω_{cg}, but it is hard to see how this could come about. If clusters formed by collapse it would tend to produce radial orbits, with $\sigma_r > \sigma_t$, which would depress Ω_{cg} from the value in equation (7).

If Ω were unity, clusters would have to be stronger concentrations of galaxies than of mass, and we would expect that gravity would attract to the cluster material rich in mass per galaxy, making the mass per bright galaxy $m(r)$ increase with increasing radius r in the cluster. Attempts to measure $m(r)$ using galaxy velocity dispersion data alone are complicated by the uncertainty in how the velocity anisotropy parameter σ_t^2/σ_r^2 varies with r; for the Coma cluster Kent and Gunn[48] could only conclude that they saw no need to assume that m varies with r. Cowie *et al.* (L. L. Cowie, J. Henriksen and R. Mushoksky, in preparation) have shown that the constraints on $m(r)$ are improved if one also imposes the condition that the gravitational field must balance the pressure-gradient force in the plasma in the cluster. Using the integrated cluster X-ray spectrum as a constraint on the distribution of plasma temperatures in the cluster, the rather accurately measured plasma density as a function of r, and the galaxy velocity dispersion data, they conclude that $m(r)$ has to be a decreasing function of r in the Coma cluster. The constraints are weaker for the Perseus cluster, but there is no evidence that $m(r)$ increases with increasing r, contrary to what we would have expected to see if Ω were unity.

We avoid this problem if we assume that cluster galaxies were created in large islands with roughly uniform mass per galaxy within the island. (The gradient in $m(r)$ in the Coma cluster is then given the usual interpretation, that galaxies near the centre suffered earlier loss of gas, which would have suppressed formation of younger stars and so lowered the galaxy luminosities.) The minimum number of bright galaxies per island is the mean number within our matching radius of $2\,h^{-1}$ Mpc: $N_{is} \geqslant 70$.

It may be possible to extend this constraint by using the fact that the concentration of galaxies around rich clusters extends well beyond $2\,h^{-1}$ Mpc. For example, the mean number of galaxies within distance $r = 20\,h^{-1}$ Mpc of an Abell cluster is about twice the number expected for a homogeneous distribution[47]. If there were a like concentration of mass within $r = 20\,h^{-1}$ Mpc the gravitational attraction of the mass would cause the galaxies at $r \simeq 20\,h^{-1}$ Mpc to have an appreciable streaming motion toward the cluster (relative to the Hubble flow), as in the LSC. When galaxy distances are estimated from redshifts using Hubble's law, $r = cz/H$, this streaming motion would make the galaxy distribution around a cluster tend to appear flattened along the line of sight[53]. Application of this test would require a large redshift sampling program, which now seems feasible and would be of considerable interest.

A more indirect constraint on the mass distribution might be mentioned. The new Center for Astrophysics (CfA) survey catalogues 1,100 galaxy redshifts in a field 6° wide by ~100° long[54]. The redshift map shows holes with diameters $\simeq 30\,h^{-1}$ Mpc, which is about what would be expected, given the clustering seen on smaller scales. The surprising result is that the holes are so empty and that the galaxies tend to distribute themselves so smoothly along the walls of the holes. If the mass were distributed like the galaxies and if Ω were close to unity this would be a strongly unstable arrangement, gravity causing mass to drain along the walls toward intersections, as is seen in the numerical N-body model simulations of the pancake model for galaxy formation[55]. Thus if $\Omega = 1$ it is doubtful that the mass is in the walls; it is more reasonable to assume that there is a general segregation of galaxies from mass on a scale of $\sim 30\,h^{-1}$ Mpc. If so then we have no problem in reconciling the low apparent densities in equations (2), (5) and (7) with a high mean mass density, but we substantially increase the demands on a theory for biased galaxy formation. If $\Omega \ll 1$, then gravity is suppressed relative to the general expansion, and a mass distribution like the galaxy distribution in the CfA redshift map might reasonably be expected to persist.

The direct way to measure Ω is through the classical cosmological model tests, as discussed many years ago by Tolman[56] and others. This approach has not received much attention in recent years because it has become apparent that galaxy evolution can mask the effects one is looking for, but the classical tests may be due for a renaissance. Loh and Spillar[57,58] have shown that a measurement of the joint distribution, $f(m, z)$, of galaxy apparent magnitude and redshift is feasible and substantially reduces the evolution problem. The standard tests depend on the curvature of a function of one variable, such as apparent magnitude as a function of redshift, and a given curvature can be produced by many reasonable combinations of galaxy evolution and cosmological effects. The function $f(m, z)$ depends on two variables, which offers a much better chance of separating the effects of galaxy evolution and cosmology. The current result[28] is $0.6 < \Omega < 2.0$ if $\Lambda = 0$. This is encouraging for the Einstein–de Sitter model but it should be considered a preliminary result because it assumes all galaxy luminosities evolve at the same fractional rate: the possible effect of evolution of the shape of the galaxy luminosity function has yet to be tested.

Models for biased galaxy formation

Three points are worth noting from the dynamical estimates of Ω described above. First, the independent estimates in equations (2), (5) and (7) yield consistent results, $\Omega \simeq 0.3$. If Ω were unity and the estimates were biased because mass clusters less strongly than galaxies, then we would have expected the Ω estimates to increase with increasing clustering scale (as measured by N_{is}). Second, if Ω were unity then galaxies would have to be placed on islands of tens to hundreds of bright galaxies each; a bias extending to nearest neighbours alone would not do. Third, whatever put the galaxies in islands cannot have perturbed the mass very much. If the Local Supercluster formed at redshift $z_i \simeq 5$, the initial mass concentration would have been $\delta M/M \simeq 0.1$, which is 10% of the original galaxy concentration. Even if

galaxies were put in place by non-gravitational forces it would require a special arrangement to keep the resulting mass perturbation so small.

One model for biased galaxy formation starts from the idea[19-21] that the first generation of stars that formed in the densest spots in the primeval mass distribution might have suppressed star formation elsewhere (perhaps blast waves from supernovae push the gas out of protogalaxies that have not yet managed to collapse to stars), so that bright galaxies would have survived only at rare extreme positive mass density fluctuations. Because the peaks of the mass distribution can be more strongly clustered than is the general mass distribution[18] (assuming the distribution is a random gaussian process with positive autocorrelation function), galaxies would be segregated from mass in the desired way. In a common implementation of this idea one assumes that a galaxy forms wherever the primeval mass density, smoothed through a window with size typical of a galaxy, exceeds the mean by more than a fixed multiple, $\nu \simeq 3$, of the standard deviation. This prescription has been studied in some detail under the assumptions that the mass of the universe is dominated by exotic dark matter with negligible primeval pressure and that the primeval mass distribution is a random gaussian process (random phases) with power spectrum P (square of the Fourier transform) that scales as $P \propto \langle|\rho_k|\rangle^2 \propto k$, where k is the wavenumber. (The assumption $P \propto k$ comes from the expected spectrum of quantum fluctuations resulting from inflation[1].)

Analytical[19] and N-body model[22] calculations show that these assumptions with the above prescription for the sites of galaxy formation make galaxies cluster more strongly than mass, as desired. However, one can use the same analytical computation to show that the bias does not extend much beyond the nearest neighbour galaxy. Thus this model would help account for the low value of Ω derived from relative motions of close pairs of galaxies (equation (5)), but would not help with the estimates based on larger clustering scales (if $\Omega = 1$).

To extend the scale of biasing one can assume that the spectrum, P, of density fluctuations increases with increasing length scale, rather than decreasing as in the above model. In this case we have to discuss in more detail whether the prescription for galaxy formation sites is reasonable. Three points should be considered.

First, the prescription uses the mass distribution averaged over a typical scale of a galaxy. Unless one assumes that the spectrum P is cut off on scales below that of a galaxy, one would expect that the first generation of stars formed in clusters much smaller than a galaxy and well before objects the size of a galaxy could have formed (because mass fluctuations tend to increase with decreasing length scales). It is hard to see how such pre-galaxy star clusters could be eliminated once formed. (The star clusters once formed could coalesce later to form galaxies.) This suggests that our criterion for star-forming regions should be the peaks in the primeval mass distribution averaged over scales well below that of a galaxy. But the analytical argument mentioned above indicates that this would suppress biasing on the scales of galaxies and larger.

Second, as mentioned above, the biased galaxy formation model requires that the Local Supercluster form at a mass excess $(\delta M/M)_i < 0.1$ and with a galaxy excess $(\delta N/N)_i \simeq 1$. I doubt that it is reasonable to expect that a 10% change in the ambient mass density could have caused a factor of two change in the survival of galaxies, because if protogalaxies were easily destroyed, survival surely would depend on many factors other than ambient mass density. Examples are the degree of subclustering in a protogalaxy, which determines how many star clusters form early and so resist dispersal, and the degree of sheltering of a protogalaxy by its neighbours. These additional random variables would tend to suppress the sensitivity of the survival probability to one variable, the ambient mass density.

Third, one might have thought that the dispersal effect which is supposed to inhibit galaxy formation would decrease with increasing distance from a new galaxy. This would tend to suppress galaxy clustering, leading to a reverse bias in which galaxies are less strongly clustered than mass, which would make the true value of Ω less than the dynamical estimates. To get the desired sign of bias, we would have to assume that tens to hundreds of bright galaxies form in islands and become robust enough to withstand disruption by their immediate neighbours, while protogalaxies well outside the islands must so lag in star formation that they can be destroyed by blast waves from the islands. My impression is that no very convincing way to do this has been proposed.

Another approach to biasing starts not from the statistics of the primeval mass distribution, but from the expected rearrangement of the mass distribution as stars form and die in supernova explosions. In this model, discussed by Ostriker and Cowie[59] and by Ikeuchi[60], a blast wave from supernovae in an early star cluster compresses the surrounding gas into a ridge, which can fragment into new star clusters whose blast waves can make still larger ridges. Islands of galaxies would be produced wherever the last and largest ridges form. As noted above, if we adopt $\Omega = 1$ and we accept the constraint on the baryon density from nucleosynthesis, we must assume that the mass of the universe is dominated by exotic, weakly interacting dark matter. The dark matter would be left behind when the blast waves gather the hydrogen to make galaxies, but then would participate in clustering once gravity takes over, giving the desired partial segregation of galaxies from mass.

This model requires two special arrangements. First, the explosions must be adjusted so as to fill space without making most of the matter so hot it cannot cool and contract to stars. Second, we must find some other way to account for the tendency of galaxies to appear in clusters and of clusters to appear in superclusters, because there is no way known to make the blast waves travel distances comparable to the sizes of superclusters. If these objects formed by the gravitational growth of primeval mass density fluctuations, as in the first model discussed above, it would require a special coincidence to account for the observations that galaxies and clusters of galaxies fit quite well into a scale-invariant clustering hierarchy[8,43]. It remains to be seen how serious these two problems are.

There are still other ways in which galaxies might have been segregated from mass. If the baryons were initially distributed in a wispy fashion in a sea of exotic dark matter, galaxies could form only in the wisps. A roughly similar effect might be obtained if galaxy formation were triggered by a network of massive cosmic strings. Both models are *ad hoc* for our purpose, but not without supporting arguments[61,62]. Another possibility is that the mass of the universe is dominated by gravitational radiation, or by weakly interacting particles with velocities that have always been high enough to resist the graviatational attraction of the mass concentrations in galaxies. However, either would significantly increase the mean mass density at high redshift, which would speed expansion and so spoil the nucleosynthesis calculations[63]. An ingenious variant of this scheme proposes that galaxies and clusters of galaxies formed by gravitational clustering of massive, weakly interacting, unstable particles[64]. These particles are then supposed to have decayed into low-mass, high velocity, weakly interacting particles, leaving behind islands of galaxies in a nearly smooth sea of dark matter. This is not without cosmological problems[65,66]. For example, if clusters of galaxies lost two-thirds of their mass, which would make the apparent density parameter derived from clustering dynamics $\simeq 0.3$, the clusters would expand by a factor of ~ 3 in radius. That means the clustering pattern would have been stronger in the past, which is contrary to the usual assumption that the clustering pattern has been growing to the present epoch. This would substantially increase the density fluctuations needed to make clusters of galaxies form by gravitational instability, and thus would increase the problem of reconciling the gravitational

instability picture with the isotropy of the microwave background[9,66].

Cosmology with low mass density

As the above models as presently understood are not very persuasive, we might consider the alternative: cosmological models with low mass density. The Einstein–de Sitter model could fail because we are assuming the wrong physics. An example is Milgrom's conjecture, that we are using the wrong gravity theory to compute masses[67]. A less spectacular mode of failure is the possibility that general relativity theory is valid, and that space sections have zero curvature, in accordance with inflation, but that the cosmological constant is non-zero[68]. This is distasteful, because of the coincidence argument mentioned at the beginning of this review, but such arguments must be examined closely. For example, suppose $\Omega = 0.2$, $h = 0.75$, $R^{-2} = 0$, and assume that initial conditions for classical cosmology were set at the end of inflation at redshift $z_{c1} = 10^{27}$. Expansion starts from $a = 1$ at $z = z_{c1}$. Four important epochs are: equal relativistic and non-relativistic mass densities, $a_1 = 10^{23.6}$; decoupling of baryons from radiation, $a_2 = 10^{24.0}$; equal values of the Λ and ρ terms in equation (1), $a_3 = 10^{26.8}$; and development of astronomy on Earth, $a_4 = 10^{27.0}$. It is curious that a_1 is relatively close to a_4, and striking that a_1 is so close to a_2; but surely it is no more startling that a_3 might be so close to a_4. It might be counted as a distinct advantage that if $\Omega \simeq 0.1$, the mass indicated by clustering dynamics is at least roughly consistent with the baryon density allowed by current estimates of element production in the hot Big Bang[63] without invoking exotic matter.

Conclusions

The Einstein–de Sitter cosmological model has been considered to be the most reasonable choice by the majority of those who cared to adopt an opinion in advance of a convincing observational test. We are now entering a very interesting period as the tests improve and, among the dynamical methods, fail to support the Einstein–de Sitter model. The observations can be reconciled with our expectations by assuming that galaxies formed in islands in a more nearly uniform sea of dark mass, but my impression is that we have seen no model that does this without a considerable degree of special arrangement. This impasse is a part of the normal process of development of an active but still immature subject, and will probably be resolved soon. It seems likely that in the next few years, as redshift surveys proceed, we will be able to improve considerably the measures of the large-scale mass distribution and so sharpen the constraints on Ω and the related problem of how galaxies form. It is somewhat more optimistic to hope for a tight constraint on Ω from the classical cosmological tests[58]. More optimistic still, but not unreasonably so, is the hope that observations of objects at high redshift will help show us how galaxies formed[69]. Meanwhile, the tension between what is observed and what we think ought to be is a most useful stimulus to research, as long as we remember that it is only a stimulus.

The discovery of black smokers, massive sulphides and vent biota in the rift valley of the Mid-Atlantic Ridge demonstrates that this assemblage of hydrothermal phenomena is not limited to intermediate-to-fast-spreading oceanic ridges. Hydrothermal exchange processes may thus be important at the ridges which extend through the Atlantic Ocean and western Indian Ocean, comprising more than half of the 55,000-km global length of seafloor spreading centres.

AN assemblage of hydrothermal phenomena including active black smokers, inactive chimneys, massive sulphides and vent biota has been discovered at a site[1] in the rift valley of the Mid-Atlantic Ridge near latitude 26°08′ N (Fig. 1). This is the first report of such an assemblage at a slow-spreading oceanic ridge (half-rate ≤ 2 cm yr^{-1}). The association of black-smoker-type hydrothermal venting, chimney-like edifices precipitated by the venting solutions, and vent biota was previously known only at sites on intermediate-to-fast-spreading ridges in the eastern Pacific Ocean, including the East Pacific Rise[2–4], the Guaymas Basin of the Gulf of California[5] and the Juan de Fuca Ridge[6,7]. Vent biota have been reported from sites at cold seeps in the Gulf of Mexico[8,9] and at the axis of the Mid-Atlantic Ridge ~310 km south of the present study site[10], and vent clams were tentatively identified near the present site[1].

The black smokers and associated phenomena were found using a combination of methods to sense far- and near-field properties of the water column and sea floor on a July–August 1985 cruise of the NOAA ship *Researcher* as part of the NOAA Vents program. Shipboard measurements of elevated values of dissolved manganese[11] and light scattering due to suspended particulate matter[12] in the water column delineated an area of hydrothermal activity. A systematic survey of that area with a deep-towed instrumented sled located active vents by measuring near-bottom water temperature anomalies and recording images of the sea floor[13]. We report here preliminary results of the seafloor imaging, near-bottom water temperature measurements and analyses of dredged hydrothermal precipitates[14]. These data complement other data sets pertaining to water chemistry[11], suspended particulate matter[12,15], and bottom sediment[16].

Instrumentation

Twelve transects were made across the study site with an instrumented sled. The sled was towed at an average speed of 1.8 km h^{-1} within 10 m of the sea floor, using an acoustic pinger to monitor and a winch to adjust altitude above the sea floor. The position of the sled was determined every 15 s to an accuracy of ±20 m relative to a net of four long-baseline (5–10 km) bottom-mounted acoustic transponders. The geographical positions of the acoustic transponders were determined using shipboard satellite navigation (Global Positioning System for three of the four transponders); the acoustic navigation net was converted to geographical coordinates with an estimated accuracy of ±150 m. In addition to the acoustic pinger and a relay transponder, the sled carried a 35-mm still camera system programmed to fire at 7.5-s intervals (inoperative 50% of the time due to malfunction); a continuously operating video camera system with recorder; a 1.5-m-long vertical array of four temperature sensors (thermistors accurate to ±0.01 °C) which recorded sequentially for 2 s every 10 s; and a pressure sensor with recorder from which pressures were converted to sled depth[17] (accuracy ± 2 m) and summed with pinger altitude for seafloor depth.

Geological setting

The discovery was made within the previously known TAG (Trans-Atlantic Geotraverse) hydrothermal field[18–21], which is located on a 10-km segment of the east wall of the rift valley between small-offset (<10 km) right-lateral transform faults[22]. The two walls of the rift valley of a slow-spreading ridge are normally nearly straight and subparallel to the bathymetric axis of the rift valley. At the TAG hydrothermal field the east wall projects westward as a broad salient which narrows the rift valley floor from a full width of ~6 km to only 3 km, coincident with a bathymetric high along the rift valley axis (Fig. 1). Thus, the east wall may be close to the subjacent intrusive heat sources that provide the increased thermal gradients which drive the upwelling limb of a sub-seafloor hydrothermal convection system. The sea floor is spreading asymmetrically at half-rates (averaged over 10 Myr) of 1.1 cm yr^{-1} to the west and 1.3 cm yr^{-1} to the east[23,24], indicative of asymmetric crustal accretion to the east[1,21].

The east wall rises from the rift valley floor near 4,000 m depth to the top of the rift mountains at ~2,000 m in a series of steps formed by underlying fault blocks. The steps are up to hundreds of metres in horizontal and vertical dimension, and tilt eastward away from the rift valley at angles up to 30° (refs 25, 26). Previous work identified a zone of hydrothermal phenomena between 2,400 and 3,100 m on the east wall[1]. These phenomena comprise layered deposits and surface stains of manganese oxide, iron oxide, iron hydroxide and iron silicate[27], as well as anomalous values of temperature[1] and helium concentration[28] in the near-bottom water, and metal enrichment in the sediment[29]. Analysis of metals in cores recovered from thin (<1.5 m) sediment between 3,100 m and the rift valley floor revealed layers with anomalously high contents (calculated on a carbonate-free basis) of copper (>1,000 p.p.m. (parts per 10^6 by weight)), iron (>8%) and zinc (>1,000 p.p.m.) at the surface and 30 cm beneath the surface, attributed to past and recent episodes of high-temperature black-smoker-type venting[1,29]. The layered hydrothermal precipitates, surface stains and near-bottom water temperature anomalies exhibit a linear distribution along fault zones, primarily between fault blocks that trend subparallel to the rift valley. The fault zones are inferred to tap hydrothermal sources, channel upwelling hydrothermal solutions and focus their discharge[20,21].

Black smokers, sulphides and vent biota

The black smokers, massive sulphides and vent biota occur at the juncture between the floor and east wall of the rift valley at

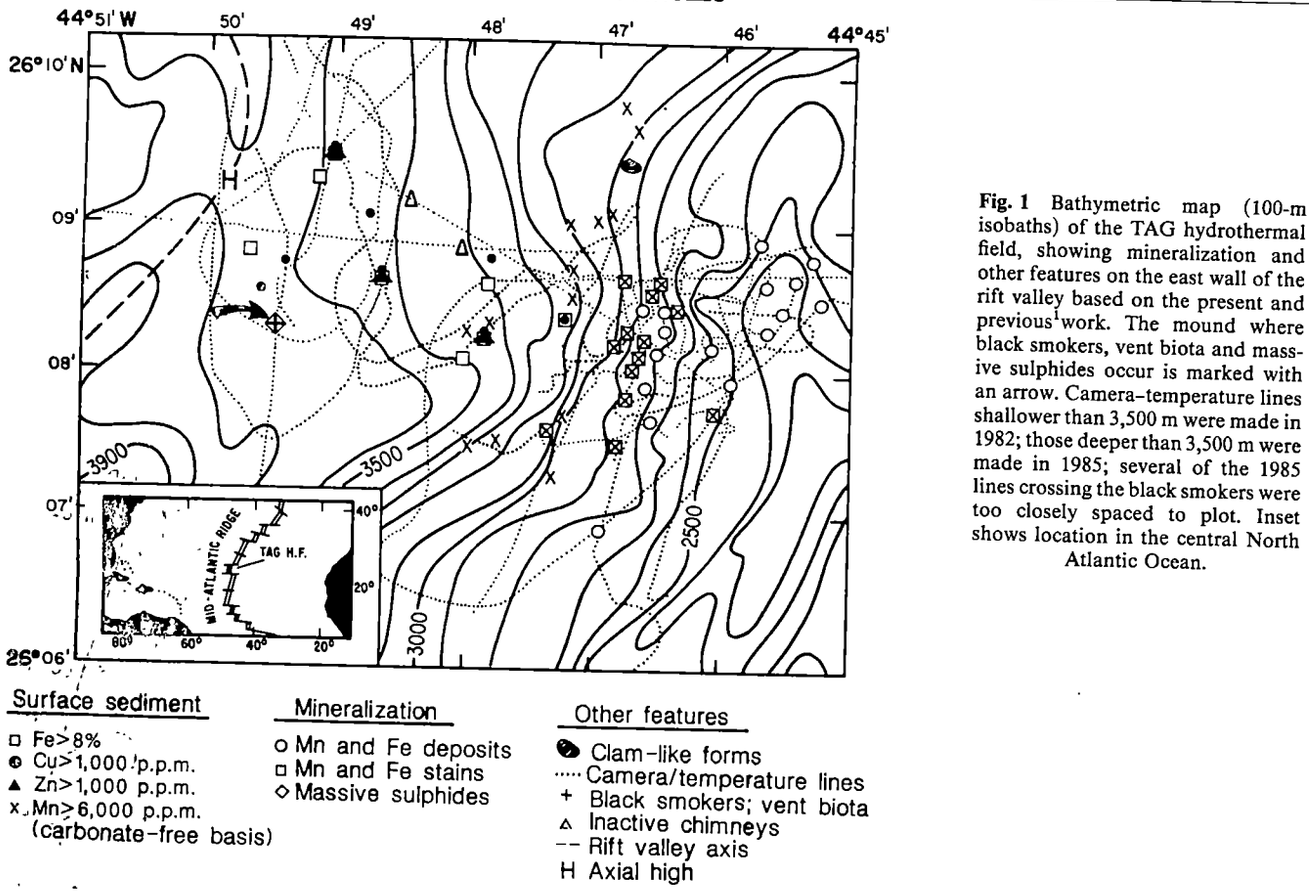

Fig. 1 Bathymetric map (100-m isobaths) of the TAG hydrothermal field, showing mineralization and other features on the east wall of the rift valley based on the present and previous[1] work. The mound where black smokers, vent biota and massive sulphides occur is marked with an arrow. Camera–temperature lines shallower than 3,500 m were made in 1982; those deeper than 3,500 m were made in 1985; several of the 1985 lines crossing the black smokers were too closely spaced to plot. Inset shows location in the central North Atlantic Ocean.

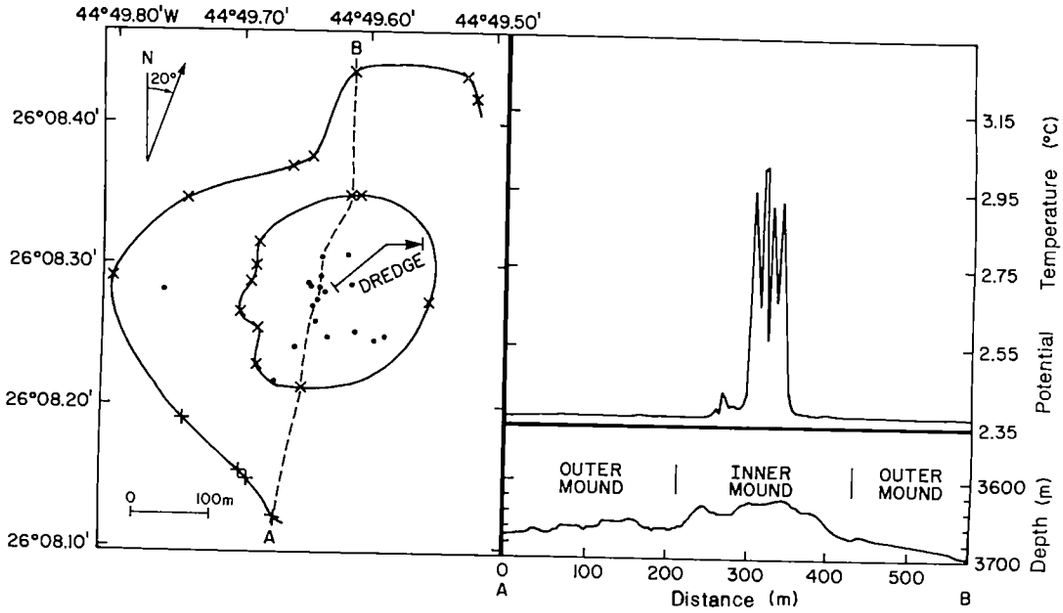

Fig. 2 Characteristics of the mound where black smokers, vent biota and massive sulphides occur at the juncture between the east wall and floor of the rift valley (Fig. 1), as delineated by camera–temperature–depth transects. Left, plan view showing boundaries of concentric inner and outer mounds (crossings marked '×'), distribution of vents (dots), azimuth of axis of rift valley (020°), and positions of transect A–B and a dredge. Lower right, bathymetric profile across the mound along transect A–B. Upper right, potential temperature profile in the water column within 10 m of the sea floor along transect A–B; the four central spikes correspond to black smokers.

water depths of 3,620–3,700 m (Fig. 1). They lie between the previously delineated hydrothermal zone 3.7 km up-slope to the east and the bathymetric axis of the rift valley 1.5 km down-slope to the west. The axial high of the rift valley lies 2 km up-slope to the north-west. The camera–temperature–depth tows delineated a compound mound with concentric inner and outer portions, each with an elliptical shape in plan view (Fig. 2). The inner mound lies between water depths of ~3,620 and 3,675 m and is up to 55 m higher than the outer mound, which lies between 3,675 and 3,700 m. The inner mound is ~250 m wide along azimuth 020° by 220 m wide along azimuth 110°; the outer mound is ~580 m wide along azimuth 020°.

A representative transect shows principal features of the compound mound (Fig. 2, transect A–B). The sea floor surrounding the mound is covered by basalt talus interspersed with sediment. The talus ranges from cobble- to boulder-sized, including angular fragments and whole pillows; some of the pillows may be in place. The sediment is thin (<1.5 m), light tan to pale red, mottled with light-coloured spots several centimetres in diameter made by burrowing organisms (~5 spots m^{-2}), fine-grained and resuspends in the wake of the sled. At the perimeter of the outer mound the talus is predominantly boulder-sized and sharply angular. Some of these talus blocks display regular, repetitive layers ~5 cm thick, which resemble successive basalt flows

ponded in lava lakes, such as are observed at the axis of the East Pacific Rise[30]. Alternatively, the layering may have been produced by bedded volcaniclastics. The sea floor within the outer mound is covered by angular talus fragments, basalt flows and interspersed sediment. The talus consists of a mixture of angular basalt fragments and reddish-yellow layered rocks inferred to be hydrothermal precipitates. Basalt pillows are present, both detached in the talus and attached as part of lava flows partially buried by talus and sediment. The sediment is red, mottled with abundant light-coloured spots at burrows (~10 spots m^{-2}), fine-grained and resuspends in the wake of the sled. Typically one large fish (≤25 cm long) was observed within each 100 m of horizontal advance of the sled.

The inner mound contrasts with the outer mound as regards substrate, hydrothermal activity and biota. The substrate is predominantly composed of reddish-yellow layered rocks which form irregular protuberances: ledges, dome-shaped masses and columns with horizontal and vertical dimensions of the order of metres. During tows across the inner mound the sled occasionally hit bathymetric highs while travelling at an altitude of ~5 m above the sea floor; thus the towing procedure systematically missed imaging the tops of the higher protuberances which may have been chimneys.

Shimmering water emanates from broad areas of fractured rocks inside the boundary of the inner mound. By analogy with temperature measurements made by submersibles in shimmering water at the Galapagos spreading centre[31] and the Guaymas Basin[32], this water could be up to 200 °C hotter than the ambient water potential temperature of 2.37 °C (Fig. 2). Towards the centre of the inner mound, suspended particulate matter in the water column increases in quantity, and changes from discrete, neutrally buoyant white flocks inferred to be pieces of bacterial mats, to wisps of white smoke, to wisps followed by plumes of black smoke.

The black smokers emanate from fractures in the layered rocks (Fig. 3), rather than from distinct chimneys. The buoyant plumes of black smoke appear to rise more slowly than those investigated on the East Pacific Rise[33,34], which ascend at rates between 1 and 5 m s^{-1}. At the TAG site, the rate of plume ascent was estimated to be <1 m s^{-1} from videotapes and from the down-current inclination of plumes (Fig. 3) in currents flowing south at several centimetres per second (estimated from particle movement at the time of observation). Particle loading in the plumes is high, as evidenced by the fact that the sea floor behind the plumes is obscured by the density of the black smoke (Fig. 3). Also, the camera sled was coated with fine, cohesive black particulate matter after tows through the smokers. Effects of the hydrothermal plumes were detected up to 400 m above the sea floor, as anomalies in dissolved manganese[11] and suspended particulate matter[12,15].

At least 11 black smokers clustered near the centre of the inner mound were seen during various transects (Fig. 2). The highest potential temperature anomaly measured from the sled at an altitude of 5 m above the sea floor was 3.86 °C. This temperature is 1.43 °C above ambient, and is associated with a

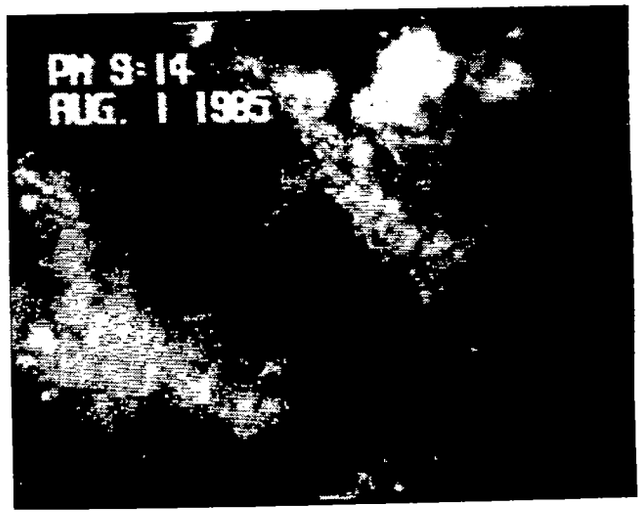

Fig. 3 A black smoker photographed from a video image recorded at an altitude of 5 m over the central portion of the inner mound (Fig. 2). The hydrothermal solutions are being discharged from seafloor fractures and the plume is inclined down-current.

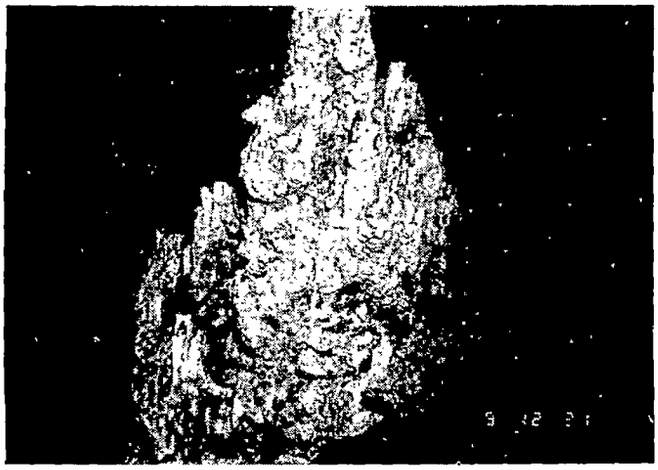

Fig. 4 A toppled chimney ~4 m from base to top, lying on the sea floor in an area of inactive chimneys at 3,500 m water depth on the lower portion of the east wall of the rift valley (Fig. 1). The sea floor around the chimney is littered with fragments of layered rocks with the appearance of hydrothermal precipitates and thin sediments with patchy black mineralized stains.

gradient of 0.21 °C m^{-1} (warming downward) over the 1.5-m vertical length of the temperature sensor array. The highest water temperature previously reported from a sled towed over hydrothermal vents in the Pacific Ocean was 0.18 °C (ref. 35), because the anomalies are attenuated by rapid heat dissipation in moving water. Direct measurements made from a submersible in similar Pacific vents have recorded water temperatures up to 400 °C (ref. 36).

The colour of the sediment interspersed between seafloor protuberances changes from red near the margins of the inner mound to black next to the black smokers. The black sediment and adjacent rocks exhibit a spectacular glitter on the videotape, interpreted as reflections from faces of euhedral pyrite crystals that settle from the black smoke. Euhedral pyrite crystals were identified in the black sediment that coated the instrument sled after tows through the black smokers (Tables 1, 2; sample 5).

The biota exhibits systematic changes from the margins to the centre of the inner mound. Translucent anemones several centimetres in diameter appear at the boundary between the outer and inner mound. Such anemones are the predominant sessile benthic invertebrate on the inner mound, with the densest population in shimmering water. Sparse translucent worms tentatively identified as vestimentiferans (M. L. Jones, personal communication) lie recumbent on rocks in limited areas closer to the centre: the thickets of vestimentiferan worms conspicuous at Pacific hydrothermal sites at shallower depths (2,600 m) were not observed. Occasional white patches (~1 m in diameter) on the rocks appear to be bacterial mats. Thousands of shrimp bask in beds around the black smokers and are highly mobile. About 200 of these shrimp, ranging in length from 3.8 to 5.1 cm, were recovered in a dredge with rocks from the inner mound (Fig. 2); the shrimp were preserved and are being studied[41]. A few crabs identified as brachyurans (A. B. Williams, personal communication) were present on rocks near the shrimp beds. Large fish (up to 25 cm long), including an eel-like form, were more abundant on the inner than on the outer mound, especially near the shrimp beds. Clams and other shelled organisms were not observed, although vesycomyid clams had been tentatively identified previously, in photographs from 3,000 m in the hydrothermal zone[1] (Fig. 1).

Area of inactive chimneys

A group of chimneys was observed on bottom images from two transects of an area at 3,500–3,600 m depth, located 2 km northeast of the mound (Fig. 1). One of the transects imaged toppled chimneys (Fig. 4) and related fragmental material at 3,500 m, with interspersed sediment marked by dark stains similar to mineralized stains observed higher on the east wall, there attributed to active hydrothermal seepage (Fig. 1). The other transect imaged 35 standing chimneys up to 5 m high along a horizontal distance of 100 m at 3,600 m depth. The absence of near-bottom water temperature anomalies over either the toppled or standing chimneys indicates that they are inactive; however, the fresh appearance of the chimneys (Fig. 4) suggests that hydrothermal venting stopped quite recently. By analogy with chimneys of similar appearance at sites in the Pacific, it is likely that these chimneys contain massive sulphides.

Hydrothermal precipitates

A single dredge of the inner mound (Fig. 2) recovered 59 kg of hydrothermal precipitates without any basalt. The hydrothermal precipitates recovered are predominantly sulphides (66 wt % of dredged material); sulphates, oxides, hydroxides, silicates and carbonates were also recovered. Preliminary petrographic descriptions and mineralogical and compositional analyses of five representative samples were performed at the Avondale Research Center of the US Bureau of Mines (B. W. Haynes, personal communication). The consolidated sulphides are broadly classified as two types. The first type (93 wt % of sulphides recovered) is a spongy-textured intergrowth of yellow pyrite and black sphalerite with irregular layering and cavities

(Tables 1, 2; sample 1). It is high in iron (38 wt %) and zinc (9 wt %) and low in copper (≤1 wt %). Oxidized crusts typically several millimetres thick are present on exposed surfaces. The characteristics of this predominant sulphide type suggest precipitation from moderate-temperature solutions discharging into open spaces and forming irregularly layered deposits of diverse shapes on the sea floor. The second type of sulphide (7 wt % of sulphides recovered) occurs in dense, curved plates up to several centimetres thick exhibiting distinct mineral zonation (Tables 1, 2; samples 2, 4). A relatively thick zone on the concave side of the plates is composed of chalcopyrite and pyrite; a thinner contiguous zone on the convex side is composed of sphalerite (Tables 1, 2; samples 2, 4). The convex surface has a yellowish- to reddish-brown oxidation crust several millimetres thick; the concave surface of some of the samples is coated with soft, black, botryoidal and reddish-brown, fine-grained iron and manganese oxides and hydroxides up to 1 cm thick. The copper content of these sulphides is high (22–30 wt %), and the zinc content is low (1–3 wt %). The characteristics of this second type of sulphide suggest precipitation in a chimney that vented high-temperature solutions. Unconsolidated sulphide particles that accumulated on the instrument sled during tows through the black smokers consist of cohesive particulate material primarily composed of pyrite (Tables 1, 2; sample 5), as described above.

Sulphates (~1 kg) were recovered in the form of coarsely crystalline aggregates of anhydrite with fine crystals of pyrite on surfaces and in cavities (Tables 1, 2; sample 3). The presence of anhydrite indicates seafloor temperatures of ~140 °C: at lower temperatures it would re-dissolve in sea water, at the ambient pressure of ~370 bar[37,38]. Studies are in progress of the mineralogy, composition and isotopic characteristics of the various hydrothermal mineral phases in the recovered samples (G. Thompson and P.A.R., unpublished data).

Conclusions

The discovery of black smokers, chimneys, massive sulphides and vent biota fills a major gap in the understanding of slow-spreading oceanic ridges. The low-temperature hydrothermal zone previously delineated at mid-depth on the east wall of the rift valley at the TAG hydrothermal field is not an isolated phenomenon, but is part of a larger hydrothermal system, probably related by physical and chemical gradients to the high-temperature area at the juncture between the wall and the floor of the rift valley (Fig. 1). The high-temperature area, with vigorous venting of black smokers and precipitation of massive sulphides, is laterally contiguous with the low-temperature zone, with weak venting of warm springs and precipitation of oxides, hydroxides and silicates.

The elliptical configuration of the compound mound, with black smokers venting from the inner mound and evidence of lava flows and extensive fracturing at the perimeter of the outer mound, suggests that the mound may overlie a crater partially collapsed over an off-axis magma chamber (Fig. 2). The parallelism between the long axis of the ellipse and the axis of the rift valley (020°) suggests the additional influence of faulting subparallel to that axis. The observation that the black smokers vent from fractures rather than from chimneys suggests that the fractures opened in response to an episode of seismicity so recent that chimneys have not had time to grow. The massive sulphides recovered and the inactive chimneys imaged formed during previous episodes of black smoker activity. The relatively slow observed rate of ascent of the plumes indicates either hydrothermal fluid temperatures lower than that of Pacific black smokers or, alternatively, high temperatures with thermal expansion partially compensated by the observed dense particle loading and/or phase separation[39]. Fluid temperature measurements and sampling by submersible are needed to resolve this question. Assuming that the inner mound is constructed primarily of hydrothermal precipitates (average density 3.0 g cm^{-3}) in the form of a semi-ellipsoid, the deposit would weigh 4.5×10^6 tonnes. The similarities in size, shape and structure of this mineral deposit to certain ancient massive sulphide deposits in the form of convex-upward mounds, such as Noranda-type deposits[40], is striking, although differences exist in petrological associations.

The record of hydrothermal activity at the TAG hydrothermal field is partially preserved in localized ponded sediment. Fluctuations in activity through time may be distinguished from spatial variations within the field by examination of this sedimentary record[1,16,29]. The relation between inactive chimneys (Figs 1, 4) and black smokers (Fig. 3) may also be deciphered from the sedimentary record. The occurrence of the full range of seafloor hydrothermal phenomena at this site on the Mid-Atlantic Ridge suggests a role for slow-spreading oceanic ridges in the hydrothermal exchange processes that affect ocean chemistry, seafloor mineralization, heat transfer and biological adaptation.

Self-incompatibility in flowering plants is controlled by the S *gene. A complementary DNA clone encoding a style protein of* Nicotiana alata *which segregates with the* S_2 *allele has now been sequenced. The* S*-allele-associated style components in different genotypes of* N. alata *and in* Lycopersicon peruvianum, *another self-incompatible species in the family Solanaceae, are homologous.*

OVER half the flowering plant families have specific self-incompatibility genes (*S* genes) which prevent inbreeding (for reviews see refs 1–6). Among homomorphic multi-allelic incompatibility systems there are two major types, showing either gametophytic or sporophytic control of the self-incompatibility response. Gametophytic incompatibility is the more common and, in many cases, is controlled by a single nuclear gene locus (*S* locus) with multiple alleles. Pollen expresses its haploid *S* genotype and matings are incompatible if the *S* allele of the pollen is matched by one of two *S* alleles expressed in the diploid tissue of the pistil. During both incompatible and compatible matings, pollen germinates and the pollen tubes grow through the stigma into the transmitting tissue of the style. Tube growth from incompatible pollen grains is arrested in the style; the tip of the tube becomes thickened, there is often a characteristic deposit of callose close to the tip, and the tip may burst. In sporophytic incompatibility, on the other hand, pollen behaviour is determined by the genotype of the pollen-producing plant; inhibition usually occurs on the stigma surface and is often associated with deposition of callose in the stigma cells. The gametophytic system is generally considered to be the ancestral form of self-incompatibility in flowering plants, with the sporophytic system being derived from it[1].

The genetics of gametophytic self-incompatibility systems has been studied extensively (see, for example, refs 1, 7–11). Several attempts have been made to identify the active product(s) of the *S* gene in both gametophytic and sporophytic systems[12–14], and recently a clone encoding part of an *S*-locus-specific glycoprotein from *Brassica oleracea* stigmas has been described[15]. In general, the early studies point to the presence of *S*-genotype-associated antigens or proteins in the pistil, but have so far failed to positively identify corresponding molecules in pollen or pollen tubes. Although several genetic and molecular models have been constructed to account for the breeding behaviour of *S* alleles[16–18], the detailed nature of the *S*-gene product and its mode of action in preventing fertilization are still unknown.

The major criteria for positive identification of an *S*-allelic product are, first, that its presence in reproductive tissues of the plant must consistently be associated with the corresponding breeding behaviour and, second, that it should show specific biological activity under appropriate bioassay conditions (for example, it should inhibit growth of pollen tubes bearing the same allele but not tubes bearing a different allele).

To elucidate the molecular basis of incompatibility, we have isolated an *S*-genotype-associated glycoprotein from styles of an ornamental tobacco, *Nicotiana alata* Link and Otto, a species which displays gametophytic self-incompatibility. Here we report the association of this glycoprotein with expression of the S_2 allele and describe a complementary DNA clone encoding the protein. We have used this cDNA to examine both expression of self-incompatibility in female tissues of the flower and the homology between different *S* alleles of *N. alata*.

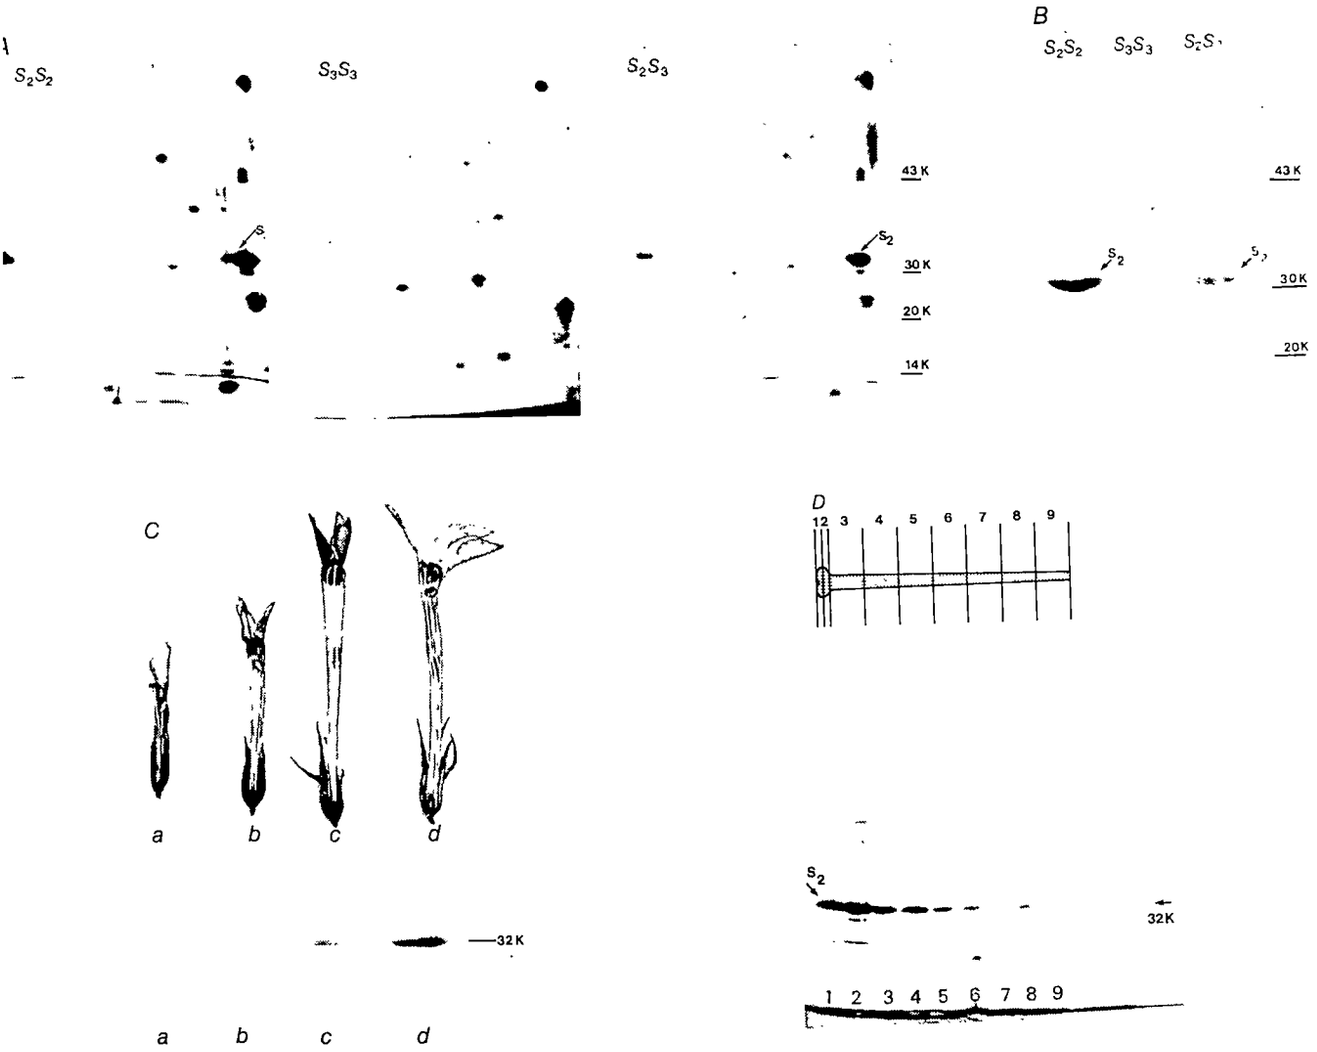
The present study represents an initial step in understanding how plants discriminate between self and non-self[19]. We examine how 'self' pollen tubes are recognized and how their growth is arrested within the female tissues of the style. This system is defined in terms of classical genetics by breeding techniques, and we have now started to define it in terms of molecular genetics.

Expression of S_2 allele

From the original acquisition, S_2S_3, S_2S_2 and S_3S_3 homozygotes were produced by bud self-pollination. Bud self-pollination of a second acquisition, S_1S_3, provided the homozygote S_1S_1, and a third heterozygote, S_1S_2, was obtained by intercrossing the two acquisitions. Extracts from styles of mature plants revealed an association of a component of relative molecular mass (M_r) 32,000 (32K) with the presence of the S_2 allele; this was apparent on single-dimension SDS-polyacrylamide gels (not shown) and in two-dimensional gels (Fig. 1*A*), which showed that the 32K component had a high *p*I. The high-*p*I proteins in extracts of styles bearing different *S* alleles could be compared on the same isoelectric focusing gel by selecting from the gel those components in the high-*p*I range (>9.5) and subjecting them to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) in the second dimension[20]. Association of the 32 K band with S_2 allele was clearly demonstrated in this selective two-dimensional gel electrophoresis (Fig. 1*B*).

Style proteins were analysed for 53 plants resulting from reciprocal crosses involving the genotypes S_2S_2, S_3S_3, S_2S_3 and S_1S_3, using conventional two-dimensional gel electrophoresis and selective two-dimensional gel electrophoresis. The results demonstrated genetic segregation of the 32K component with breeding behaviour identifying the S_2 allele. Forty progeny plants in which the 32K component was present in style extracts, all rejected S_2 pollen. The remaining 13 plants, apparently lacking the 32K component, all accepted S_2 pollen. Thus, no recombination was observed between S_2 breeding behaviour and presence of the 32K component in the style.

§ Present addresses: Howard Florey Institute of Experimental Physiology and Medicine, University of Melbourne, Parkville, Victoria 3052, Australia (P.J.R., J.D.P., G.W.T., J.P.C., R.J.C.); Imperial Cancer Research Fund, London WC2A 3PX, UK (J.D.H.); Genentech Inc., South San Francisco, California 94080, USA (H.D.N.).



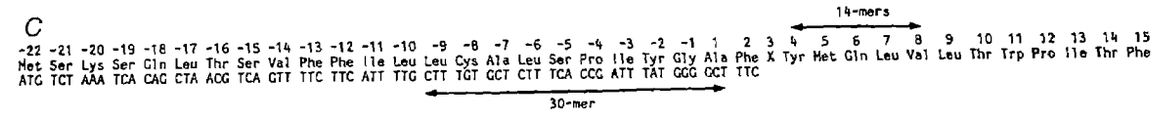


Fig. 1 Correlation of expression of the S_2 allele of *Nicotiana alata* with the presence of a 32K glycoprotein in style extracts, *A*, Two-dimensional gel electrophoresis of style extracts from mature plants of *N. alata*, genotypes S_2S_2, S_3S_3 and S_2S_3. A high-*p*I component of M_r 32,000 is present in the parent acquisition S_2S_3 and in bud-selfed progeny with the genotype S_2S_2, assigned by test crossing. The 32K component is absent from progeny of the same bud-selfing with an assigned genotype of S_3S_3. *B*, Selective two-dimensional gel electrophoresis of style extracts from mature plants as shown in *A*. The 32K band is present in style extracts of all plants which carry a functional S_2 allele. *C*, Selective two-dimensional gel electrophoresis of style extracts from flowers of genotype S_2S_3 at different developmental stages. The 32K band is absent from style extracts prepared at the green-bud stage when the self-incompatibility response is absent (*a*), but appears, together with expression of self-incompatibility, at the time of petal colouration (*b*) and is present in higher concentrations in extracts prepared from styles of mature flowers (*c*, *d*). *D*, Selective two-dimensional gel electrophoresis of extracts from segments of mature styles. A diagram representing the stigma and upper part of the style is shown; the stigma sections were 1 mm long and the style sections 6 mm long. The 32K glycoprotein is present at highest concentrations in the sections which include the stigma (1 and 2), and in the upper segments of the style (3, 4 and 5).

Methods. *A*, Seed of *N. alata* of incompatibility genotypes S_2S_3 and S_1S_3 was provided by Dr K. K. Pandey. Crosses were made by hand on emasculated flowers in a pollinator-proof glasshouse and scored as incompatible if flowers abscised without capsule development, or compatible if filled seed capsules were formed. Plants homozygous for the S_2 and S_3 alleles were obtained by self-pollination of immature flowers at the green-bud stage using mature pollen from the same plant and stigmatic secretion from a mature, emasculcated flower to aid pollen germination on the surface of the immature stigma. As incompatibility is first expressed at the petal colouration stage, self-pollen tubes are not always arrested when flowers are pollinated at the green-bud stage. Abscission of fruits containing low numbers of 'selfed' seeds was prevented by smearing the floral pedicels with 1% indoleacetic acid (IAA) in crude lanolin. Genotypes were assigned by test crossing to original acquisitions. Style extracts were prepared by crushing six styles lightly in 0.3 ml of extraction buffer [50 mM Tris-HCl *p*H 8.5, 10 mM EDTA, 1 mM $CaCl_2$, 1 mM phenylmethylsulphonyl fluoride (PMSF), 1 mM dithiothreitol (DTT)]. The extracts were centrifuged and the protein concentations measured[30]. Extracts containing 15 μg of protein were analysed on two-dimensional gels run according to Mau *et al.*[20].Protein spots were visualized by silver staining. *B*, Extracts were prepared from six mature styles as described for *A*, and samples containing 15 μg of protein were loaded onto the isoelectric focusing gel. After running according to Mau *et al.*[20], the region corresponding to the *p*I range >9.5, which contains the S_2-glycoprotein, was excised and run on a 15% SDS-polyacrylamide gel and stained with Coomassie blue. As many of the proteins present in the extract are of low *p*I, the pattern shown in conventional two-dimensional gels is considerably simplified by this procedure. *C*, Style extracts of flowers at the developmental stages shown were prepared and examined by selected two-dimensional gel electrophoresis as described for *B*. *D*, Six mature styles were harvested, aligned and sectioned with a razor blade according to the diagram. Each group of sections was extracted separately with 0.3 ml of buffer and the extracts examined by selective two-dimensional gel electrophoresis as described for *B*. Protein bands were visualized by silver staining.

Selective two-dimensional gel electrophoresis was also used to demonstrate the association of the 32K component with development of S_2 function in maturing styles (Fig. 1*C*). The 32K component was present at highest concentrations in upper segments of the style (Fig. 1*D*), the zone in which the arrest of incompatible pollen tubes occurs. Thus, the 32K glycoprotein segregates with S_2 breeding behaviour, appears concomitantly with S_2 function in maturing styles and occurs in highest concentration in the part of the style in which inhibition of incompatible pollen tube growth occurs. This 32K glycoprotein is termed the S_2-glycoprotein. The appearance of *S*-allele-associated style proteins in mature but not immature styles has been noted for other self-incompatible species, and the concentration of *S*-allele-associated proteins in the stigma and upper style

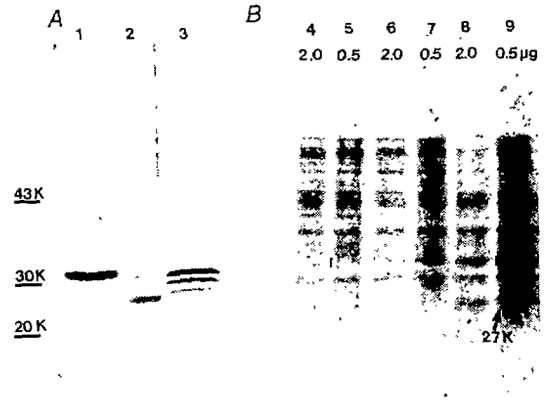

Fig. 2 Protein products specific to the S_2 allele. *A*, Purification and deglycosylation of the S_2-glycoprotein. Lane 1, S_2-glycoprotein isolated by chromatographic procedures (M_r 32,000); lane 2, S_2-glycoprotein after chemical deglycosylation (M_r 26,000); lane 3, S_2-glycoprotein after enzymatic deglycosylation. Four species are detected by silver staining: a strongly staining band of 32K which corresponds to the undegraded glycoprotein, two 30K species running closely together (the separation of these is not clear in the photograph) and a fourth species of M_r 28,000. *B*, Identification of an *in vitro* translation product specific to mature styles. The figure shows *in vitro* translation products of mRNA isolated from *N. alata* ovary (lanes 4 and 5), green-bud style (lanes 6 and 7) and mature style (lanes 8 and 9). The amount of mRNA used in each experiment is indicated. The 27K translation product unique to mature style mRNA is indicated. *C*, Amino-acid sequence of the N-terminus of the mature S_2-glycoprotein and the C-terminus of a putative signal sequence for this protein, as determined by N-terminal analysis and deduced from DNA sequence analysis. Amino acids 1–15 were determined by N-terminal analysis of the isolated glycoprotein where X denotes no clear assignment. From the sequence Tyr-Met-Gln-Leu-Val (amino acids 4–8), the following three pools of oligodeoxyribonucleotide 14-mers, each of 8-fold degeneracy, were prepared: 5′ d(ACA^{G}AGT^{C}TGCATA^{G}TA (pool I), 5′ d(ACC^{T}AGT^{C}TGCATA^{G}TA (pool II) and 5′ d(ACC^{T}AAT^{C}TGCATA^{G}TA (pool III). The nucleotide sequence complementary to a portion of cDNA synthesized when pool I was used to prime cDNA synthesis is shown. This sequence is in the same sense as the mRNA and encodes 22 amino acids of a putative signal peptide and two amino acids at the N-terminus of the mature S_2-glycoprotein. A synthetic 30-mer probe complementary to the sequence indicated was synthesized as described below.

Methods. *A*, Flowers were emasculated at the onset of petal colouration; 2 days later, the fully mature styles were removed and stored at −70 °C. (Styles refer to stigma and style which were removed together; the ovary was not included.) Frozen styles (3 g; 220 styles) were ground to a fine powder in liquid nitrogen using a mortar and pestle, then ground further in 50 ml of extraction buffer [0.1 M Tris-HCl *p*H 8.5, 1 mM $CaCl_2$, 0.1 M NaCl, 1 mM PMSF, 1 mM DTT, 10 mM EDTA and 1% (w/w) insoluble polyvinyl pyrrolidone (Polyclar AT)]. The homogenate was centrifuged (10,000g; 15 min) and the supernatant equilibrated with 5 mM ammonium bicarbonate *p*H 8.6, 1 mM NaCl, 1 mM $CaCl_2$, 1 mM EDTA, by passage through a Sephadex G-25 column (1.6×22 cm; void volume 11 ml). The first 16 ml that eluted after the void volume was collected (28.6 mg total protein as bovine serum albumin) and applied to DEAE-Sepharose (2×13 cm), equilibrated with the same ammonium bicarbonate buffer. As the S_2-associated glycoprotein is known from isoelectric focusing experiments to have a high *p*I (>9.5), it does not bind to DEAE-Sepharose at *p*H 8.6, but was present in the unbound fraction together with one other major component and several minor components. The unbound fractions were combined (2.78 mg protein as BSA), concentrated to 16 ml and fractionated further by chromatography on concanavalin A (Con A)–Sepharose. Then the Con A–Sepharose was washed with 5 vol. 0.1 M methyl-α-D-mannoside in 10 mM sodium acetate *p*H 7.0, 0.1 M NaCl, 1 mM $MgCl_2$, 1 mM $CaCl_2$, 1 mM $MnCl_2$ and subsequently with sodium bicarbonate (0.25 M, *p*H 8.8) (four changes during a 1-h period). Four volumes of sodium bicarbonate (0.25 M *p*H 8.8) containing 0.03% glutaraldehyde were added to the beads, the two were mixed and then the beads were washed with 0.1 M sodium bicarbonate *p*H 8.0, containing 0.5 M NaCl, resuspended in the sodium acetate buffer (without methyl-α-D-mannoside) and packed into a column (0.8×14 cm). The unbound fraction from DEAE-Sepharose was equilibrated in acetate buffer by passage through a Sephadex G-25 column equilibrated with acetate buffer, then applied to the Con A-Sepharose column. Unbound material was collected, the column was washed with 10 vol. acetate buffer, and the bound material eluted with 0.2 M methyl-α-D-mannoside in acetate buffer. The eluted material was separated from the methyl-α-D-mannoside by passage through a Biogel P150 column. Yield was 490 μg of protein (1.7% of total style protein). Chemical deglycosylation of the S_2-associated glycoprotein: the isolated S_2-glycoprotein (lane 1) was deglycosylated (lane 2) using the trifluoromethanesulphonic acid (TFMS) procedure[31], and the deglycosylated proteins were analysed on 15% SDS-polyacrylamide gels which were stained with Coomassie blue. Enzymatic deglycosylation of the S_2-associated glycoprotein: Isolated glycoprotein (5 μg) in SDS sample buffer (10 μl) was heated at 100 °C for 2 min, then cooled and 46.5 U endoglycosidase F (Miles Laboratories) added. The mixture was incubated at 35 °C for 2 h, then applied to a 15% SDS-polyacrylamide gel, which was stained with silver stain. *B*, Poly(A)$^+$ mRNA (0.5 or 2.0 μg) was isolated from mature styles, green-bud styles or ovary[32], and translated using an amino-acid-depleted rabbit reticulocyte lysate kit (Amersham) in the presence of tritiated leucine, lysine, phenylalanine, proline and tyrosine. Translation products were separated by SDS-PAGE using 12.5–20% SDS-polyacrylamide gradient gels. The products were visualized by autoradiography after treatment of the gel with Amplify (Amersham). *C*, N-terminal sequencing of the S_2-glycoprotein purified as described in *A* was performed using an Applied Biosystems Model 470 A gas-phase sequencer. Isolated glycoprotein (~200 μg) was applied in aqueous solution to a glass fibre disk and evaporated to dryness. The resultant phenylthiohydantoin amino-acid derivatives were identified on an IBM-CN column (IBM, Danbury, Connecticut) using a sodium acetate–acetonitrile trifluoroacetic acid gradient, in a Beckman-Altex high-pressure liquid chromatograph. From the N-terminal sequence, three pools of 14-mers (oligodeoxyribonucleotides) of 24-fold degeneracy to Tyr-Met-Gln-Leu-Val were synthesized by the solid-phase phosphoramidite method[33] using an Applied Biosystems (ABI) Model 380A DNA Synthesizer. The 14-mers were labelled at the 5′ end using [α-^{32}P]ATP (5,000 Ci mmol^{-1}) and T_4 polynucleotide kinase. The labelled 14-mers (500 μg ml^{-1}) were used to prime cDNA synthesis. Specifically primed cDNA products were separated on an 8% acrylamide/7 M urea gel. Oligonucleotide pool I primed the synthesis of a cDNA fragment of ~100 nucleotides, whereas no cDNA products were detected when either pool II or pool III was used to prime cDNA synthesis. The cDNA fragment was purified and sequenced[34] to give unequivocal assignment for 72 nucleotides as shown. From this sequence, a single 30-mer (oligodeoxyribonucleotide) complementary to the cDNA sequence encoding amino acids −9 to +1 was synthesized[33]. This 30-mer was used to screen a cDNA library as described in Fig. 3 legend.

segments has been noted for *Lycopersicon peruvianum*[20], another member of the Solanaceae that has a gametophytic self-incompatibility system. Previous studies with *N. alata*[21] also demonstrated the developmental regulation and distribution of *S*-allele-associated style components.

The absolute correlation between the presence of the 32K glycoprotein component in the style and the ability of the style to reject S_2 pollen, represented strong evidence that the 32K protein was a product of either the S_2 allele or of a gene closely linked to it that does not appear to recombine with S_2 in the present breeding programme. We attempted to isolate the S_2 product and to clone the cDNA encoding the protein.

Isolation of S_2-glycoprotein cDNA

A method for isolating the 32K component from styles was established, based on the fact that it is a glycoprotein with a high *p*I. Chemical deglycosylation of the 32K component, isolated by a combination of ion-exchange and affinity chromatography, yielded a single product (M_r 26K) (Fig. 2*A*). The carbohydrate component contains fucose, arabinose, xylose, mannose, galactose and possibly glucose, but the organization of these monosaccharide residues into carbohydrate chains is unknown. At least part of the carbohydrate occurs as *N*-linked chains, as the isolated component was susceptible to degradation with endoglycosidase F (Endo F), yielding three products as well as the undegraded glycoprotein of M_r 32K (Fig. 2*A*). The Endo F products comprised two species running closely together, each with an estimated M_r of 30,000, and a single species of M_r 28,000. A product of M_r 27,000, which is slightly larger than the chemically deglycosylated protein, was found on *in vitro* translation of messenger RNA isolated from a mature style but was absent from translation products of

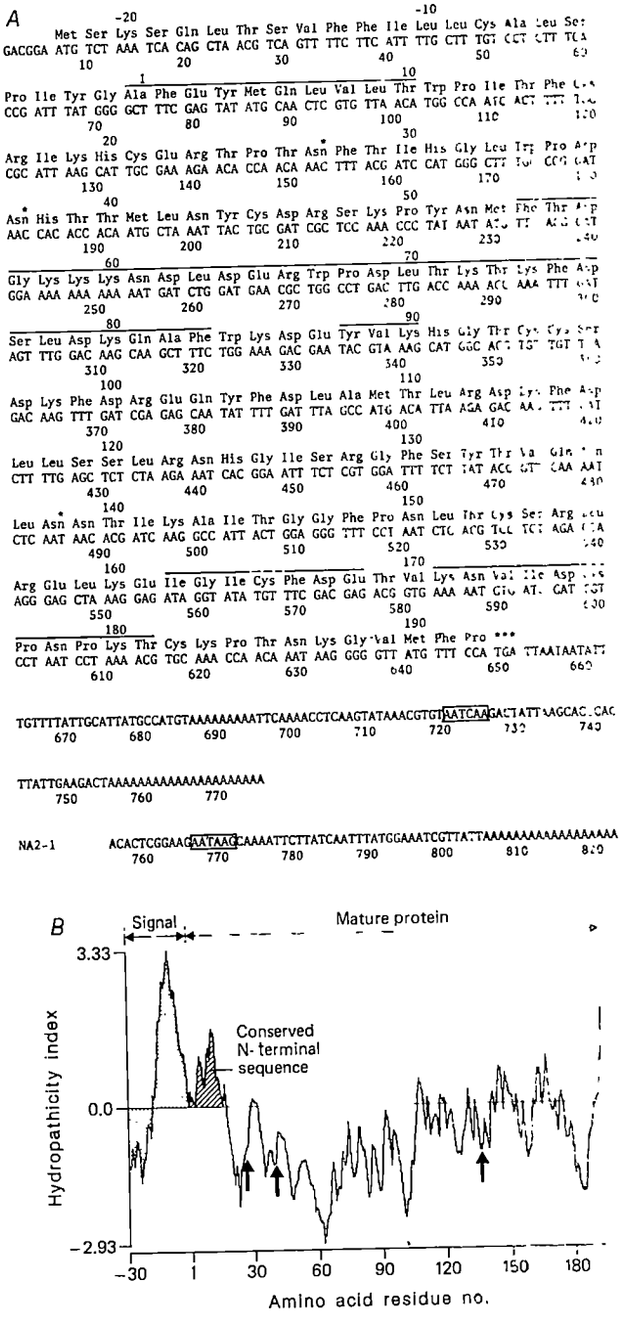

Fig. 3 *A*, The nucleotide sequence and predicted amino-acid sequence of the cDNA encoding the S_2-glycoprotein of *N. alata*, as defined by the sequence of clone NA-2-2. Nucleotides 19–754 are identical to those of clone NA-2-1. The cDNA insert from clone NA-2-1 had an additional 50 nucleotides at the 3′-untranslated end preceding a polyadenylation site, as shown beneath the last line of the NA-2-2 sequence. Only one strand with the polarity of the mRNA is shown. Nucleotides are numbered beneath the DNA sequence. The predicted amino-acid sequence is given above the nucleotide sequence and is numbered beginning with 1 for the first amino acid of the mature protein. The putative signal peptide is indicated by negative numbers. The overlined amino acids are those residues identified by protein sequencing. Broken overlining indicates those residues that could not be identified unambiguously by amino-acid sequencing. Potential glycosylation sites are indicated by asterisks, and potential polyadenylation signals at residues 720–725 and 766–771 (for NA-2-1) are boxed. *B*, A hydrophobicity plot of the deduced amino-acid sequence of the unprocessed S_2-glycoprotein. The region of the profile corresponding to the putative signal peptide (amino acids −22 to −1) is stippled. The hydrophobic N-terminal sequence, which exhibits striking homology to the *S*-allele-associated style components from *L. peruvianum*, is shaded. The positions of the three putative *N*-glycosylation sites are indicated by arrows.

Methods. *A*, Poly(A)$^+$ mRNA isolated from mature S_2S_3 styles[32] was used to construct a cDNA library in λgt10 (ref. 35). The library was screened for sequences specific to mature style by differential hybridization to single-stranded ^{32}P-cDNAs prepared from ovary, green-bud style and mature style poly(A)$^+$ mRNAs. Prehybridization (2 h at 42 °C) was in 5×Denhardt's, 5×SSC, 50 μg ml^{-1} sonicated salmon sperm DNA, 50 mM Na-phosphate *p*H 6.8, 1 mM Na-pyrophosphate, 100 μM ATP and 50% deionized formamide. The cDNA probes were used at 4×10^7 c.p.m. ml^{-1}. Filters were washed in 0.1×SSC, 0.1% SDS at 42 °C. One clone (NA-2-1) which hybridized to mature style cDNA, but not to cDNA from ovary or green-bud style, also hybridized to the synthetic 30-mer described in the legend to Fig. 2*C*. The same hybridization solution as described above was used for hybridizations with the 30-mer (10^8 c.p.m. μg^{-1}, $0.4–1\times10^6$ c.p.m. ml^{-1}), except that the formamide concentration was 20% and the temperature was decreased to 37 °C. A second cDNA library in λgt10 was constructed by a method designed to optimize isolation of full-length clones[22]. A library containing 200,000 plaques was obtained from 5 μg of mature style poly(A)$^+$ RNA. From this library, a clone, designated NA-2-2, which hybridized to the *Eco*RI insert from NA-2-1 and the synthetic 30-mer, was identified. The insert was labelled with [α-^{32}P]dATP using DNA polymerase I (Klenow fragment)[36]. The 30-mer was labelled with [γ-^{32}P]ATP using T_4 polynucleotide kinase. The cDNA inserts from clones NA-2-1 and NA-2-2 were ligated into the bacteriophage vector M13mp8 RF DNA[37] and sequenced by the chain termination method[38,39]. Sequence data obtained in this way were analysed and manipulated using the computer programs of Staden[40], as modified by Dr A. P. Kyne. Peptide sequencing: The 32K glycoprotein was electroeluted from selective two-dimensional SDS-polyacrylamide gels (60 μg) and purified by 'reverse-gradient' HPLC[20] before reduction and alkylation[41] and desalting by 'reverse-gradient' HPLC[20]. The sample was divided into two equal portions and fragmented by either CNBr cleavage[42] or *S. aureus* protease digestion using an enzyme/substrate ratio of 1:50 in 1% ammonium bicarbonate[43]. The peptides were purified for sequence analysis by multi-dimensional microbore HPLC[41]. HPLC was performed on a Perkin-Elmer liquid chromatograph (model LC4) equipped with a model LC95 ultraviolet detector, a model LS4 fluorimeter and a model LS1 100 integrator. Fractions were collected either with a Pharmacia Frac 100 or manually. *B*, The hydrophobicity profile was determined using the predictive rules of Kyte and Doolittle[44] and a span of nine consecutive residues.

mRNA from both ovary and styles harvested at the green-bud stage (Fig. 2*B*). As the 32K S_2-glycoprotein was not detected in extracts of ovary or styles from flowers at the green-bud stage, it was concluded that the 27K component corresponds to the *in vitro*-translated product of S_2 mRNA. This component is slightly larger than the 26K chemically deglycosylated glycoprotein, consistent with the presence of a signal peptide that is cleaved during secretion of the S_2-glycoprotein from the transmitting tract cells to the extracellular space.

The N-terminal sequence of the isolated glycoprotein was determined and three pools of 14-mers of 24-fold degeneracy to amino acids 4–8 were prepared and used to prime cDNA synthesis (see Fig. 2 legend). A specifically primed fragment of ~100 nucleotides, produced using one of the three pools of 14-mers, was purified and sequenced. From this sequence a single 30-mer complementary to the cDNA sequence encoding amino acids −9 to +1 was synthesized (Fig. 2*C*). A cDNA library was prepared in λgt10 using mRNA isolated from mature styles of *N. alata* of genotype S_2S_3. The library was subjected to differential screening using ^{32}P-labelled cDNA prepared from mRNA isolated from mature and green-bud styles. Plaques that hybridized strongly only to the mature style cDNA were selected and rescreened using cDNA prepared from mature style and ovary mRNA. Ovary cDNA was chosen for the second screen because electrophoretic analysis of extracts of mature style and ovary indicated that these tissues have in common some proteins that are not present in green-bud styles (data not shown). The protein profiles of other plant organs were too diverse compared with mature style to be useful for differential screening. Clones that hybridized to mature style cDNA, but not to ovary or green-bud style cDNA, were screened with the synthetic oligodeoxyribonucleotide 30-mer described above. One of the clones that hybridized with the 30-mer as well as the cDNA prepared from mature style mRNA, but not ovary or green-bud style mRNA, was chosen for further study. This clone was designated NA-2-1.

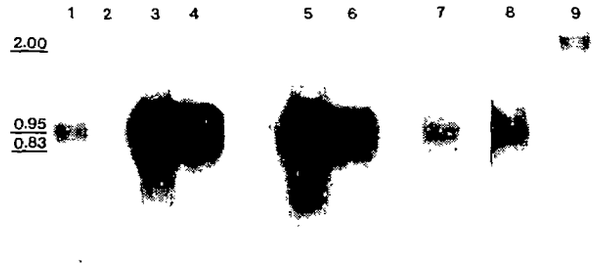

Fig. 4 Northern blot analysis of mRNAs from styles of different *S* genotypes isolated from *N. alata* and *L. peruvianum*. Lanes 1–4, *N. alata* genotypes S_2S_3 (lane 1, ovary 5 μg; lane 2, green bud 5 μg; lane 3, mature style 2 μg; lane 4, mature style 0.5 μg); lanes 5, 6, *N. alata* genotype S_2S_2 (lane 5, mature style 5 μg; lane 6, mature style 0.5 μg); lane 7, *N. alata* genotype S_3S_3 (mature style 5 μg); lane 8, *N. alata* genotype S_1S_3 (mature style 5 μg); lane 9, *L. peruvianum* mature style (5 μg). Numbers on the left are size markers.

Methods. mRNAs were isolated as described previously[32] and electrophoresed in formaldehyde/1.2% agarose gels[45] using a running buffer containing 20 mM morpholinopropanesulphonic acid *p*H 7.0, 5 mM sodium acetate and 0.1 mM EDTA *p*H 8.0. The RNAs were transferred to nitrocellulose filters and probed with ^{32}P-labelled[36] S_2 cDNA (10^8 c.p.m. μg^{-1}, 2×10^6 c.p.m. ml^{-1}). The size markers used were *Eco*RI/*Hin*dIII restriction fragments of λDNA. Prehybridization (2 h at 42 °C) and hybridization (16 h at 42 °C) was carried out in 5×Denhardt's, 5×SSC, 50 μg ml^{-1} sonicated salmon sperm DNA, 100 μM ATP and 50% deionized formamide. Filters were washed in 0.1×SSC, 0.1% SDS at 42 °C. All exposures were for 3 h, except for S_1S_3 *N. alata* mRNA (lane 8) and S_1S_3 *L. peruvianum* mRNA, where films were exposed for 18 h.

Nucleotide sequence analysis of the cDNA insert in clone NA-2-1 showed that it contained an open reading frame, but had no ATG that could act as an initiation codon. To obtain a clone containing a full-length cDNA insert, another cDNA library was prepared using a method[22] which optimizes the recovery of full-length clones. This library (200,000 plaques) was screened with both the cDNA insert from NA-2-1 and the 30-mer shown in Fig. 2*C*. A second clone, designated NA-2-2, hybridized to both these probes. Figure 3*A* shows the nucleotide sequence of the cDNA insert from NA-2-2. The cDNA sequence at the 5′ end of the NA-2-2 insert is identical to the sequence of the cDNA fragment synthesized by primer extension (Fig. 2*C*), and includes an ATG that could act as an initiation codon. In addition, the sequence of the NA-2-2 insert matches exactly the sequence of the NA-2-1 insert from nucleotide 19 of the NA-2-2 cDNA (Fig. 3*A*). The NA-2-2 sequence contains an open reading frame of 642 base pairs (bp) which encodes a protein with a predicted M_r of 24,847, including a putative signal sequence of 22 amino acids. Figure 3*A* shows the sequence regions that have been confirmed by sequencing of peptides generated from the S_2-glycoprotein by either CNBr cleavage or digestion with *Staphylococcus aureus* protease. Of the predicted 192 amino-acid residues of the mature S_2-glycoprotein, 61 have been confirmed by amino-acid sequencing of peptides. We therefore conclude that the sequence shown in Fig. 3*A* encodes the mature S_2 protein and a signal sequence that directs the transfer of the S_2-glycoprotein from the transmitting tract cells to the extracellular space. This putative signal sequence has features that are typical of eukaryotic signal sequences[23]—a relatively hydrophilic sequence of five amino acids at the C-terminal end, a relatively hydrophobic sequence (−6 to −14) and a more hydrophilic sequence at the N-terminal end (see Fig. 3*B*). The amino acids at the C-terminal end include glycine at the cleavage site, an aromatic residue at −2 and a helix breaker, proline, at −4, all of which are common features of the C-terminal region of signal sequences. In the mature protein sequence there is relatively hydrophobic sequence at the N-terminus (Fig. 3*B*) which is homologous with that of *S*-allele-associated style components from *L. peruvianum*[20] (see Fig. 6). There are also three predicted glycosylation sites (residues 27, 37 and 138), based on the consensus glycosylation sequence (Asn-X-Ser/Thr)[24], in the hydrophilic region of the protein. As six moles of *n*-acetylglucosamine were detected per mole of isolated S_2-glycoprotein (unpublished observations), it is possible that each of these glycosylation sites carries an *N*-linked carbohydrate chain. The fact that enzymatic deglycosylation with Endo F (Fig. 2*A*) yielded three products separable by SDS-polyacrylamide gel electrophoresis, suggests that these sites are in fact *N*-glycosylated. As well as these potential *N*-linked carbohydrate chains, there may also be *O*-linked chains. As no hydroxyproline was detected in the amino-acid analysis (unpublished observations), there is no opportunity for Hyp-glycosylation. As there are nine cysteine residues in the mature protein, there is considerable potential for internal sulphydryl linkages as well as at least one free sulphydryl group which might be functionally significant.

Apart from differences at the 5′ end, clones NA-2-1 and NA-2-2 also differed in the lengths of their 3′-untranslated sequences. The two clones were identical as far as nucleotide 754, the polyadenylation site in clone NA-2-2; from this point the cDNA insert from clone NA-2-1 had an additional 50 nucleotides of untranslated mRNA and a poly(A) tail of 18 residues (see Fig. 3*A*). This difference at the 3′ end suggests that there are alternative polyadenylation sites in S_2 RNA transcripts. The putative signals for the two sites are indicated in Fig. 3*A*; neither has the sequence AATAAA which is typically found in animal messages[25,26], but the polyadenylation signals in plant genes apparently show much greater sequence variation than is found in animal genes[27,28].

Hybridization analyses

The S_2 cDNA was used as a probe in Northern blot hybridization experiments with mRNAs prepared from mature styles of *N. alata* genotypes S_1S_3, S_2S_3, S_2S_2 and S_3S_3, as well as from mature styles of *L. peruvianum* genotype S_1S_3 and green-bud styles and ovaries of *N. alata* genotype S_2S_3 (Fig. 4). In all mature styles bearing the S_2 allele, a predominant mRNA species of ~940 nucleotides hybridized to the cDNA probe. A mRNA of identical size was detected in preparations of poly(A)$^+$ mRNA isolated from S_3S_3 and S_1S_3 styles of *N. alata*, the extent of hybridization being ≤1% the level obtained in styles bearing the S_2 allele. This result indicates that the transcripts of the different *S* alleles are homologous. The same probe did not hybridize to green-bud mRNA; however, a weak signal corresponding to 940 nucleotides was detected in S_2S_3 ovary mRNA.

Self-incompatibility is not expressed in green buds, nor is the S_2-glycoprotein detected in extracts of green buds; it is therefore not surprising that the S_2 cDNA probe did not hybridize with green-bud mRNA. The hybridization with ovary mRNA was unexpected as the S_2-glycoprotein is not detected in extracts of ovary; it is possible that low levels of the glycoprotein are produced in the ovary to ensure arrest of any self-pollen tubes that manage to evade the self-incompatibility mechanisms expressed in the style. The RNA blot analysis also revealed that styles from *L. peruvianum* (genotype S_1S_3) synthesized readily detectable levels of a 2.5-kilobase (kb) mRNA that hybridized with the NA-2-1 cDNA insert. This finding is consistent with the extensive homology observed at the N-terminal sequences of the S_2-glycoprotein from *N. alata* and both the S_1 and S_3 proteins from *L. peruvianum* (Fig. 6). The S_1 and S_3 proteins from *L. peruvianum* each have an estimated M_r of 28,000 and the RNA blot analysis indicated that the mRNA transcripts encoding these proteins are also identical in size. The predicted proportion of noncoding mRNA in the *L. peruvianum* S_1 and S_3 transcripts is significantly greater than for the S_2 transcript from *N. alata*.

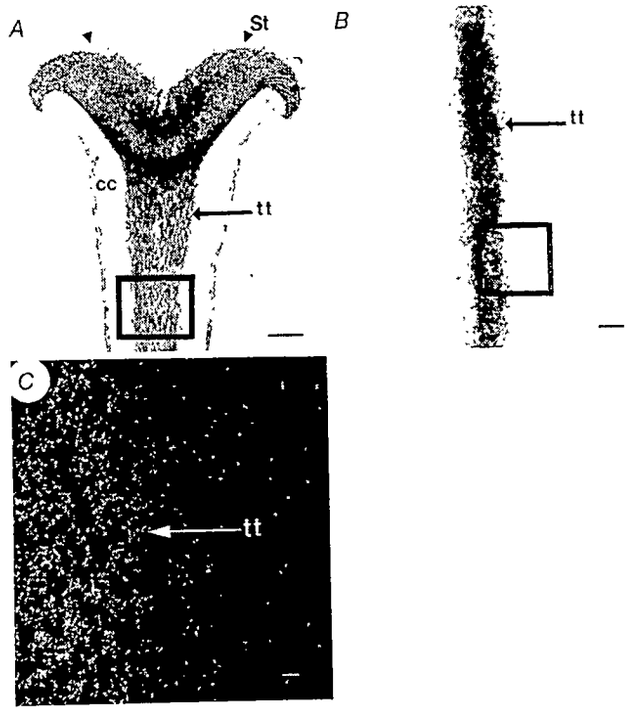

Fig. 5 Hybridization histochemistry of probe for cDNA encoding the 32K style glycoprotein from *N. alata*, genotype S_2S_3. *A*, Light micrograph of longitudinal section through a mature style (genotype S_2S_3) embedded in JB-4 resin (Polysciences) and stained with Richardson's blue. The central core of transmitting tissue (tt) is surrounded by the cortex (cc). The stigma surface (St) is indicated. Scale bar, 250 μm. *B*, Autoradiograph of a frozen longitudinal section through the style after hybridization with ^{32}P-labelled S_2 cDNA (obtained by direct exposure to X-ray film). Scale bar, 100 μm. The area shown corresponds to the boxed area in *A*. *C*, Darkfield photograph of a longitudinal section through the style shown in *B* after hybridization (obtained by liquid emulsion autoradiography). Scale bar, 10 μm. The area shown corresponds to the boxed section *B*.

Methods. Mature styles of *N. alata* (genotypes S_2S_3 and S_1S_3) were placed in a mould with OCT Tissue Tec and frozen in Freon 22 cooled in liquid nitrogen. Longitudinal sections (6–8 μm thick) were cut at −20 °C using a Frigocut microtome (Reichert Jung) and attached to glass slides precoated with 1% gelatin using 0.25% formaldehyde as a crosslinking agent. The sections were fixed at 4 °C for 5–10 min in 2% glutaraldehyde in 33% ethylene glycol and 0.1 M sodium phosphate buffer. Prehybridization and hybridization conditions were as described by Rall *et al.*[46]. The ^{32}P-labelled S_2 cDNA (5×10^8 c.p.m. μg^{-1}) was hybridized to the sections at 40 °C for 60 h; direct exposure time was 2 days using Cronex MRF 31 Medical Recording Film (Du Pont); exposure with liquid emulsion (Emulsion K5, Ilford Nuclear Research) was 7 days.

Hybridization to style sections

The cDNA encoding the S_2-glycoprotein was also used in hybridization histochemical experiments using longitudinal sections of mature S_2S_3 and S_1S_3 styles. Figure 5 shows that there was specific binding of the cDNA probe to the cells of the S_2S_3 transmitting tissue, with no binding to the cortical or epidermal cells. The transmitting tract is the tissue through which the pollen tubes grow on their way to the ovary and it is in this tissue that we would expect the *S* gene to be expressed. The cDNA probe also bound to the transmitting tissue of S_1S_3 styles; although identical conditions were used, binding was very faint compared with that obtained using mature S_2S_3 styles. This result is consistent with the weak hybridization detected in the Northern blot experiments. In control experiments there was essentially no hybridization.

Homology between *N. alata* and *L. peruvianum*

N-terminal sequence analysis of the proteins associated with *L. peruvianum* self-incompatibility alleles S_1 and S_3 revealed striking homologies to the N-terminus of the *N. alata* S_2-glycoprotein[20]. The proteins associated with the S_1 and S_3 alleles of *L. peruvianum* were identified by electrophoretic analysis of style extracts and were purified by electroelution and sequenced as described by Mau *et al.*[20]. Figure 6 shows the extent of homology between the *N. alata* S_2-glycoprotein and the two *S*-associated proteins isolated from *L. peruvianum*. The homology at the N-terminal ends of the *S*-allele-associated style components of *N. alata* and *L. peruvianum* is consistent with the hypothesis that the *S* gene has been conserved in evolution to prevent inbreeding of plant species[1].

Discussion

We have cloned the cDNA encoding a glycoprotein from the female sexual tissue of *N. alata* which segregates with the S_2 allele of the gene controlling self-incompatibility. This cDNA hybridizes with mRNAs from styles of other *S* genotypes of *N. alata* and also with mRNAs from styles of *L. peruvianum*, another species in the family Solanaceae which has a gametophytic self-incompatibility system. Specific homology in the N-terminal sequences of *S*-genotype-related style proteins for these two species has also been demonstrated.

Taken together, the segregation of the S_2-glycoprotein with function of the S_2 allele, the *in vitro* activity of the isolated S_2-glycoprotein as a pollen tube inhibitor[29], and the homology at the N-terminus of *S*-genotype-associated style components from *N. alata* and *L. peruvianum*, provide strong evidence that the cDNA described here encodes the product of the S_2 allele. However, conclusive evidence can only come from transformation of the *S* genotype by gene transfer.

The *S* gene is considered to have a tripartite structure—two conserved portions encoding pollen activity and style activity and a variable part encoding the allelic specificity[1]. The conservation of the hydrophobic N-terminal sequences of the *S*-allele-associated components from *N. alata* and *L. peruvianum*[20] is compatible with this model; these sequences may represent a fragment of the conserved portion encoding style activity. The S_2 cDNA can now be used as a probe to obtain cDNA clones for other *S*-alleles from *N. alata* as well as other related species, an approach which should elucidate the expression of different allelic specificities. Although it is likely that the allelic differences are expressed as differences in the protein component of the style glycoprotein, the possibility that the allelic differences reside in the glycosyl moiety cannot be excluded. In this case, the allelic differences would be expressed primarily as glycosyl transferases of different specificities, and differences would then be detected in the structures of the glycosyl moieties of the products of different *S* alleles. Analysis of the carbohydrate moiety of the *S*-glycoprotein is presently limited by difficulties in obtaining sufficient material.

Comparison of the *N. alata* S_2 cDNA sequence with nucleotide sequences encoding *S*-genotype-associated proteins from female tissues of other plant species may provide some insight into the evolution of self-incompatibility. Recently, a cDNA clone encoding part (~30%) of an *S*-locus-specific glycoprotein from *Brassica oleracea*, a species having a sporophytic self-incompatibility system[15], has been described; there is no apparent homology between this partial sequence and that of the *N. alata* S_2 cDNA. However, the possibility of homology with the other undescribed 70% of the molecule remains. Once a full-length clone for the *B. oleracea* protein is available, comparison of the two sequences should give a greater under-

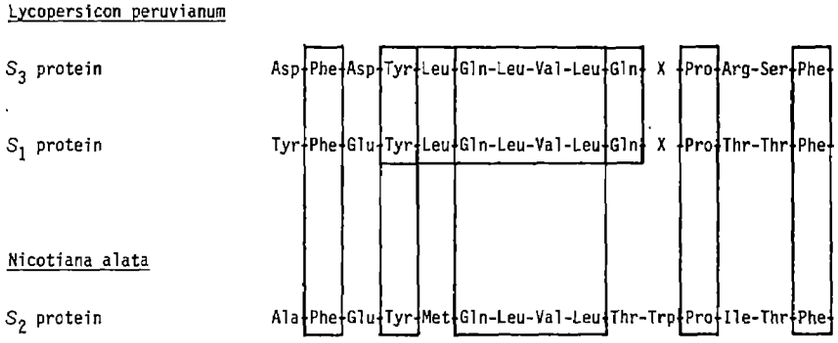

Fig. 6 A comparison of the amino-terminal sequences of *L. peruvianum* S_1- and S_3-associated proteins with *N. alata* S_2 protein. Identical amino acids are boxed.

standing of the evolutionary relationship between the sporophytic and gametophytic systems.

A fundamental question in understanding how self-incompatibility is expressed is whether the pollen tube and style *S*-gene products are identical. To date, we have not been able to identify a protein from pollen which corresponds to the *S* genotype. There are two reasons for expecting the products of a particular *S* allele to differ in pollen and style: first, it is difficult to envisage how two identical molecules could interact to cause inhibition of pollen tube growth. It is possible that the *S*-gene products from the style and pollen tube, although generated from the same allele, are not identical. Non-identical products could be generated by different splicing of the same transcriptional unit to produce different mRNAs, or there may be different post-translational modifications such as glycosylation[29]. In this way, differences leading to complementary sites on the two *S*-gene products might be generated. The second reason for expecting differences in the structures of the two *S*-gene products relates to their secretion. It is assumed that the cells of the style transmitting tract secrete the *S*-gene product into the extracellular matrix; the presence of the signal sequence predicted by the S_2 cDNA sequence is compatible with secretion of the product. The pollen tubes grow through the style in the extracellular matrix and must in some way recognize the *S*-gene product. It is difficult to envisage how the recognition which results in pollen tube arrest could occur if the pollen *S*-gene product, as well as the style *S*-gene product, is secreted. It is more likely that the pollen *S*-gene product is either membrane-associated or wall-associated, so that the interaction with the style *S*-gene product could signal cytoplasmic events leading to arrest of pollen-tube growth.

The cloning of the cDNA encoding the S_2-glycoprotein represents the initial step in resolving these questions, which have broader implications in the field of cell–cell recognition in plants. It is likely that an understanding of how allelic differences are expressed by plant genes and how products of these alleles interact to initiate a response involving changes in cell-wall metabolism, will lead to principles which may apply to more complex systems involving plant cell–cell interactions, for example, in host–pathogen and host–parasite interactions.

We thank Dr K. K. Pandey (Grasslands, Palmerston North, New Zealand), for providing *N. alata* seed of genotypes S_2S_3 and S_1S_3, Mr Darron Broom for management of the glasshouse and Ms Susan Mau for collection of plant material. We also thank Lucy Duncan for assistance in preparation of the synthetic oligonucleotide probes; Marie John for assistance with amino-acid sequencing; Dr Tony Bacic for the monosaccharide analyses; Marg Strode for preparation of the manuscript; and Tony Kyne for making the MELBDBSYS suite of computer programs available to us. The work was supported in part by funds from Agrigenetics Research Associates.

'Missing image' in gravitational lens systems?

D. Narasimha*, K. Subramanian† & S. M. Chitre‡

Gravitational lens models involving extended mass distributions generally predict an odd number of images[1], with one of the images close to the centre of the principal lens galaxy. In all the lens systems observed up to now, only an even number of images have been unambiguously detected. A number of suggestions[2-4] have been advanced to explain the absence of the 'odd' image, but none of these is sufficiently compelling. We suggest here that the presence of a compact nucleus with mass in the range 5×10^9 to 5×10^{10} solar masses ($M_\odot$), contained within a region of size $\leq$50 pc at the centre of a lens galaxy, would dim the odd image significantly without affecting the rest of the image configuration.

We argue that a massive compact nucleus with even a small fraction ($\leq$2%) of the total galaxy mass contained within ~50 pc would have negligible influence on the properties of the images located outside the core of the galaxy. But the proximity of the odd image to the nucleus allows it to be pulled closer to the galactic centre, at the same time becoming significantly dimmer. We demonstrate below that the effect becomes pronounced for a nuclear mass exceeding $\sim5\times10^9\ M_\odot$ contained within ~50 pc. It turns out that the exact size of the nucleus is not particularly important, although the intensity of the odd image increases as the nucleus becomes more extended.

Consider a spherically symmetric density distribution of matter for the core of the underlying lens galaxy. The scattering function[5] representing the bending of light rays for an impact parameter small compared with the radius of the galactic core is given by

$$I_G(Z_0)=\pi\sigma_G Z_0^* \tag{1}$$

Here, in the usual notation, σ_G is the central surface density of the galaxy and Z_0 is the complex number giving the image position in the deflector plane. Suppose, in addition we consider the effect of a nucleus of mass M_N and radius R_N, with a constant surface density. Then the scattering function of the nucleus can be written as

$$\begin{aligned} I_N(Z_0)&=\frac{M_N}{R_N^2}Z_0^*, \quad |Z_0|<R_N \\ &=M_N/Z_0, \quad |Z_0|>R_N \end{aligned} \tag{2}$$

With the help of the above scattering functions we can relate the image position Z_0 to the source position Z, through the equation[5]

$$\begin{aligned} Z&=Z_0-\frac{4GD}{c^2}I_G^*-\frac{4GD}{c^2}I_N^* \\ &=Z_0(1-\kappa_G-\kappa_N), |Z|<R_N \end{aligned} \tag{3}$$

where

$$\kappa_G=\frac{4GD}{c^2}\pi\sigma_G, \qquad \kappa_N=\frac{4GD}{c^2}\pi\left(\frac{M_N}{\pi R_N^2}\right)\equiv\frac{R_0^2}{R_N^2} \tag{4}$$

$R_0=[(4GD/c^2)M_N]^{1/2}$ is the radius of influence of the nucleus and $D=\mathrm{DD}\times\mathrm{DDS}/\mathrm{DS}$, where DD, DDS and DS are the distances between observer and deflector, deflector and source, and observer and source, respectively. G is the gravitational constant and c is the speed of light in vacuum.

Table 1 Image properties in the presence of the galactic nucleus

Lens system	$M_N\ (M_\odot)$	$M_G\ (M_\odot)$	Intensity ratio: Without nucleus	Intensity ratio: With nucleus	Ref.
0957+561	1.4×10^{10}	4.8×10^{11}	2.5×10^{-2}	1.0×10^{-6}	6
2345+007	1.3×10^{10}	1.4×10^{12}	1.8×10^{-2}	8.0×10^{-5}	7
2016+112	2.5×10^{10}	3.4×10^{12}	1.5×10^{-2}	4.0×10^{-6}	8

M_N, mass of galactic nucleus; M_G, mass of parent lens galaxy (both in units of solar mass, $M_\odot$). The intensity ratio is that between the odd (third) image and the external bright image.

In the absence of the nucleus the image would have been located at a position Z_0^I given by

$$Z=Z_0^I(1-\kappa_G) \tag{5}$$

Let $Z=\gamma e^{i\theta}$, $Z_0=\gamma_0 e^{i\phi}$ and $Z_0^I=\gamma_0^I e^{i\psi}$. In the context of the present problem, as will become clear later, both κ_G and κ_N exceed unity. Then, without the presence of the nucleus, the 'odd image' is located at

$$\gamma_0^I=\frac{\gamma}{(\kappa_G-1)} \tag{6}$$

The introduction of the nucleus shifts the image to the position

$$\gamma_0=\frac{\gamma}{(\kappa_G+\kappa_N-1)}=\frac{(\kappa_G-1)\gamma_0^I}{(\kappa_G+\kappa_N-1)} \tag{7}$$

Note that for values of κ_G exceeding unity and for the location, in the absence of the compact nucleus, of the odd image γ_0^I within a critical radius, $\simeq\kappa_G^{1/2}R_0$, the nucleus does not create additional sub-images of the odd image (ref. 3, section 2(e), (f)). The amplification A^I of the image in the absence of the nucleus is obtained using equation (6):

$$A^I=\frac{\gamma_0^I}{\gamma}\frac{d\gamma_0^I}{d\gamma}=\frac{1}{(\kappa_G-1)^2} \tag{8}$$

whereas after the introduction of the nucleus the amplification A follows from equation (7):

$$A=\frac{\gamma_0}{\gamma}\frac{d\gamma_0}{d\gamma}=\frac{1}{(\kappa_G+\kappa_N-1)^2} \tag{9}$$

Suppose the parent galaxy has a mass $M\simeq5\times10^{11}\ M_\odot$, within a core-radius $\simeq$3 kpc. Assuming $D\simeq600$ Mpc, we get $\kappa_G\simeq6.5$. If we now consider a nucleus with mass $M_N\simeq10^{10}\ M_\odot$ and radius $R_N\simeq50$ pc, then we have $\kappa_N\simeq470$. Clearly κ_N is very large compared with κ_G, so that from equations (4) and (7) we have

$$\gamma_0\simeq\frac{\kappa_G}{\kappa_N}\gamma_0^I=\kappa_G\left(\frac{R_N}{R_0}\right)\left(\frac{\gamma_0^I}{R_0}\right)R_N \tag{10}$$

Thus for $\gamma_0^I\leq\kappa_G^{1/2}R_0$ and for the foregoing choice of parameters, the image in the presence of the nucleus is located at

$$\gamma_0\leq\kappa_G^{3/2}\left(\frac{R_N}{R_0}\right)R_N\leq\tfrac{3}{4}R_N.$$

The amplifications before and after the introduction of the nucleus are given by equations (8) and (9):

$$A^I\simeq3\times10^{-2}; \qquad A\simeq4\times10^{-6} \tag{11}$$

It is evident from this idealized example that after the introduction of the nucleus the odd image is depressed in intensity by a factor of $\sim10^4$, or equivalently dimmed by ~10 mag, in addition to being brought closer to the centre of the galaxy (and the nucleus) by a factor of ~80.

We now incorporate the effects of the compact nucleus on the image properties by adopting the prescription outlined for

realistic lens models[6]. In fact, we merely add the gravitational effect of the compact nucleus to the lens models which we have previously constructed[6-8], without altering any of the parameters of those models.

Table 1 summarizes the numerical results for three multiple quasar systems: 0957+561, 2345+007 and 2016+112. In these models, without the inclusion of the effects of the nucleus the intensity of the odd (third) image is a few percent of that of the external bright image. But in the presence of the nucleus the intensity of the third image is enormously diminished, and the intensity ratio is lowered by a factor anywhere from 10^2 to 10^4; that is, the odd third image is dimmed by ~6–9 mag. A remarkable feature is that the properties of the main images, such as their positions and intensities, are left practically unaltered by the presence of the nucleus, while the third image is pulled significantly closer to the centre of the nucleus. The masses of the parent lens galaxy required to obtain the observed configuration are in the range 5×10^{11}–$3.4\times10^{12}\ M_\odot$, with the mass of the nucleus $\simeq1.3\times10^{10}$–$2.5\times10^{10}\ M_\odot$ contained within ~50 pc. Further, the intensity of the third image would increase if the nucleus is assumed to be more extended or the mass of the nucleus lower than the values given in Table 1.

We note that the present model does not necessarily involve any singularities (for example, black holes or strings) in the density distribution of matter, although such singularities can also play a similar role in explaining the absence of the odd image. We consider that it is better to try to account for most of the observed features of the gravitational lens system, including the missing odd image, in the framework of a conventional, smooth density distribution, before invoking the presence of singularities. Indeed, Young *et al.*[9] have inferred from photometric and spectroscopic observations that the nucleus of the giant elliptical galaxy M87 contains a compact mass $\simeq5\times10^9\ M_\odot$ within 100 pc (see also Sargent *et al.*[14]).

The presence of a black hole in the central region of a lens galaxy could cause the complete disappearance of the third image, due to the action of the black hole as a 'mini-lens'. In contrast, a massive compact nucleus will merely dim the image by a substantial amount[3]. The dimmed image could be detected if the source size (for example, the extended narrow-emission-line region in the quasar) is comparable to the radius of influence of the nucleus, for, in such a situation, some fraction of the large emission-line region is unlikely to be significantly affected by the lens action of the massive nucleus.

Will the existence of clumpiness in the lens affect the intensity of the odd image? For parameters appropriate to the present problem and for clumps in the form of solar-mass stars, neither the overall bending nor the intensity amplification of the large radio and emission-line regions are sensibly influenced. But for the compact optical continuum region we cannot neglect the effects of minilensing. However, in such a situation arguments[10,11] based on flux conservation and the large optical depth to mini-lens action[12] enable us to assign a probability distribution[13], $P(A)$, to the intensity amplification of the odd image which peaks at $A\simeq4\times10^{-6}$. As a result the clumpiness in the lens galaxy or the nucleus is not expected to affect our conclusions about the dimness of the odd image.

A testable prediction of the present suggestion is the observation of an image of the quasar optical continuum region within ~0.2 arc s from the centre of the lens galaxy, with visual magnitude fainter by nearly 6 mag than the external bright image. Equally, if the source size is large compared with R_0 in some frequency, such as the narrow-emission-line region, then in the present model the image could still be observed near the centre of the lens galaxy. On the other hand, the detection of a bright odd image in the optical continuum will invalidate the hypothesized presence of a compact massive nucleus in the core of the lens galaxy and would imply that the nucleus is either less massive than $5\times10^9\ M_\odot$ or has a linear size larger than 50 pc.

The numerical computations were carried out on the CYBER 175 and CDC 205 computers at the University of Calgary. D.N. was supported by a Canadian NSERC grant to S. R. Sreenivasan. K.S. was supported by SERC.

Resolution of Crab nebula filaments into chains of quasistellar knots

Sidney van den Bergh* and Christopher J. Pritchet†

* Dominion Astrophysical Observatory, Herzberg Institute of Astrophysics, 5071 W. Saanich Road, Victoria, British Columbia, Canada V8X 4M6
† Department of Physics, University of Victoria, PO Box 1700, Victoria, British Columbia, Canada V8W 2Y2

We have clearly resolved a number of the Hα emitting filaments in the Crab nebula into chains of knots with diameters ≤1.0 arc s. This resolution was possible because sub-arcsecond seeing is common on Mauna Kea, Hawaii (altitude 4,204 m) but quite rare at the sites of other large telescopes situated at lower altitudes. Individual filaments resemble beads on a string which shows that these objects are rope-like structures. In the brightest filament close to the Crab pulsar the quasistellar knots are slightly displaced from the spine of the low-density filament on which they are superposed. This segregation might be understood if the dense knots have been accelerated outwards by a lesser amount than the low-density filament in which they were originally embedded. The present results show that a substantial fraction of the line emission of the Crab nebula originates in the small and very dense quasistellar knots that lie along the spines of filaments. This will affect estimates of the mass and composition of the Crab nebula, and observations of the motions of quasistellar knots should enable one to study the expansion (and eventually perhaps even the acceleration) of the Crab nebula with much greater precision than was possible previously.

On 12 October 1985 (UT) we obtained frames of two fields in the Crab nebula with the 320×512 pixel RCA charge-coupled device (CCD) detector at the prime focus of the Canada–France–Hawaii Telescope. These 600-s exposures were made in 0.8-arc-s seeing through a ~100-Å-wide filter centred on Hα. The scale of the resulting images was 0.41 arc s per pixel. On these frames many of the Hα emission filaments resemble necklaces (see Figs 1 and 2) composed of 'beads' of differing sizes. Some of these beads appear stellar whereas others are barely resolved with diameters ~1.0 arc s. Typically such knots are strung out along the spines of individual filaments at separations of a few seconds of arc. Bright and faint filaments appear to have the same basic structure. However, in bright filaments individual knots tend to be more luminous (and more closely spaced) than they are in fainter filaments. The appearance of the Hα emission filaments, and the fact that most knots are located in filaments, suggests that they are (in three dimensions) rope-like structures rather than sheets seen edge-on. One might

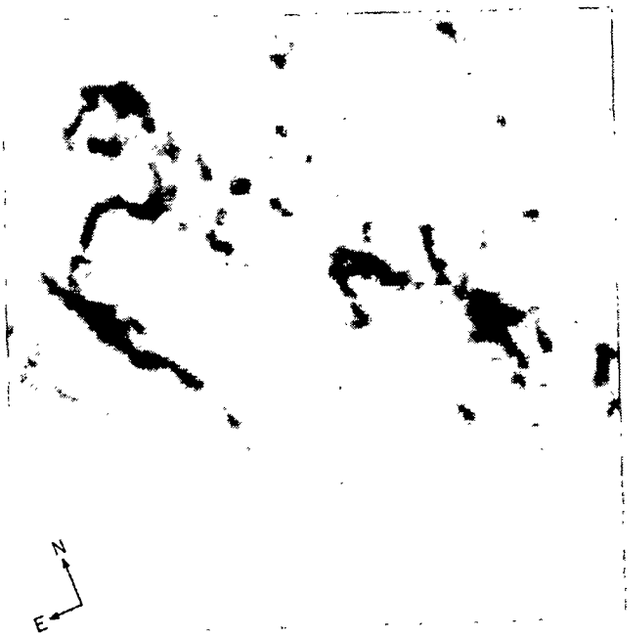

Fig. 1 Hα filament located north of centre of the Crab nebula. The filament is seen to be resolved into a string of quasistellar knots with diameters ≤1.0 arc s. The figure is 60 arc s on a side. Pixel size is 0.41 arc s.

Fig. 2 Filament located west of the Crab pulsar, which is marked by an arrow. This frame was taken in 0.8-arc-s seeing. The figure is 60 arc s on a side.

speculate that individual knots are due to instabilities within these filaments. The distribution of these knots and the pressures needed to form and confine them should provide information about the otherwise unprobed small-scale distribution and properties of the hot thermal plasma and magnetic field between and around the filaments.

Our CCD frames cover two 2×3-arc-min fields. One of these was centred on the Crab pulsar and the other is located slightly to the west of the base of the Crab jet[1]. We estimate that the total number of Hα emission knots in the Crab nebula is a few hundred. At an assumed distance[2,3] of 2 kpc the ≤1.0-arc-s diameters of individual knots correspond to linear dimensions ≤0.01 pc. The total emitting volume of all knots in the Crab nebula is therefore only a few $\times 10^{-4}$ pc^3. A substantial fraction of the total Hα emission of the Crab nebula must originate within this very small volume.

Important questions that remain to be answered by future observations are: (1) Do the quasistellar Hα knots also radiate in the light of elements other than hydrogen? (2) What is the range of physical conditions within these knots? (3) What are the lifetimes of quasistellar knots? (4) How do the spectra of knots differ from those of the filaments in which they are embedded?

The observations reported above were obtained with the Canada-France-Hawaii Telescope, which is operated by the NRC of Canada, CNRS of France and the University of Hawaii. We thank Peter Stetson and David Duncan for their assistance with the processing and reproduction of the digital images shown in the figures.

A flare-induced cascade model of γ-ray bursts

P. A. Sturrock

Center for Space Science and Astrophysics, Stanford University, Stanford, California 94305, USA

Although there is no agreement concerning the model and mechanisms responsible for γ-ray bursts, it is generally agreed that they are produced by neutron stars[1]. With few exceptions[2], it is thought that an intense magnetic field plays a key role. The favoured radiation mechanism is optically thin synchrotron radiation[3], but it is difficult to find any way of maintaining the electron energy since the radiation cooling time is extremely short. As a resolution of this difficulty, I propose that the basic energy-release mechanism is a flare in the magnetosphere of a neutron star. This involves reconnection that leads to an electric field parallel to the magnetic field. This accelerates an electron along the magnetic field, producing high-energy γ rays (by curvature radiation) that promptly annihilate in the magnetic field, resulting in an electron-positron cascade as in radio pulsars[4]. This model offers an explanation of the continuum spectrum, of the 511-keV annihilation line, and possibly of the optical radiation that seems to accompany some γ-ray bursts.

An electron of energy E_e (eV) moving in a magnetic field B (gauss) at a large pitch angle produces predominantly photons of energy E_ϕ (eV) where

$$E_\phi = 10^{-19.7} E_e^2 B \quad (1)$$

Hence if observed photons of energy 10^5 eV are in fact produced in a magnetic field of order 10^{12} gauss, the emitting electrons must have energy of the order of $10^{6.4}$ eV. Since the power S emitted by a single electron by this process is given by

$$S_1 = 10^{-26.1} E_e^2 B^2 \quad (2)$$

we see that the timescale characteristic of radiation cooling of the emitting electron is given by

$$\tau_R = 10^{14.4} E_e^{-1} B^{-2} \quad (3)$$

For the parameters of interest, τ_R is of the order of 10^{-16} s. The problem is to find a process that can energize electrons as rapidly as, or more rapidly than, they are being de-excited by synchrotron radiation.

Basically, the excitation must be achieved by an electric field. One possibility is that this electric field is intrinsic to the photon

flux itself, so that absorption of photons is going on at the same high rate as the emission of photons. This occurs only if the optical depth of the emitting region is of order unity or more, and this possibility is ruled out since observed spectra do not display a Wien peak. (On the other hand, as Hameury *et al.*[5] have shown, excitation of electrons by a distinct 'primary' beam of photons that have *not* been produced by synchrotron radiation, *can* lead to optically thin synchrotron radiation. Their model is in some respects similar to the one to be presented herein.)

Another possibility is that the electric field required to excite an electron is provided by a close encounter with another charged particle—electron, positron, or ion. However, we find that the particles responsible for exciting the radiating electrons must have an enormous density, of order 10^{31} cm^{-3} or more. Clearly, the focus of the inquiry then changes to a study of radiation from that very dense plasma. Hence we have not solved a difficult problem, but merely replaced it by another problem more difficult still.

For the above reasons, it has been proposed[3,6,7] that excitation of the electrons is maintained by a collective plasma process. This process must generate an intense electric field since, to maintain the electron energy against loss by synchrotron radiation for the parameters proposed, the electric field must have a value of $10^{9.5}$ e.s.u. or more. A further requirement is that the electric field must be transverse to the magnetic field and have a frequency comparable with the orbital frequency of the electrons in the magnetic field. For the parameters quoted, this frequency is of the order of $10^{17.8}$ Hz, corresponding to a photon energy of $10^{3.4}$ eV. If this were the case, we would expect the source to emit more energy in X rays than in γ rays, which is normally not the case.

It is clearly very difficult to propose an acceptable mechanism by which electrons may be energized as rapidly as they are being cooled by synchrotron radiation. As a resolution of this dilemma, I propose that energy lost by synchrotron radiation is not restored to the emitting electron.

The impulsive nature of γ-ray bursts and the 'light curves' of the γ-ray flux are reminiscent of solar flares[8]. It is not inconceivable that the energy released during a γ-ray burst has been stored as magnetic free energy in a neutron-star magnetosphere, so it is attractive to consider the consequences of a neutron-star flare. Although there are several models of solar flares, all current models involve magnetic-field reconnection by the tearing mode or a similar processes.[9] Magnetic reconnection violates the 'frozen-flux' condition and therefore develops electric fields that have a non-zero component parallel to the magnetic field. We now examine the consequence of the development of such an electric field in a neutron-star magnetosphere. Since this same situation arises in most models of radio pulsars, we may draw upon pulsar theory in investigating the present problem.

In the presence of a strong electric field parallel to the magnetic field, electrons rapidly accelerate, but their acceleration is soon limited by curvature radiation[4]. The radiation-reaction limited energy, measured in eV, is given by

$$E_{eRL} = 10^{8.1}\, \mathscr{E}^{1/4}\, R_c^{1/2} \tag{5}$$

where $\mathscr{E}$ (e.s.u.) is the electric field strength and R_c (cm) is the radius of curvature. During magnetic reconnection, the strength of the electric field may approach $10^{-2}(v_A/c)B$, where v_A is the Alfvèn speed[10]. In the present situation, the Alfvèn speed is likely to be close to the speed of light so that $\mathscr{E}$ might well be of the order of 10^{10} e.s.u. Adopting $R_c \approx 10^6$, we then see that E_{eRL} will be of the order of $10^{13.6}$ eV. On using the formula

$$E_\phi = 10^{-22.2}\, E_e^3\, R_c^{-1} \tag{6}$$

we see that these electrons will emit photons with energy of the order of $10^{12.6}$ eV by curvature radiation.

As in the case of radio pulsars, a photon of this energy would not escape from the magnetosphere but would rapidly annihilate to produce an electron and a positron, each of which has approximately half the energy of the annihilated photon. As shown some time ago[4], annihilation occurs approximately at a location where the photon 'sees' a transverse magnetic field $B_\perp$ that satisfies

$$E_\phi B_\perp = 10^{18.6} \tag{7}$$

The newly created electrons and positrons have non-zero pitch angles and so radiate by the synchrotron process. These photons also will have such high energy that they will be immediately annihilated by the magnetic field. This cascade ends when photons are produced that are of sufficiently low energy that they may escape. If the above process were to occur only in a small region where the magnetic field strength is constant, the emitted spectrum will be of limited extent. The lower limit of the spectrum, $E_{\phi,L}$, is given approximately by the gyrofrequency:

$$E_{\phi,L} \approx 10^{-7.9}\, B \tag{8}$$

The upper limit to the spectrum, $E_{\phi,U}$, is given approximately by

$$E_{\phi,U} = 10^{18.6}\, B^{-1} \tag{9}$$

Between these limits, the shape of the spectrum is essentially that of a single electron as it radiates away its energy by the synchrotron process. We find, from Equation (B.18) of ref. 4, that the spectrum of a single electron is given by

$$N_{\phi,1} = 10^{9.9}\, B^{-1/2}\, E_\phi^{-3/2} \tag{10}$$

where $N_{\phi,1}\, dE_\phi$ us the number of photons with energy in the range E_ϕ to $E_\phi + dE_\phi$. The γ-ray burst spectra compiled in refs 11 and 12 exhibit great variation. However, a few cases are found to approximate a power-law form over a substantial range of energy. In these cases, we find that the index is indeed close to -1.5.

In most cases, it is likely that radiation will be produced by an extended volume of the magnetosphere in which the field strength varies over a wide range. The resultant spectrum will then differ from the above form, the actual spectrum depending on the magnetic-field geometry, and on the way that energy release is distributed.

One simple model is to assume that the flare occupies most of the volume of a dipole magnetic field and that the free energy density is proportional to B_0^2, where B_0 is the potential field of the dipole. In this case, we find that the emergent gamma-ray spectrum is composed of three sections: below $E_{\phi,LM}$, the spectrum is flat; between $E_{\phi,LM}$ and $E_{\phi,UM}$, the slope is $-3/2$ as in equation (10); above $E_{\phi,UM}$, the slope is -3. $E_{\phi,LM}$ and $E_{\phi,UM}$ are given by equations (8) and (9), with B replaced by B_M, the maximum value of the magnetic field strength in the magnetosphere. Some observed spectra fit this form reasonably well; the required values of B_M are found sometimes to be as high as 10^{13} gauss or more. It is possible that curvature radiation will make some contribution to the observed spectrum, and this may be the origin of the high-energy tail to the spectrum as measured in some cases by the the γ-ray spectrometer on board the Solar Maximum Mission[13].

If N_L is the total number of leptons (electrons and positrons) produced in the terminal stage of the cascade, the total spectrum of the fluence from the gamma-ray burst is given by

$$N_\phi = N_L N_{\phi,1} \tag{11}$$

However, N_L will also be the total number of photons emitted in the 511 keV line when the electrons and positrons annihilate. In some circumstances, the plasma will be so dense that annihilation occurs in the magnetosphere, and the line will be broad due both to particle velocities and the variation of gravitational potential energy. In other circumstances, the plasma will be sufficiently thin that most annihilation occurs at the surface of the star. In this case, the line should be fairly sharp. It is clear from the above formulas that comparison of the fluence in the annihilation line to the fluence in the continuum gives an esti-

mate of the mean strength of the magnetic field in the emitting region.

By using equation (11) to estimate the total number of electrons and positrons involved in a gamma-ray burst, and estimating the lifetime of the electrons either from *in situ* annihilation or flow to the surface of the star, we may estimate the electron-positron number density. This may vary over a wide range, but a typical value would be 10^{20} cm^{-3}. The fact that synchrotron radiation is optically thin implies that $\sigma_T nc < 1$, where σ_T is the Thomson cross-section and b is the instantaneous thickness of the radiating region of the magnetosphere. One is thus led to infer that b is less than about 10^4 cm—perhaps much less—but this is not unreasonable if energy release occurs in the neighbourhood of a thin (possibly moving and evolving) current sheet.

An electric field acting on an electron-positron plasma will tend to develop a two-stream flow. In solar physics, an electron stream moving at high speed through the corona develops plasma oscillations that then radiate at radio frequencies to produce a 'type III radio burst'[14]. In the present situation, the plasma frequency will be in the infrared, optical, or possibly (as Liang[15] has already suggested) in the ultraviolet part of the spectrum. Since the radiation is produced by a collective process, the brightness temperature can be much higher than the plasma temperature. Hence the development of plasma oscillations and radiation from these oscillations could be responsible for the optical radiation that is believed to accompany some γ-ray bursts[16,17].

Many questions remain, the most pressing of which is the origin of the free magnetic energy released during the flare. We know that all large solar flares, and possibly all small ones also, are due to the interplay of two flux systems. It is believed that in some flares 'new' flux slowly intrudes into an 'old' flux system, followed at some later stage by reconnection[18]. On the other hand, it appears that in most large flares a magneto-hydrodynamic (MHD) process leads to the rapid injection of new flux into the old flux, and that 'driven' reconnection occurs during this process[19]. In the case of a neutron-star magnetosphere, it is hard to understand why spontaneous reconnection in the magnetosphere should be so slow as to produce a burst lasting many seconds, so it seems more likely that the reconnection accompanies a slower MHD process which must therefore involve a dense plasma.

It is natural to suppose that the process responsible for stressing the magnetosphere is external to the star. For instance, the stressing could be caused by the sudden infall of material due possibly to a tidally disrupted comet or to an instability of an accretion disk. However, one should bear in mind also the possibility that the stressing might arise from a process internal to the star. It is known from studies of radio pulsars that the magnetic field of a neutron star slowly decays[20]. This requires a loss of flux from the interior and from the crust. This loss of flux might conceivably occur episodically. For instance, if the internal magnetic field is sufficiently strong and the crust sufficiently weak, the accumulation of dense magnetic flux just below the crust may on occasion lead to the fracture of the crust and the sudden injection of new flux into the magnetosphere. If this indeed occurs, a γ-ray burst may be the detectable signal of a 'magnetic volcano' on a neutron star.

Tidal reorientation and the fracturing of Jupiter's moon Europa

Alfred S. McEwen

Department of Geology, Arizona State University, Tempe, Arizona 85287 and US Geological Survey, 2255 N. Gemini Drive, Flagstaff, Arizona 86001, USA

The most striking characteristic of Europa is the network of long linear albedo markings over the surface, suggestive of global-scale tectonic processes. Various explanations for the fractures have been proposed: freezing and expansion of an early liquid water ocean[1], planetary expansion due to dehydration of hydrated silicates[2], localization by weak points in the crust generated by impacts[3], and a combination of stresses due to planetary volume change and tidal distortions from orbital recession and orbital eccentricity[4,5]. Calculations by Yoder[6] and Greenberg and Weidenschilling[7] have shown that Europa may rotate slightly more rapidly than the synchronous rate, with a rotation period (reorientation through 360°) ranging from 20 to >10^3 yr if a liquid mantle is present, or up to 10^{10} yr if the satellite is essentially solid[7]. Helfenstein and Parmentier[8] modelled the stresses due to nonsynchronous rotation, and concluded that this could explain the long fractures in part of the anti-jovian hemisphere. In this note, I present a global map of lineaments with long arc lengths (>20° or 550 km), and compare the lineament orientations to the tensile stress trajectories due to tidal distortions (changes in the lengths of three principal semiaxes) and to nonsynchronous rotation (longitudinal reorientation of two of the principal semiaxes). An excellent orthogonal fit to the lineaments is achieved by the stresses due to nonsynchronous rotation with the axis radial to Jupiter located 25° east of its present position. This fit suggests that nonsynchronous rotation occurred at some time in Europa's history.

The global lineaments on Europa appear to be major extensional openings, ~10–50 km in width, filled with new crustal material. They are darker and redder than the terrain they transect, so are probably composed of a different material[3]. Water ice makes up at least 95 wt% of Europa's surface[9], so both the bright areas and the dark bands probably consist of mostly water ice, but with a greater percentage of dark contaminants in the bands. The band widths are very uniform, and are probably intrusions confined by the fracture walls rather than extrusions onto the surface. Some of the widest bands have central bright stripes, perhaps due to late-stage injections of clean ice[2].

Extension fractures may form either when the principal stresses are tensile or when the principal (macroscopic) stresses are compressive[10]. Extension fracturing during compression may be due to local tensile stresses at flaws or heterogeneities when confining pressures are low[10] or the fracturing may be caused

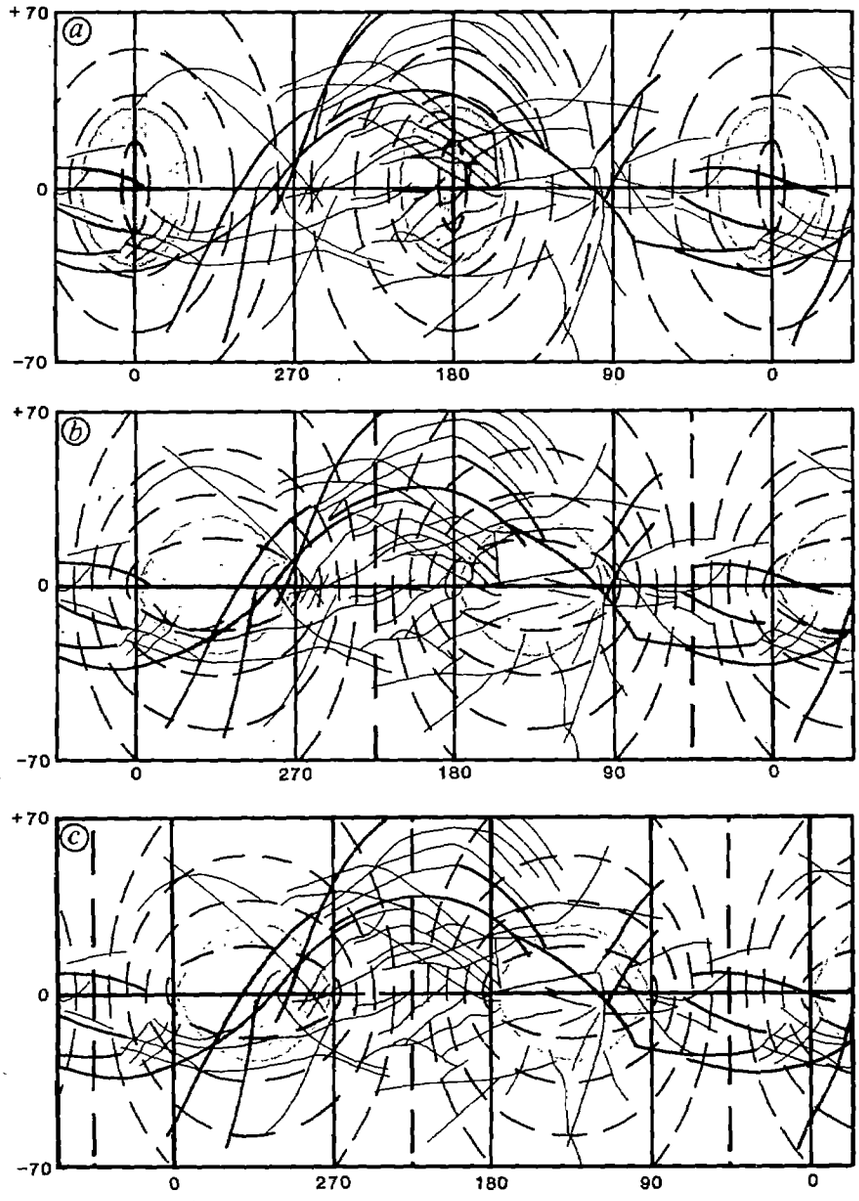

Fig. 1 Map of lineaments on Europa in Mercator projection. Heavy lines indicate great-circle lineaments. Superimposed over map (dashed lines) are trajectories for *a*, tensile and/or compressive stresses due to tidal distortions (data from ref. 5); *b*, tensile stresses due to nonsynchronous rotation with the axis radial to Jupiter at its present position (continuing nonsynchronous rotation; stress trajectories from ref. 8); and *c*, tensile stresses due to nonsynchronous rotation with the axis radial to Jupiter shifted 25° east. Shaded areas are where both principal surface stresses are compressional; applies to *a* only if trajectories are tensile.

by intrusions into the cracks resulting in forces on the crack faces[11]. In either case, extension fractures form nearly perpendicular to the most tensile or least compressive stresses.

The best evidence for strike-slip faulting on Europa consists of minor apparent rotations near the anti-jovian region[12]. A strike-slip mechanism has been proposed for some of the long global lineaments on the basis of preferred 60° orientations of lineament intersections to each other[4] and to the tensile stresses due to tidal distortions[5]. However, there were errors in the longitudinal positions of the lineaments used in these analyses, as great as 15° (ref. 4) and 40° (refs 5, 8), so the preferred orientations are suspect. Furthermore, the tidal stresses are probably much too weak to fracture the crust in shear[5,13]. If fractures initiate at depths where the vertical stress is the most compressive, then normal faults or graben may form[14], but may become extension faults due to intrusions[11]. Therefore, I interpret the majority of the global lineaments as extension fractures.

The lineament map, produced from Mercator projections of global mosaics of Europa[15], is shown in Fig. 1. Only those lineaments visible in the global mosaics (resolution 11–23 km per pixel) and with arc lengths of at least 20° are mapped. Images utilized in the mosaics are acquired at low phase angles (3–32°), so all of the lineaments are identified by albedo markings rather than topography. Positions are accurate to within 5°, determined by comparison with geodetic control[16]. Lineaments are uniformly distributed over Europa's surface, although they appear concentrated at low latitudes in Mercator projections.

Superimposed on the lineament map are the stress trajectories for tidal distortion of a thin elastic shell (Fig. 1*a*), nonsynchronous rotation with the axis radial to Jupiter at its present position (Fig. 1*b*) and nonsynchronous rotation with the axis radial to Jupiter located 25° east of the present position (Fig. 1*c*). The tidal stress trajectories (Fig. 1*a*) can represent either (1) tensile stresses due to orbital recession, or (2) compressive stresses due to orbital contraction, or (3) cyclical tensile and compressive stresses due to orbital eccentricity. Stress trajectories for nonsynchronous rotation (Fig. 1*b*,*c*) are tensile. The principal surface stresses are tangential (most tensile or least compressive) and normal (least tensile or most compressive) to the tensile trajectories; the stresses are reversed for compressive trajectories. Three regions of the surface may be defined by the signs of the surface stresses (++, +−, and −−, with tensile stresses positive). Extension fractures (in all three regions) should be concentrated at a 90° angle to the tensile stress trajectories, but are least likely to form in the areas of compress-

ive (−−) surface stresses, so these regions (shaded in Fig. 1) are excluded from the analysis of lineament orientations.

Very long lineaments oriented along great circles seem most likely to be due to global stresses, whereas the shorter, small-circle, and irregular lineaments may have been influenced by impacts or crustal heterogeneities. Therefore, the approximately great-circle lineaments (those whose plane passes within 15° of the centre of the sphere) of long arc length (>30°) are shown as heavy lines on Fig. 1.

Lineament orientations to the stress trajectories were measured at intervals of 12° arc length (330 km) along each lineament. No preferred orientation with respect to tidal stresses is seen (Fig. 2*a*), contrary to previous reports [4,5], and the tidal-stress magnitudes are probably not sufficient to fracture the ice crust[5,13].

The lineaments are generally oriented at high angles to the tensile stress trajectories predicted for ongoing nonsynchronous rotation (Fig. 2*b*), consistent with extension fractures. However, if the satellite (or its crust) is continually rotating at a rate faster than synchronous, as expected[7] if a liquid water mantle is present[17], then the stresses would continuously change and fractures of different ages would not follow the same stress pattern. This can be simulated by moving the stress trajectories in Fig. 1*b* along the equator (with the lineaments fixed); only fractures that lie along the equator are consistent with all positions. The position giving the best fit (most orthogonal) occurs with the axis radial to Jupiter located ~25° east (relative to the surface) of its current position (Figs 1*c* and 2*c*). The 25° east position may represent the mean of stresses from reorientation through ~50° to its present position. This suggests that the fracturing resulted from an epoch of nonsynchronous rotation resulting in ~25–50° eastward reorientation of the satellite or its crust relative to the radial to Jupiter. Several additional observations support this hypothesis: (1) the great-circle lineaments give an especially good fit to the stresses (Fig. 2*c*); (2) a region of isotropic stress near the anti-jovian point[18] may be explained by stretching this region over the tidal bulge[7]; (3) many lineaments terminate or break up into discontinuous spots[3] in the regions of compressive surface stresses; and (4) the predicted stress magnitude due to a 25° reorientation is 2–3 times greater than the probable tensile strength of the ice crust[8].

An eastward reorientation of the satellite, preserving the equator, is the direction of movement that would result from faster-than-synchronous rotation. Therefore, the proposed reorientation seems best explained by the mechanism described by Yoder[6] and Greenberg and Weidenschilling[7], that is, orbital eccentricity forced by resonant interaction with Io and Ganymede, resulting in non-zero tidal torque on a Europa in synchronous rotation. An alternative hypothesis is reorientation due to a large impact[19], but this seems unlikely for Europa because (1) no large impact scar is apparent on the surface; (2) a 25–50° reorientation, preserving the equator, is improbable by this mechanism; and (3) the global fracture pattern is not like that expected from a large impact[20]. Stable synchronous rotation is expected if the satellite has a perfectly circular orbit (not true of Europa) or if the satellite has a permanent mass asymmetry (like the Earth's Moon). The remarkable absence of topographic relief on Europa[1] is consistent with the absence of a mass asymmetry.

One possible explanation for the fracture pattern is continuous nonsynchronous rotation but with episodic fracturing when stresses have built up to exceed the tensile strength of the crust. However, this model requires some mechanism to synchronize the failure of many separate fractures. Another possibility is that venting of water vapour is very rapid[17], resulting in complete resurfacing by condensed frost in a fraction of the rotation period, so that only very recent fractures ($\sim 10^3$ yr or less)[7,8] are seen. However, the observed impact craters imply an age of at least 10^7 yr (refs 1, 3), Europa's photometric function does not support the contention that a very low-density (condensed) frost

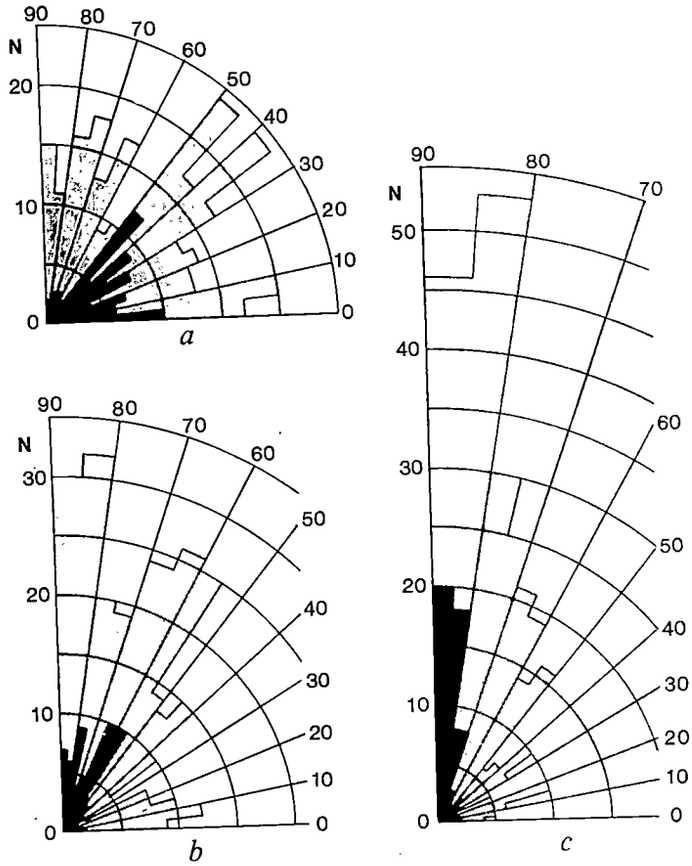

Fig. 2 Rose diagrams for angles of intersection between stress trajectories and lineaments. Black areas are for great-circle lineaments. *a*, *b* and *c* correspond to stress trajectories in Fig. 1.

layer is present[21], and a thin ice shell of variable thickness[17] seems unlikely to form such long, linear fractures.

Assuming that the satellite is essentially solid, there are several alternative scenarios: (1) its figure may gradually creep to a new configuration over time, resulting in very slow nonsynchronous rotation[7], (2) an asymmetry may be dynamically supported by solid-state convection[2], with slowly changing convection patterns leading to epochs of nonsynchronous rotation separated by periods of synchronous rotation, or (3) the fracturing may be due to the final stages of nonsynchronous rotation before a mass asymmetry was frozen into place.

I thank R. Greenberg, E. M. Shoemaker, M. C. Malin, P. Helfenstein, B. K. Lucchitta, and J. M. Moore for critical reviews. This research was supported by NASA Planetary Geology grant NAGW-1 to Arizona State University.

Ionic structure in aqueous electrolyte solution by the difference method of X-ray diffraction

N. T. Skipper, S. Cummings*, G. W. Neilson† & J. E. Enderby*

H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK

Neutron diffraction difference methods based on isotopic substitutions offer a means of directly probing the detailed structure around a solute dissolved in a host solvent[1], but there are two main drawbacks to their implementation. First, they rely on the use of separated isotopes which are expensive and sometimes of limited availability. Second, the experiments have to be performed at a sophisticated central facility to obtain sufficiently intense beams of thermal neutrons. We have therefore initiated a series of experiments aimed at introducing difference methods to X-ray diffraction studies of liquid and amorphous systems. Difference methods have been attempted before[2], but the absence of definitive neutron data did not allow the method to be made fully quantiative. We now present the first results obtained from such a study in which the difference technique is applied to a concentrated aqueous electrolyte solution and the cation–cation distribution function $g_{MM}(r)$ is determined directly. The success of the method rests on the ability to identify nearly isomorphic pairs of elements, whose isomorphism can be quantified by reference to similar results obtained from the first-order difference method of neutron diffraction[3].

For the case of a salt MX dissolved in water, there are ten partial structure factors, $S_{\alpha\beta}(k)$ which contribute in varying degrees to the total structure factor $F(k)$ (ref. 1). However, the (first-order) difference, $\Delta_M(k)$, between the total structure factors for any two chemically identical but isotopically distinct solutions can be written in terms of a linear combination of only the four correlations associated with the isotopically substituted ion species[1]. Furthermore, the second-order difference[4] between three such solutions gives information directly about the partial structure factor of the substituted species $S_{\alpha\alpha}(k)$. Fourier transformaiton of $\Delta_M(k)$ and $S_{\alpha\alpha}(k)$ gives information regarding the structural properties of the ion-water subsystem and the ions themselves through the radial pair distribution functions:

$$g_{\alpha\beta}(r)-1=\frac{1}{2\pi^2 nr}\int \mathrm{d}k(S_{\alpha\beta}(k)-1)k\sin kr$$

where n is the total number density of the system and is typically 0.1 Å^{-3}.

The electrolytes chosen for this study were nickel chloride and magneisum chloride, and X-ray diffraction experiments were carried out on the following three aqueous solutions (all 4.2 M): $NiCl_2$ in H_2O (I), $MgCl_2$ in H_2O (II) and a 50:50 mixture of $MgCl_2$ and $NiCl_2$ in H_2O (III).

The X-ray structure factors, $F(k)$, of the three solutions were obtained from the raw intensity data by standard correction and normalization procedures[1].

By adopting the same formalism as in the neutron diffraction case[4], but with the important difference that X-ray atomic form factors, f, are k-dependent, the first-order difference $\Delta_{Ni}(k)$ of the X-ray diffraction patterns for two isomorphic solutions can be written as:

$$\Delta_{Ni}(k)=A(S_{NiO}(k)-1)+B(S_{NiH}(k)-1)+C(S_{NiCl}(k)-1)+D(S_{NiNi}(k)-1) \quad (1)$$

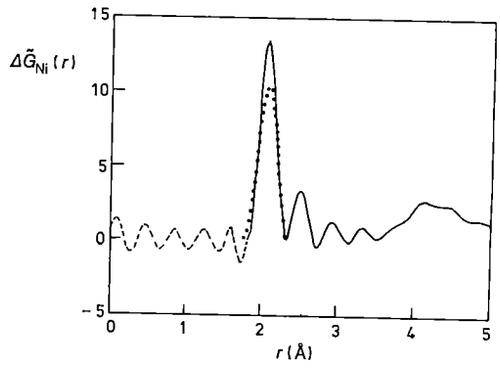

Fig. 1 The nickel ion total radial distribution function in 4.2 M aqueous chloride solution, derived from X-ray diffraction. The oscillations (dashed line) at low r are caused by termination errors in the Fourier transformation. The dotted curve is the nearest neighbour Ni–O correlation derived from neutron diffraction.

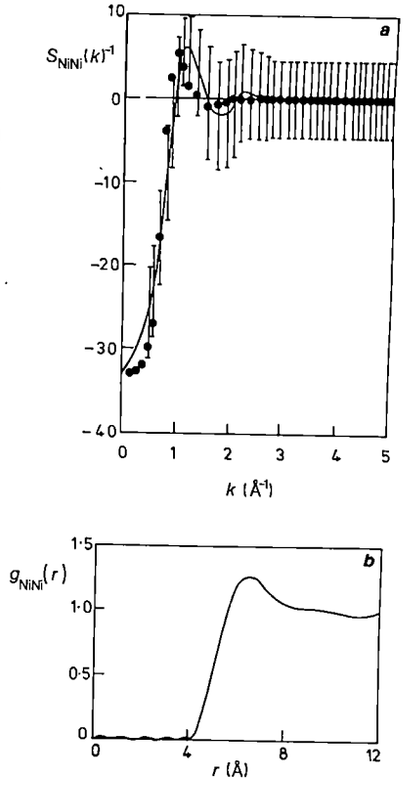

Fig. 2 *a*, The nickel–nickel partial structure factor, $S_{NiNi}(k)$ in 4.2 M aqueous nickel chloride solution. Curve (with error bars), X-ray diffraction; solid circles, neutron diffraction. The errors were determined by the same means as used in the neutron diffraction study[4]: a 1% systematic error was introduced into the coefficients of the $F(k)$s. *b*, The corresponding Ni–Ni radial distribution function $g_{NiNi}(r)$ obtained by Fourier transformation of the curve in *A* after a damping function was used.

where $A=2f_O(k)\Delta f_M(k)c_Oc_{Ni}$, $B=2f_H(k)\Delta f_M(k)c_Hc_{Ni}$, $C=2f_{Cl}(k)\Delta f_M(k)c_{Cl}c_{Ni}$, $D=\Delta f^2{}_M c^2_{Ni}$, and $\Delta f_M(k)=(f_{Ni}(k)-f_{Mg}(k))$, $\Delta f^2_M=f^2_{Ni}(k)-f^2_{Mg}(k)$, c_β is the concentration of species β.

The coefficients are such that A and $C \gg B$, D so that $\Delta_{Ni}(k)$ is dominated by the nickel-oxygen and nickel chloride terms. The Fourier transformation of $\Delta_{Ni}(k)/A$, written as $\Delta\tilde{G}_{Ni}(r)$, gives $g_{NiO}(r)$ directly, together with a convolution of the other three radial distribtion functions, and has the form

$$\Delta\tilde{G}_{Ni}(r)=g_{NiO}(r)+\sum_{\beta\neq o} a_\beta \int H_\beta(|\mathbf{r}-\mathbf{r}'|)g_{Ni\beta}(|\mathbf{r}'|)^{-1}\,\mathrm{d}\mathbf{r}' \quad (2)$$

where β = H, Cl or Ni, $H_\beta(|\mathbf{r}-\mathbf{r}'|)$ is a convolution function associated with the k-dependence of the form factor and a_β are constants which relate to the concentration of species β.

Three $\Delta G_{Ni}(r)$ were calculated for the three possible differences between the $\tilde{F}$(k) values for the three solutions studied. The largest and therefore the most accurately defined difference is

that calculated from solutions I and II, and is shown in Fig. 1. Because the first peak in $g_{NiO}(r)$ is well separated from any peaks in $g_{NiCl}(r)$, $\Delta G_{Ni}(r)$ can be used to check the isomorphism of Ni and Mg. This is achieved by comparing the result for the Ni–Ô nearest-neighbour correlation with that derived from the formally exact difference method of neturon diffraction. As can be seen from Table 1 and Fig. 1, the two methods yield structural parameters which are in excellent agreement. The fact that the width of $g_{NiO}(r)$ is smaller in the X-ray case reflects the superior instrument resolution obtained with our X-ray diffractometer (a θ–θ D/MAX system manufactured by Rigaku, Tokyo), relative to that of the D4 neutron diffractometer (now improved) at the Institut Laue–Langevin, even though the k-range of the scattering was about the same in both cases.

Having established that Ni and Mg are isomorphic, the cation–cation structure factor $S_{NiNi}(k)$ can be determined from a double difference[4] between the $F(k)$ values for the three solutions:

$$S_{NiNi}(k)-1=\frac{1}{c_{Ni}^2(f_{Mg}-f_{Ni/Mg})}\times\left[\frac{(F_I(k)-F_{II}(k))}{(f_{Ni}-f_{Mg})}-\frac{(F_I(k)-F_{III}(k))}{(f_{Ni}-f_{Ni/Mg})}\right] \quad (3)$$

where $f_{Ni/Mg}(k)=(f_{Ni}(k)+f_{Mg}(k))/2$.

The Fourier transformation of $S_{NiNi}(k)$ yields $g_{NiNi}(r)$. The results shown in Fig. 2 are in good agreement with those obtained from an earlier neutron diffraction experiment in which isotopic substitution was used and represent the first ion–ion radial distribution function obtained by X-ray methods alone.

Table 1 Comparison of peak position $\bar{r}_{NiO}$, coordination number $\bar{n}$ and half-width Δr for $g_{NiO}(r)$ derived from X-ray and neutron diffraction

Method	$\bar{r}_{NiO}$ (Å)	$\bar{n}$	Δr (Å)
X-ray	2.07 (2)	6.0 (2)	0.23 (2)
Neutron	2.07 (2)	5.8 (2)	0.26 (2)

The above results clearly demonstrate the power of the X-ray difference method. The proof that Ni and Mg are isomorphic in aqueous electrolyte solution means that a comprehensive study in which counter-ion, concentration and temperature are varied, can now be undertaken. For example, it will be possible to obtain accurate information regarding the ion–oxygen distribution at a much lower concentration than is currently practicable with the neutron difference method. Experiments on $NiBr_2$ and $MgBr_2$ aqueous solutions will help resolve the controversy regarding the existence of inner-sphere complexing in bromide solution.

The X-ray difference method may play an increasingly important role in the determination of the structural properties of a variety of liquid and amorphous systems, and a systematic procedure is being developed in order to identify other isomorphic pairs.

We thank SERC for their continuing support of the aqueous solution programme, and Mr Philip Gullidge for assistance in the calibration and preparation of samples. J.E.E. thanks NATO for the award of a travel grant (RG125/80) which allowed some of the ideas contained in this paper to be discussed with Professor Harold Friedman at SUNY, Stony Brook.

Constant-geometry edge-flaking of brittle materials

E. A. Almond & N. J. McCormick

National Physical Laboratory, Teddington, Middlesex TW11 0LW, UK

Lithic tool manufacture was the earliest technological exploitation of the brittle fracture of hard materials, and archaeologists have traced and reproduced the evolution of flake tools through various stages of development from the early simple flake knives (Fig. 1) to the sophisticated multi-faceted edges of stone axes. The technology advanced during the period of gunflint manufacture. Of special interest are the simple geometrical relationships between the dimensions of flakes formed in certain controlled conditions[1,2]. The phenomenon of edge-flaking is also encountered in the attrition of tool cutting edges and in the chipping of precision edges of metrological components, where it is avoided rather than understood, by empirical radiusing (rounding-off). In our effort to improve the efficiency of cutting edges, we have observed that a law of constant geometry seems to apply to the flakes formed at rectangular edges, and the effect is relatively insensitive to the test material.

Our experimental approach has been to indent rectangular blocks of the test material with increasing loads at different distances from an edge until a flake breaks off. The distance at which flaking occurs is approximately equal to the flake thickness (Fig. 2). We used a conical diamond indentor with a tip radius of 0.2 mm and an apex angle of 120°. We initially observed that the size of the flakes formed in a tungsten carbide/cobalt tool material decreased with decrease in distance from the edge, and the width-to-height and thickness-to-height ratios of the flakes were approximately constant (Fig. 3). When the same test procedure was extended to other materials it was found that similar height-to-width and thickness-to-width ratios applied for flakes formed in various glasses, a high-carbon steel, an alumina ceramic, a Thames Valley flint (Fig. 4*a*), a polymethyl methacrylate polymer and a range of tungsten carbide/cobalt tool materials. Furthermore, when the boxed volume (defined as the product of the height, width and thickness of the flake) was plotted against the true volume (calculated from the weight and

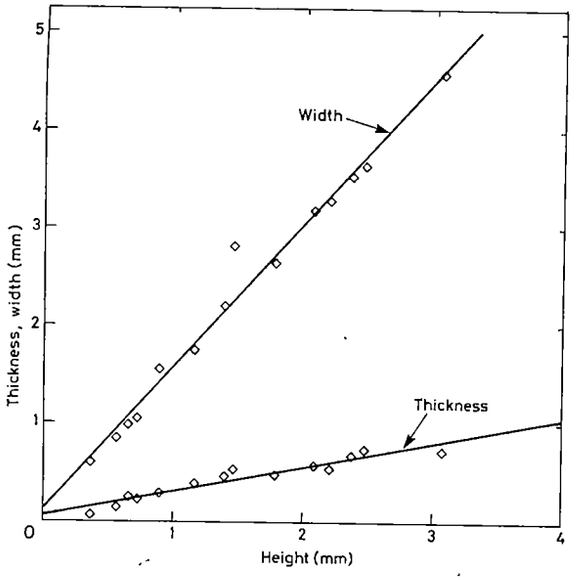

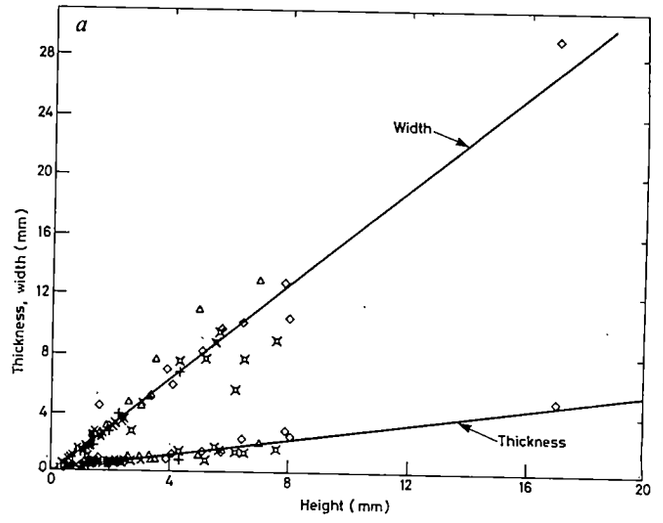

Fig. 3 Variation of flake width and thickness with flake height for a 9 wt% cobalt tungsten carbide tool material; correlation coefficients, $r = 0.9901$ and 0.9564, respectively. (The correlation coefficient r is defined as[7] $r = \sum(x-\bar{x})(y-\bar{y})/(\sum(x-\bar{x})^2 \sum(y-\bar{y})^2)^{1/2}$, where x, y and $\bar{x}, \bar{y}$ are respectively the coordinates of a data point and the corresponding point on the best straight line obtained by minimizing the sum of the squares of the residuals.)

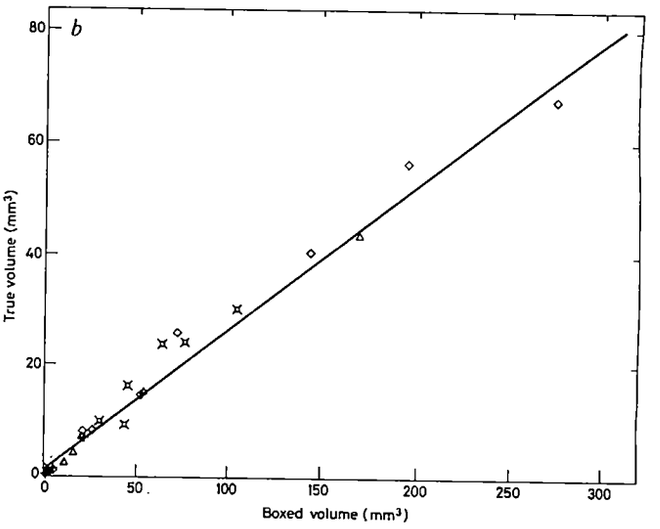

Fig. 4 *a*, Variation of flake width and thickness with flake height ($r = 0.9685$ and 0.9579, respectively); *b*, relation between flake volume and boxed volume ($r = 0.9997$). Data for various glasses ( ), Thames Valley flint (◇), an alumina ceramic (△), a 9 wt% cobalt tungsten carbide tool material (×) and a high-carbon steel (+); *b* also contains results from ref. 3.

density of the flake) a linear relationship was observed (Fig. 4*b*), with a slope of ~0.25 for all the materials tested.

Although detailed inspection of the data in Fig. 4 indicates that they may belong to separate curves according to the size of the test piece, manufacturing technique and hardness, the observed linear relationship has unexpected implications. Thus, for edge flakes produced by statically loaded indenters: (1) the volume lost from the edge depends only on the distance of the loading point from the edge and is relatively independent of the material; and (2) the shape of the flake varies little; it is scaled in proportion to the distance from the edge.

Examination of previous data[3] showed that the observations of constant geometry also held for flakes produced by ball indenters of 2–5 mm diameter using tungsten carbide/cobalt tool materials for the indenter and the test materials. However, in the earlier work the measurement techniques were not sufficiently sensitive to detect the flake size dependence on distance from the edge.

The existence of a constant-geometry law for the dimensional ratios implies that a similar law might apply for the angle of inclination between the flat and curved vertical faces of the flake, and for the angle subtended by the flake faces at the indentation. However, although the latter tended towards 146°, (as expected from the ratio of 20:3 for the width and thickness dimensions), it was not possible to develop a consistent measurement criterion because the faces were convex and the curvatures varied considerably. This applied even more to the angle of inclination, because the flake surface was also convex in the thickness direction and the flakes were not normally symmetric about a vertical plane through the indentation, as can be seen in Fig. 2.

There must be a materials dependence of the flaking phenomenon, and this is found in the magnitude of the load required to initiate flaking at a given distance from the edge, which varies, for example, from 164 N for a silica glass to 6.15 kN for a 9 wt% cobalt tungsten carbide tool material at a distance of 0.71 mm from an edge. The mechanism of flake formation is not yet understood, but it is not restricted to fracture nucleation by hertzian cracking and conical fracturing as has been suggested for flakes produced in lithic tools with blunt hammers in percussive conditions[1,2]. In our tests, although circumferential crack paths of hertzian origin have been observed at some of the

fracture initiation sites, the fracture path more commonly passes through the centre of the indentation, which is characteristic of the tensile stress field resulting from plastic deformation or densification under the loading point[4]. It would probably be more appropriate to consider flaking as two energy-dissipative processes: a load-dependent crack initiation mechanism which occurs in the deformed region below the indenter, and a crack propagation stage determined by the strain energy release rate in linear elastic fracture mechanics conditions[5].

The fact that good reproducibility of flake geometry was obtained with different indenter shapes and different materials may be related to the quasi-static loading mode used in our tests. Thus, stone-age humans adopted pressure loading 25,000 yr ago to dress the edges of cutting tools[6], and it is tempting to conclude that this technique was favoured because it was more precise and reproducible than the percussive loading methods developed by their ancestors.

We acknowledge valuable discussions with Dr Mark Newcomer of the Institute of Archaeology, London, and the loan from his collection of the tool shown in Fig. 1.

Inferred oxygen isotope profile of Archaean oceanic crust, Onverwacht Group, South Africa

S. E. Hoffman*, M. Wilson† & D. S. Stakes‡

* College of Oceanography, Oregon State University, Corvallis, Oregon 97331, USA
† Department of Geological Sciences, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0
‡ Department of Geology, University of South Carolina, Columbia, South Carolina 29208, USA

Whole-rock oxygen isotope data from a suite of mafic and ultramafic samples from the Onverwacht Group, the basal unit of the Archaean greenstone succession of the Barberton Mountain Land, South Africa, show a range of values from $\delta^{18}O \simeq +3$ to $\delta^{18}O \simeq +14$, a range which coincides with those of Phanerozoic ophiolites and oceanic crust. When the samples are arranged in an inferred ophiolitic pseudostratigraphy, from basal serpentinized ultramafic cumulates through altered mafic extrusives, they have an oxygen isotope distribution profile which is indistinguishable from that of Phanerozoic ophiolites. The distinctive isotopic profiles and secondary mineral assemblages in Phanerozoic ophiolites are caused by hydrothermal interaction between seawater ($\delta^{18}O \simeq 0$) and oceanic crust ($\delta^{18}O \simeq +5.8$). The existence of a similar isotopic and metamorphic profile in the Onverwacht Group argues strongly that these rocks were hydrothermally altered by an Archaean ocean whose isotopic composition was indistinguishable from modern sea water.

The Barberton Mountain Land is one of the oldest surviving Archaean greenstone belts. Whole-rock Sm-Nd measurements have given the oldest ages: 3.54 ± 0.03 Gyr (ref. 1) and 3.56 ± 0.24 Gyr (ref. 2). Other isotopic systems have given ages clustered about 3.3 Gyr (refs 3–8).

The rocks of the greenstone belt are divided stratigraphically into the Moodies, Fig Tree, and Onverwacht Groups. The Onverwacht Group, in the stratigraphy of Viljoen and Viljoen[9], encompasses six formations of mafic and ultramafic extrusive and intrusive rocks which have been altered to chloritic greenschists, actinolitic amphibolites, and serpentinites, and which include minor intercalations of felsic volcanics and volcaniclastic and carbonate sediments[9,10]. The lithologies of each formation are described in detail by Viljoen and Viljoen[9] and by Tankard *et al.*[10]. The upper subgroup, the Geluk, also known as the Mafic to Felsic Unit, is composed of the Swartkoppie, Kromberg, and Hoogenoeg Formations[9]. The lower subgroup, the Tjakastad, also known as the Lower Ultramafic Unit, is composed of the Komati, Theespruit, and Sandspruit Formations[9]. In order to account for what they described as repetitious cycles of volcanics and sediments up to 20 km in total thickness, Viljoen and Viljoen[11] proposed a model of cyclical volcanism and sedimentation.

CIT, California Institute of Technology; US, University of Saskatchewan. Gregory and Taylor[20] reported a $\delta^{18}O$ value for RQ of +8.45‰ obtained at CIT. Analytical reproducibility for the data plotted in Fig. 1 is calculated as 2σ<0.3‰.

More recent mapping in the Barberton Mountain Land[12–15] has produced evidence that the stratigraphic succession may not be one of simple supercession. Williams and Furnell[12] recognized structural unconformities within the Onverwacht Group which suggested isoclinal folding and faulting, and De Wit[13] proposed that thrust faulting had occurred, resulting in tectonic repetition of strata. These studies[12–15] suggest that the 20-km thickness is a tectonic artefact rather than the result of volcanological or sedimentological processes.

De Wit[14] has compiled a revised stratigraphy which consists of the layered ultramafic complexes at the base, progressively overlain by the Komati Formation, the Hoogenoeg and Kromberg Formations, the rhyodacites and silicic porphyries of the Mafic to Felsic Unit, the Fig Tree Group, and the Moodies Group. De Wit and Stern[16] previously proposed that the Onverwacht Group constitutes an Archaean ophiolite sequence. In this paper, we report an additional parallel between the Onverwacht Group and Phanerozoic ophiolites and oceanic crust: a whole-rock oxygen isotope distribution which reflects cooling and alteration by convective seawater hydrothermal activity.

A total of thirty-three powdered 'whole-rock' samples from rocks collected in the Komati Formation, the Hoogenoeg Formation, and the Stolzburg Ultramafic Complex by Roger Hart and

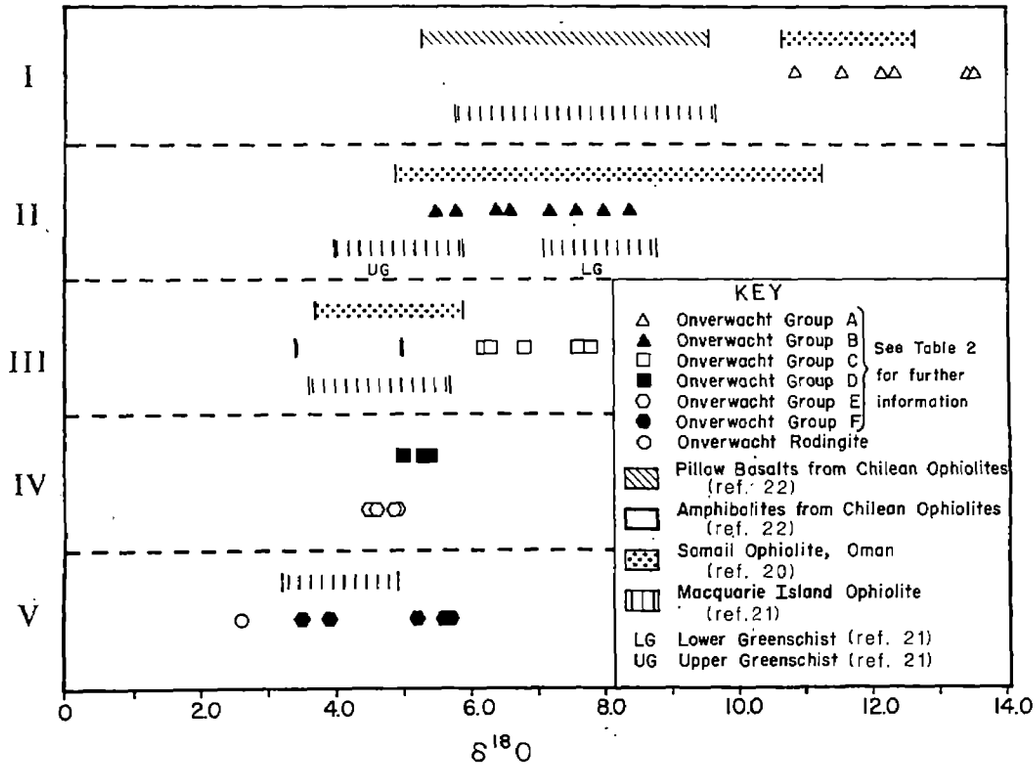

Fig. 1 Whole-rock ^{18}O distribution in the Onverwacht Group plotted in an ophiolitic pseudostratigraphy (size of symbols is larger than range of calculated experimental error), along with data from the Oman ophiolite[20], the Macquarie Island ophiolite[21], and Chilean ophiolites[22]. The Onverwacht data are compared with the following lithologies from the Phanerozoic ophiolites: I, pillow basalts; II, sheeted dykes; III, gabbros; IV, (only Onverwacht data shown); V, serpentinized harzburgites.

Maarten De Wit were analysed for their bulk oxygen isotope composition at the California Institute of Technology and at the University of Saskatchewan. Oxygen was liberated using the fluorine technique[17] at CIT, and the bromine pentafluoride technique[18] at the University of Saskatchewan. Data are reported relative to standard mean ocean water (SMOW, $\delta^{18}O = 0‰$). On this scale, NBS-28 (quartz) has a $\delta^{18}O$ value of +9.6[19]. Statistical data on analytical precision and accuracy as well as interlaboratory comparisons are shown in Table 1.

The data from sixteen whole-rock analyses at CIT and 32 whole-rock analyses at the University of Saskatchewan are listed in Table 2. The samples are grouped according to their alteration mineralogies and relict textures. The results of the 32 analyses from the University of Saskatchewan and the analysis of RA13177 from CIT are shown in Fig. 1. The Onverwacht rocks are plotted according to an ophiolitic pseudostratigraphy which is derived in part from the revised stratigraphic model of De Wit[14]. The pseudostratigraphy proceeds 'upsection' from ultramafic rocks (Groups D, E, and F in Table 2, and IV and V in Fig. 1) through progressively less mafic rocks to altered pillow basalts (Groups A, B, and C in Table 2 and I, II, and III in Fig. 1). Figure 1 also shows ranges of $\delta^{18}O$ for corresponding samples from the Samail ophiolite in the Sultanate of Oman[20], the Macquarie Island ophiolite[21], and ophiolites of Southern Chile[22]. There is a rough correlation between $\delta^{18}O$ and lithology for the samples from Oman, Macquarie Island, Chile, and the Onverwacht Group, although there are also significant overlaps between fields. The range of whole-rock $\delta^{18}O$ values relative to SMOW for the Onverwacht Group ($\delta^{18}O = +2.6$–$13.6‰$) coincides almost entirely with the combined range of the Macquarie Island, Samail, and Chilean ophiolites ($\delta^{18}O = +3.2$–$12.7‰$). If the rodingite from the Stolzburg Ultramafic Complex is excluded (RA13175, Table 2), the ranges completely coincide except for two Onverwacht samples, RA5061 and RA5062, which are dominantly composed of smectite[23], a mineral which is enriched in ^{18}O (ref. 24).

Chemical data from the samples listed in Table 2[23] show that the concentrations of all major oxides and most minor elements are distinctly correlated with oxygen isotope value, water content, and CO_2 content[23]. This indicates that chemical alteration of the rocks was coincident with the redistribution of their oxygen isotope content.

Basaltic rocks altered in subaerial hydrothermal systems by meteoric water have substantially different oxygen isotope signatures from those altered in submarine systems by seawater because meteoric water is depleted in ^{18}O relative to seawater. This depletion results from isotopic fractionation during evaporation and increases with increasing latitute[25]. The average whole-rock $\delta^{18}O$ value for rocks altered in meteoric hydrothermal systems is significantly lower than that of rocks altered by seawater at the same temperatures of alteration[25]. That is, metamorphic assemblages of the same grade will be much more depleted in ^{18}O, and thus have lower $\delta^{18}O$ values, in a meteoric hydrothermal system. For example, greenschist-facies rocks altered in meteoric hydrothermal systems at temperatures sufficient for the formation of actinolite and chlorite have $\delta^{18}O$ values relative to SMOW between roughly −2 and +4 (ref. 25). In contrast, oxygen isotope studies of Phanerozoic submarine greenstones have revealed that their $\delta^{18}O$ values range from +2.8 to >+10 (refs 24–26). Taking into account the analytical accuracy of the study, Fig. 1 shows that the Onverwacht rocks fall totally within the combined fields for Phanerozoic oceanic crust and ophiolites ($\delta^{18}O \simeq +2.8$ to $>+10$)[20–22,24–26].

This coincidence of isotopic and lithologic characteristics between samples from the Onverwacht Group and those from Phanerozoic ophiolites and oceanic crust could indicate that the Onverwacht rocks were altered by Archaean sea water in an oceanic environment. If one assumes that the $\delta^{18}O$ value of the Archaean ocean was essentially equivalent to that of the present ($\simeq 0‰$), then it is possible that the same conditions and processes which produced the oxygen isotope distribution in the Samail[20], Macquarie Island[21], and Chilean[22] ophiolites were also responsible for the oxygen isotope distribution observed in samples from the Onverwacht.

There have been relatively few stable isotope studies on samples from Archaean greenstone belts, but there is some evidence that the $\delta^{18}O$ value of the ocean has changed very little over the past 3 Gyr. Beaty[27] analysed more than 150 samples from six areas within the Abitibi greenstone belt (2.8 Gyr). In each of the six areas, he found an increase in $\delta^{18}O$ with strati-

Samples are divided into groups according to their alteration mineralogies and their relict igneous textures. Results from California Institute of Technology were obtained in 1982 using the fluorine extraction method[17]. Results from the University of Saskatchewan were obtained in 1984 using the bromine pentafluoride method[18]. The average difference between analyses from the two different laboratories is 0.3‰, with $2\sigma < 0.5$‰.

* Mineralogy of spinifex-textured komatiites: spinifex blades now altered to serpentine (and magnetite); interstices between blades now altered to tremolite and magnetite.

† RA5063 and RA13176 are partially altered orthopyroxenites; RA5068 and RA5069 are serpentinized dunites; RA13175 is a rodingite with a probable orthopyroxenite precursor; RA13177 is a massive serpentine whose precursor is not determinable.

graphic height which correlated with the hydrothermal alteration of the sequence, and in five of the six areas, he found that the altering fluid was probably sea water with a $\delta^{18}O$ value between −2 and +2 (ref. 27). Thus, the data of Beaty[27] and Beaty and Taylor[28,36] support the assumption that the $\delta^{18}O$ of sea water has varied little for at least the past 3 Gyr.

The Onverwacht oxygen isotope data also strongly imply that the range of temperatures over which submarine hydrothermal alteration occurs has not markedly changed over the past 3.4 Gyr. The range of temperatures at which rocks are altered in a submarine hydrothermal system is mainly dependent upon the temperature of the magma and the tectonically controlled configuration of the seawater convection system relative to the magma chamber, not on the temperature of the intake water (that is, ambient bottom water). Thus, the Onverwacht rocks provide little data to clarify the debate on Archaean bottom water temperatures. However, it should be noted that most estimates of Archaean seawater temperatures and $\delta^{18}O$ values are based upon analyses of cherts. In a study of Phanerozoic cherts recovered from Deep Sea Drilling Project cores, Hein and Yeh[29] determined that the samples did not reflect palaeoenvironmental (bottom water) temperatures but rather diagenetic temperatures of formation which were generally greater than 30 °C. While bottom water temperatures have fluctuated in the Cretaceous, Phanerozoic ambient bottom temperatures have been generally less than 10 °C.

Based predominantly on studies of Onverwacht cherts, Perry and Tan[30] suggested that the $\delta^{18}O$ value of the Archaean ocean was significantly lower than at present and that there has been a secular increase in the ^{18}O content of the oceans over the history of the Earth. However, their evaluation of their samples as having no significant post-depositional diagenetic history is suspect in view of more recent studies. The evidence for intense hydrothermal alteration, silicification, and recrystallization in Onverwacht strata is overwhelming[6,23,31]. In addition, many Onverwacht "cherts" are in fact silicified pyroclastic deposits[31,32], and the silicifying fluids appear to have been evolved hydrothermal solutions resulting from the interaction between seawater and underlying mafic and ultramafic strata[31]. Thus, the $\delta^{18}O$ values of Onverwacht cherts reflect their interaction with diagenetic fluids significantly different from Archaean ambient bottom water.

On the basis of oxygen isotope measurements of oceanic crustal samples and mass balance calculations, Muehlenbachs and Clayton[33] proposed that the $\delta^{18}O$ value of the oceans has been buffered via "processes associated with the creation, aging, and destruction of the oceanic crust"[33]. They calculated that at present-day seafloor creation rates, the oceans would achieve a $\delta^{18}O$ value of ~0 roughly 250 Myr after the onset of seafloor spreading[33]. If seafloor creation rates were five times the present day values[34], this 'time constant' would equal only 60 Myr (ref. 33).

Abbott and Hoffman[34] proposed a model for the evolution of plate tectonic processes as a function of the aging of oceanic crust over time. This model postulates that seafloor creation rates 3.8 Gyr ago were as much as five times present-day values. If the time constant calculated for this seafloor creation rate is indeed 60 Myr (ref. 33), then the oxygen isotope composition of the oceans would have been buffered by hydrothermal alteration before the formation of the Onverwacht Group. Therefore, the oxygen isotope distribution in the Onverwacht could be the result of the same types of processes which Gregory and Taylor[20] and Cocker *et al.*[21] proposed to explain the distributions observed in the Samail and Macquarie Island ophiolites.

In such a system[35], sea water with $\delta^{18}O = 0$‰ interacts with ultramafic and gabbroic rocks (~ +5.7–6.0‰) at depth, altering their mineralogies and isotopically exchanging oxygen (and hydrogen) at temperatures above 500 °C over a range of mostly low (<1) water/rock ratios. The interaction leaches ^{18}O from the rocks, enriching the fluids in ^{18}O. These ^{18}O-enriched fluids percolate upward into overlying strata where they alter those rocks to greenschist mineralogical assemblages at somewhat lower temperatures. The interaction of these rocks with ^{18}O-enriched fluids at lower temperatures causes them to be relatively enriched in ^{18}O. The high positive $\delta^{18}O$ values of the overlying basalts result from low-temperature seafloor alteration (weathering). Stratigraphic preservation in the Onverwacht may not permit the kind of detailed modelling of the structure of the hydrothermal system as was performed by Gregory and Taylor[20] and Cocker *et al.*[21], particularly with regard to the effects of magma chamber configuration on the fluid flow regime. However, the general principle of oxygen isotope redistribution under conditions of subseafloor hydrothermal metamorphism is undoubtedly applicable.

Detailed descriptive information on the samples analysed in this study may be obtained by writing to S.E.H. We thank R. Hart for permission to analyse rock samples from his Onverwacht collection and Drs H. P. Taylor Jr and K. Kyser for access to their laboratories. Thanks also to K. Kyser, E. Nesbit, E. Suess, R. Duncan, M. Lyle, D. Abbott and M. De Wit, all of whom reviewed earlier drafts of the manuscript and substantially improved it through their comments. S.E.H. was funded by grant no. DPP-8120473 from the NSF Division of Polar Programs. M.W. and laboratory expenses at the University of Saskatachewan were funded by a grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada to T. K. Kyser. D.S.S. was at the California Institute of Technology during part of this study. Isotopic analyses at CIT were funded

by a grant from NSF Division of Ocean Sciences, OCE80-19021, to Dr H. P. Taylor Jr.

Input of excess CO_2 to the surface ocean based on $^{13}C/^{12}C$ ratios in a banded Jamaican sclerosponge

Ellen R. M. Druffel & Livia M. Benavides*†

The CO_2 content of the atmosphere has increased during the past two centuries as a result of the combustion of fossil fuels for energy[1] and the reduction of forest and soil carbon reservoirs on land[2]. The amount of CO_2 added to the atmosphere from fossil-fuel burning is known from historical records[1] (±10%), but the contribution from reduction of the terrestrial biosphere is far less certain. Several authors have estimated the relative contributions from the two sources by measuring the change in the $^{13}C/^{12}C$ ratio in atmospheric CO_2 as revealed in tree rings[3–8] (CO_2 derived from these two sources is depleted in ^{13}C with respect to that in the atmosphere). Using trees in the Northern Hemisphere, recent estimates of the integrated CO_2 release from the terrestrial biosphere since AD 1800 ranged from 70% (ref. 5) to 90% (ref. 9) of that released from fossil fuels. Here we present surface ocean $\delta^{13}C$ and $\delta^{18}O$ records measured in the skeleton of a living sclerosponge (*Ceratoporella nicholsoni*), which accretes aragonite in isotopic equilibrium with the surrounding sea water/dissolved inorganic carbon (DIC) system. The $\delta^{13}C$ record reveals a decrease

† Present address: Avenue Pardo 239, Apto 1310, Lima 18, Peru.

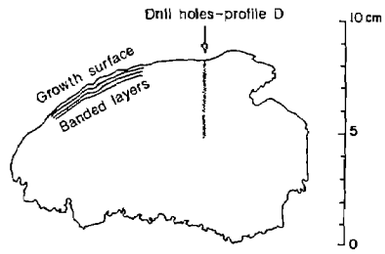

Fig. 1 Schematic diagram showing the sampling intervals for stable isotopes along profile D (0.5-mm drill holes) and for ^{210}Pb and ^{14}C analyses (0.5–1.0 mm bands)[19]. The $\delta^{18}O$ and $\delta^{13}C$ measurements obtained from the profile with the highest resolution are discussed in the text. Data obtained from three other profiles are not reported because an unexpected ageing effect after drilling was observed for these samples. Although it is standard practice to store aragonitic $CaCO_3$ samples indefinitely, we found that the $\delta^{18}O$ values of these drilled samples were lower by 0.3–0.4‰ after storage periods of a few months; most of the $\delta^{13}C$ results were decreased by 0.1–0.15‰. When samples were stored for a period of months after baking this effect was even greater. The effect of baking was observed previously by Land *et al.*[17], but these workers did not mention storage effects. We suspect that high-speed drilling of dense aragonite heats up the material sufficiently to cause partial conversion to calcite, a mineral that can exchange its CO_3^{2-} with other sources of CO_2. The results reported here are for samples that were analysed within 48 h of drilling, thus ensuring the smallest possible ageing effect.

of 0.50‰ from 1820 to 1972. Using a model of the world carbon cycle and a deconvolution of our $\delta^{13}C$ data, we estimate that the amount of excess CO_2 derived from the terrestrial biosphere is ~38% of that from fossil-fuel sources. Our model calculations support a preindustrial CO_2 concentration in the atmosphere of 280 p.p.m.v. (parts per million by volume), in agreement with direct measurements of air occluded in Antarctic ice cores[10].

Tree-ring records may not accurately reflect changes in atmospheric $\delta^{13}C$ with time because of kinetic isotope fractionation during the diffusion of CO_2 through the leaf stomata and during carboxylation of ribulose diphosphate during photosynthesis[11,12]. Small variations of the fractionation associated with these and other[11,12] processes may alter the tree-ring $\delta^{13}C$ record, rendering it unrepresentative of the actual change in the atmosphere due to excess CO_2 input.

Another approach for determining the relative contributions of fossil-fuel and forest/soil CO_2 is to examine $\delta^{13}C$ records obtained from the surface waters of the oceans. Nozaki *et al.*[13] found a reduction in $\delta^{13}C$ of 0.50‰ from 1900 to 1974 in a banded coral (*Diploria*) from Bermuda. However, other authors have found changes in coral $\delta^{13}C$ for this period that are too large to be attributed solely to the input of excess CO_2 from the atmosphere (ref. 14 and E.R.M.D., unpublished data). Corals contain symbiotic algae (zooxanthellae) whose photosynthetic activities fractionate the DIC pool from which the coral accretes its aragonite. This and other processes constitute the 'vital effect' which, as in trees, might vary with time masking the actual $\delta^{13}C$ change in sea water. Isotopic studies of corals devoid of symbiotic algae reveal a $\delta^{13}C$ record more representative of the ambient DIC in sea water, as that part of the vital effect associated with photosynthesis is absent[15,16]. However, Land *et al.*[17] found a direct correlation between the $\delta^{13}C$ and $\delta^{18}O$ in several shallow-water ahermatypic corals, indicating a common effect on both stable isotope ratios. Land *et al.* proposed that this was caused by variable retention rates of metabolic CO_2 in the internal DIC pool, another process contributing to the vital effect.

In the present study, we used the sclerosponge *Ceratoporella nicholsoni* as a recorder of $^{13}C/^{12}C$ and $^{18}O/^{16}O$ ratios in sea water. This animal has no symbiotic algae and appears to precipitate aragonite without a vital effect. The sclerosponge was

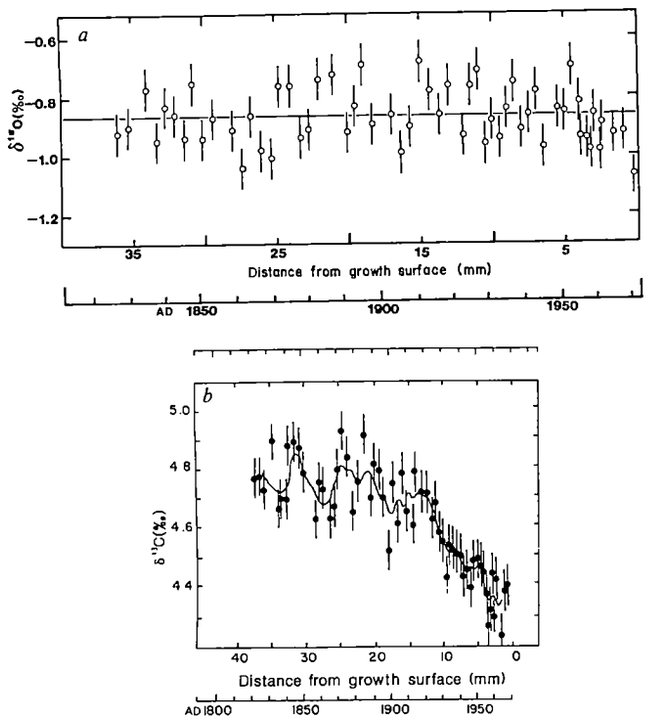

Fig. 2 *a*, $\delta^{18}O$ measurements for drilled samples along profile D. There is no apparent trend in these data, suggesting that there was no significant change in the long-term averaged SST, salinity and water composition from 1820 to 1972 on the reef. The solid line represents a least-squares fit of the data. Error bars represent 1σ error of ±0.07‰, determined from numerous triplicate analyses. *b*, $\delta^{13}C$ measurements for drilled samples along profile D. A decrease of 0.50‰ from the mid-1800s to 1972 is apparent. The solid line represents a cubic spline function fitted to the data (with 4-point smoothing). The error bars represent a 1σ error of ±0.07‰.

collected in 1972 in the fore-reef zone of Chalet Caribe Reef from the north-west coast of Jamaica at a depth of 26 m. This area is laved by open ocean waters. The major current system influencing this western Caribbean location is the precursor to the Gulf Stream.

The sclerosponge (~7 cm in diameter) was cut into slabs 3–4 mm wide which were studied using a dissecting microscope to ensure that they had been cut parallel to the growth axis. The slabs were cleaned ultrasonically to eliminate remnants of worm tubes and dust from cutting. A thin slab (1 mm) was X-rayed in an attempt to discern growth bands of varying density; however, despite the use of high-contrast film, no bands were detected. Dark-light band pairs, approximately 1 mm wide, were visible to the naked eye. These bands were identified by Hartman and Goreau[18] as a part of the organic matrix of the sclerosponge. The slabs were mapped using these organic bands (a total of 26) and sectioned for radioacarbon and ^{210}Pb analyses[19]. To obtain higher resolution of the stable isotope records, samples were drilled along a profile on a single slab (see Fig. 1). The profiles were drilled at intervals of 0.5 to 1.0-mm. For stable isotope analyses, the samples were baked at 375 °C for 1 h and converted to CO_2 by acidification with 100% orthophosphoric acid under vacuum at 50 °C. A VG Micromass 602E mass spectrometer was used to make the measurements.

The growth rate of this Jamaican sclerosponge was determined[19] using ^{210}Pb and bomb ^{14}C distributions in growth layers near the active growing surface. From these measurements and from the pre-bomb ^{14}C distributions in the sclerosponge bands, the specimen was estimated to have lived from ~AD 1700 to 1972; the average growth rate was 0.25 ± 0.05 mm yr^{-1} using the two methods. This gives an uncertainty of ±30 yr for our oldest year assignment (AD 1825).

Figure 2*a* and *b* shows the $\delta^{18}O$ and $\delta^{13}C$ results, plotted against distance from the growing surface and also against date of formation based on the bomb ^{14}C chronology[19].

The $\delta^{18}O$ measurements in Fig. 2*a* show no obvious trends. The entire data set gives an average $\delta^{18}O$ value of −0.87‰ (s.d. = 0.07‰). These data suggest that there was no significant long term variation in any of the factors controlling the $^{18}O/^{16}O$ ratio of the accreted aragonite[20–25] (that is, sea surface temperature (SST), salinity or seawater composition). Variations in $\delta^{18}O$ caused by seasonal SST changes are insignificant, as each sample represents a 2.5-yr growth interval. Surface salinity measurements were made along a transect extending from the shore to the collection site, which was ~600 m offshore. These results reveal that salinity values at the collection site (36.055–36.059‰) were within the range of values present in the western Caribbean Sea. The slight salinity gradient away from shore (on the order of +0.03‰) may represent a small input of fresh water from the island. A variation of this magnitude, however, would not significantly affect the $\delta^{18}O$ values (±0.015‰).

A cubic spline function was fitted to the $\delta^{13}C$ data set, with 4-point smoothing (solid line in Fig. 2*b*). $\delta^{13}C$ values from sclerosponge layers accreted during the nineteenth century average $+4.78 \pm 0.09$‰ (1 s.d.). Superimposed on this average value is an inter-annual oscillation of 0.2‰ with a timescale of approximately two decades. A trend toward values that are 0.40–0.50‰ lower is evident in the upper 15 mm of the sclerosponge skeleton. This result is similar to that of Nozaki *et al.*[13], who revealed a decline in $\delta^{13}C$ of 0.50‰ in a Bermuda coral. Although there is little correlation between the short-term variations of $\delta^{13}C$ as recorded in the surface ocean by the sclerosponge and the Bermuda coral (Fig. 3), partially because of the uncertainty in the chronology of the sclerosponge bands, the overall trend toward lower values by 1972 is the same.

There is no apparent correlation between the $\delta^{13}C$ and $\delta^{18}O$ values in samples from the sclerosponge, in contrast to the direct relationship found in ahermatypic corals[17]. Thus, the two quantities are independent, which is essential if we are to conclude that the isotopic ratios in the skeletal material represent accretion in equilibrium with the seawater/carbonate system.

The $\delta^{18}O$ and $\delta^{13}C$ values expected for equilibrium inorganic precipitation of calcite in surface waters of the northwestern Atlantic Ocean are −1.4 to −2.3‰ (at SST of 28 ± 1 °C) and 2.4 to 2.6‰, respectively[17,26–28]. To compare these ranges with our data, we had to take into account the additional fractionation that occurs during the accretion of aragonite as opposed to calcite, which is +0.6‰ for $\delta^{18}O$ (ref. 29) and 1.8‰ for $\delta^{13}C$ (ref. 28). Thus, values for aragonite precipitated recently in equilibrium with surrounding sea water in the northern Jamaican region are −0.8 to −1.7‰ for $\delta^{18}O$ and 4.2 to 4.4‰ for $\delta^{13}C$. Our results fall within these ranges (average $\delta^{18}O$ of −0.87‰, $\delta^{13}C$ range of 4.2–4.5‰). This evidence, in addition to the fact that there is no apparent correlation between $\delta^{13}C$ and $\delta^{18}O$, suggests that the vital effect is insignificant and that the sclerosponge precipitates aragonite in equilibrium with the DIC/water

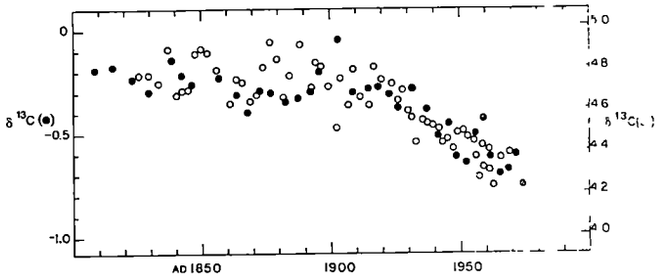

Fig. 3 $\delta^{13}C$ trend in surface ocean water in the north-west Atlantic as revealed by a Bermuda coral[13] (●, 5-yr averages) and by a Jamaican sclerosponge (present study) (○, 2.5-yr averages). A decrease of 0.50 ± 0.10‰ is apparent from the mid-1800s to 1972.

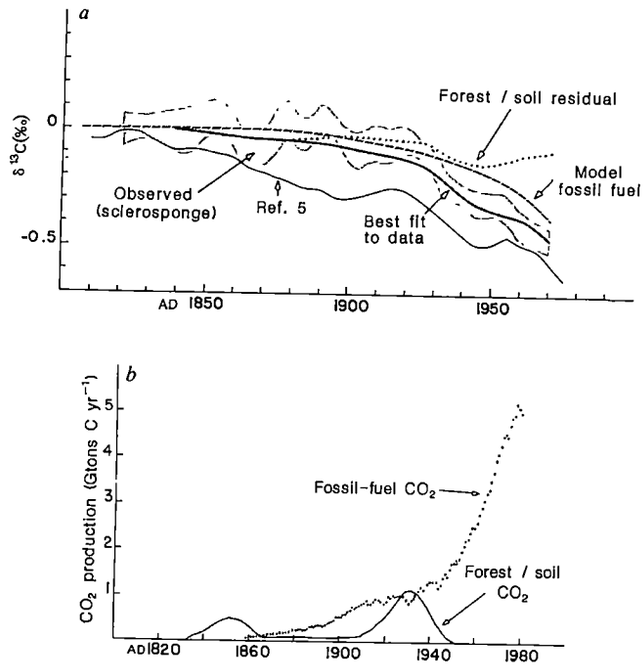

Fig. 4 *a*, Model calculations of the $\delta^{13}C$ trend in surface ocean waters. The stippled area represents the observed values from the sclerosponge. The decrease due to fossil-fuel CO_2 alone (– – –) was calculated from historical records[1,33]. The forest/soil component (.....) was calculated by eliminating the fossil-fuel curve from the model-derived best fit of the observed sclerosponge measurements (heavy solid line). The surface-ocean curve calculated from the tree-ring data of Stuiver *et al.*[5] is shown for comparison (light solid line). *b*, Annual CO_2 production from fossil-fuel burning[1] and from forest/soil sources (present work) during the past two centuries. Integration of the two curves reveals that ~28% of the total excess CO_2 released into the atmosphere during 1820–1972 was derived from the terrestrial biota.

system in which it lives. In contrast to corals, sclerosponges pump large amounts of water through their channels[18]; this may provide a mechanism for the removal of metabolic CO_2 from the animal tissue, thus eliminating significant retention of respired CO_2 in the calcioblastic layer, and hence in the accreted aragonite.

Assuming that sclerosponges accrete aragonite in equilibrium with the surrounding sea water, their skeletons contain valuable information regarding the input of excess CO_2 to the oceans. Knowledge of both the timing and magnitude of the $\delta^{13}C$ change obtained from the stable isotope records in banded sclerosponge layers enables us to estimate the relative contributions to the atmosphere and oceans of the two major sources of CO_2: fossil fuels and forest/soil carbon.

A one-dimensional mixing model of the world carbon cycle, similar to that of Emanuel *et al.*[30], was used to estimate the timing and magnitude of excess CO_2 input to the atmosphere from the two major sources mentioned above. In this model, the ocean is constructed of 19 layers that are mixed diffusively, in a manner similar to the box-diffusion model of Oeschger *et al.*[31]. The biota is represented by the five major terrestrial carbon reservoirs. Values of the atmospheric P_{CO_2} (partial pressure of CO_2) calculated using the model agreed (to within ±2 p.p.m.v.) with measurements obtained by Keeling *et al.*[32] from 1958 to 1982 at Mauna Loa.

The stippled region in Fig. 4*a* shows the range of $\delta^{13}C$ values in the surface ocean as recorded in the sclerosponge bands. Using the model, we calculate that the reduction in $\delta^{13}C$ expected in average surface ocean waters due to the input of fossil CO_2 alone[1,33] is 0.37‰ by 1972 (broken line); this is two-thirds of the value observed in the sclerosponge record. If we assume that the north-west Atlantic is representative of average global surface ocean water, then it seems that there is an additional source of excess CO_2, presumably from deforestation and soil manipulation on land. In the model, we have added CO_2 derived from the reduction of the forest/soil reservoir ($\delta^{13}C = -26$‰) in order to obtain the best fit of the observed ocean $\delta^{13}C$ curve (heavy solid line in Fig. 4*a*). The change in $\delta^{13}C$ in the surface ocean calculated from the composite tree-ring curve of Stuiver *et al.*[5] is slightly greater than our observed trend (Fig. 4*a*). Figure 4*b* shows the annual CO_2 production (in gigatons C yr^{-1}) from the two sources of excess CO_2. The forest/soil contribution is approximately 38% the size of the fossil fuel contribution, representing a net input to the atmosphere of 53 G tons C from the terrestrial biosphere between 1820 and 1972. Using the combined observed ocean trend (Fig. 3) from the Bermuda coral and Jamaican sclerosponge, the estimate of the forest/soil CO_2 contribution remains the same.

Although the shape of the forest/soil curve is difficult to determine with any certainty because of the large signal-to-noise ratio in the ocean $\delta^{13}C$ records, these data do suggest that the change in $\delta^{13}C$ due to forest/soil CO_2 input was minimal between 1950 and 1972; this is in agreement with the results of studies of tree rings[5,9] and atmospheric CO_2 (ref. 34). Also, there was a significant decrease in $\delta^{13}C$ from 1845 to 1865, suggesting that the forest/soil component was an important net source of CO_2 to the atmosphere during the nineteenth century. However, it appears from the sclerosponge data that most of the excess terrestrial CO_2 was expelled into the atmosphere during the period 1920–1950 (Fig. 4*b*).

The bimodal nature of the forest/soil CO_2 input, as revealed here, has also been demonstrated by deconvolution of ice-core CO_2 data[35] and of tree-ring $\delta^{13}C$ records[5,36]. The similarity of recent results derived from independent geochemical data sets indicates that our understanding of the excess CO_2 problem is approaching a consensus—(1) the net input of CO_2 to the atmosphere from the biosphere between 1800 and 1975 was approximately half of that from fossil fuels, and (2) the net production of biospheric CO_2 has undergone two periods of peak production in the past two centuries, at 1820–1850 and 1880–1930.

An estimate of the partial pressure of CO_2 in the atmosphere during the early 1800s can be made using these data. Using historical records of the industrial production of CO_2 from fossil fuels[1,33] and the P_{CO_2} record in the atmosphere[32], the preindustrial P_{CO_2} is estimated at 292 p.p.m.v., if the biosphere was neither a sink nor a source of CO_2. Considering the biotic source of excess CO_2, which is estimated here to have been ~38% the size of the fossil-fuel source, the preindustrial P_{CO_2} is decreased to 280 p.p.m.v.; this value is in agreement with measurements made by Neftel *et al.*[10] of air trapped in ice cores from Siple Station, Antarctica.

We thank Peter Williams, Peter Brewer, Phil Dustan, Dave Keeling, Lloyd Keigwin, Ann McNichol, Barrien Moore, Bill Emanuel and Werner Deuser for helpful discussions; Phil Dustan for providing the sclerosponge; Sheila Griffin for technical support; Debbie Shafer for helping with the modelling efforts; Stephen Rodriguez for collecting the salinity samples; and Molly Lumping for typing the manuscript. This research was supported by NSF grants OCE81-11954 and OCE83-15260.

Molecular evidence for a terrestrial component of organic matter dissolved in ocean water

Kathleen J. Meyers-Schulte & John I. Hedges

School of Oceanography, WB-10, University of Washington, Seattle, Washington 98195, USA

Dissolved organic matter (DOM) in seawater represents one of the largest active carbon reservoirs on Earth[1]. Although mass-balance calculations suggest a substantial riverine input to the marine DOM pool[2], a terrestrial organic component has not been positively identified in open-ocean water. By using lignin-derived phenols as molecular-level probes of DOM (analogous to previous studies in sediments[3–5]), we report here the first unambiguous evidence for the presence of terrestrially derived DOM in open ocean water. Dissolved humic substances, isolated by resin adsorption from near-surface water of the eastern equatorial Pacific, yield lignin-derived phenols in compositional patterns which resemble those obtained from Amazon River water[6,7]. Total phenol yields from these open-ocean humic isolates are, on average, ~10% of those from Amazon humic substances, indicating that ~10% of dissolved marine humic material (and at least 0.5% of the bulk marine DOM) is terrestrially derived.

The concentration of terrestrially derived organic matter in the marine DOM pool is one of the most ill-defined factors in the global carbon cycle[1]. The potential for a significant terrestrial contribution is evident from the calculation that the global DOM input by rivers[2] is sufficient to support ~70% of the oceanic DOM pool at its measured (^{14}C) average age of 3,400 yr[8]. Evidence that riverine DOM mixes conservatively in selected estuaries[9] suggests that most riverine DOM passes through estuaries to coastal waters[10], where its subsequent fate is unknown.

Direct biochemical analyses of marine DOM have yielded limited source-related information because the overall abundance of recognizable biochemicals is low (10–20%)[11–13] and their geographic origins are usually ambiguous. A portion of the DOM is comprised of a complex mixture of acidic polymers called humic substances which are produced by microbial degradation and condensation of biochemicals and can be isolated by adsorption onto resin[14]. Bulk isotopic and chemical analyses of humic isolates from seawater indicate a predominant marine origin[15–18], but these measurements are not well suited for detection of minor constituents, and cannot preclude a terrestrial component. Degradative analyses of humic substances allow the greater sensitivity inherent in molecular level analyses, but to date have either yielded products of unclear geographic origin[18], have been applied to landlocked marine water[10] which may not be representative of the open ocean, or have not detected a terrestrial component of marine humus[19].

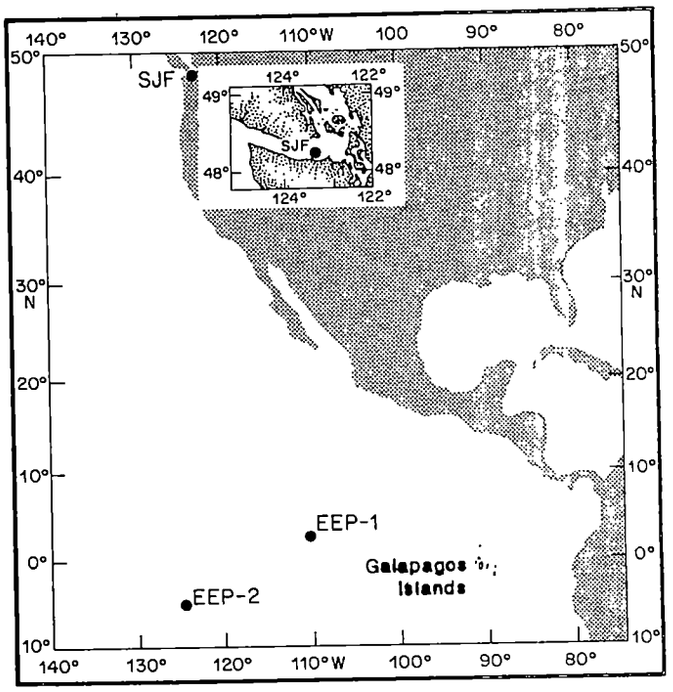

Fig. 1 Seawater sampling sites.

Using the lignin-biomarker technique[5], we report here the first direct evidence for the presence of terrestrially derived organic matter in open-ocean DOM. Lignin is a phenolic polymer which is produced solely by vascular land plants as structural units of their cell walls[20]. Its exclusive terrestrial source, high natural abundance on land, inherent chemical stability[21] and unmistakable suite of cupric oxide oxidation products render lignin an attractive molecular tracer for terrestrial organic matter in aquatic environments[6,7,22]. On oxidation by cupric oxide, lignin of all vascular plant tissues produces vanillyl phenols, which can be used as unambiguous general tracers of terrestrially derived material. In addition, syringyl phenols (produced only from angiosperm lignin) and cinnamyl phenols (produced only from non-woody tissues) denote specific vascular tissue sources[4,22]. Finally, the weight ratio of vanillic acid to vanillin, symbolized as $(Ad/Al)_V$ of fresh (undergraded) vascular plant tissues ranges from 0.1 to 0.2 (ref. 23), whereas higher values are characteristic of biodegraded lignin[6].

Previous applications of the lignin-biomarker technique to dissolved humic substances from lakes and rivers have demonstrated the ubiquitous presence of lignin structural units[6,7,22]. In particular, humic substances from the Amazon River system produce high yields of lignin oxidation products characterized by low syringyl/vanillyl (S/V) and cinnamyl/vanillyl (C/V) weight ratios and relatively high $(Ad/Al)_V$ values[6,7]. Because the Amazon is by far the world's largest river system and contributes approximately 20% of the total freshwater input to the ocean[2], it serves as a good model for the expected terrestrial component within the marine DOM pool.

We chose to study water from the Pacific Ocean which is at the most extreme end of the global ocean circulation pattern and least affected by direct river input. Both surface (depth 5 m) and sub-thermoclinic (150 m) water samples (400 l) were collected from two stations in the eastern equatorial Pacific Ocean

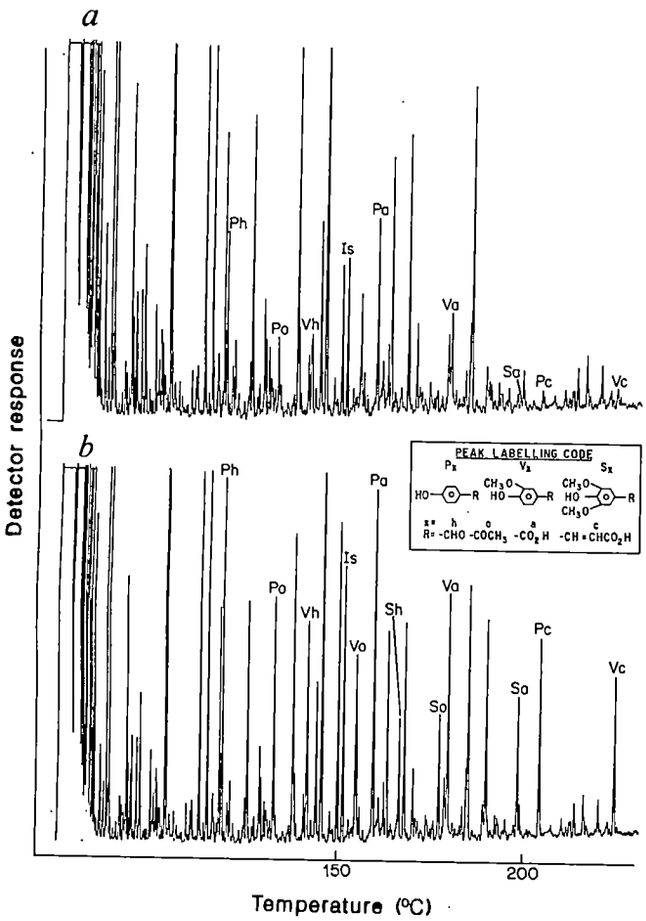

Fig. 2 Gas chromatographic traces of the cupric oxide oxidation products of the humic substance isolates from station EEP-1 (Fig. 1), sub-thermoclinic water: *a*, analysed directly as TMS derivatives; *b*, coinjected with a standard mixture of TMS-phenols. Peak identities (named as unsilylated forms): Ph, *p*-hydroxybenzaldehyde; Po, *p*-hydroxyacetophenone; Vh, vanillin; Is, ethylvanillin (GC internal standard); Vo, acetovanillon; Pa, *p*-hydroxybenzoic acid; Sh, syringaldehyde; So, acetosyringone; Va, vanillic acid; Sa, syringic acid; Pc, *p*-coumaric acid; Vc, ferulic acid. For chromatographic method, see ref. 22.

(EEP-1 and EEP-2, Fig. 1). In addition, a sample from coastal inland waters (SJF, Fig. 1; Salinity $S = 33.3‰$) was analysed. We chose to use XAD-2 (rather than XAD-8) resin to isolate and concentrate humic substances from seawater because XAD-2 gave comparable DOM recoveries in the coastal sample and produced no phenolic contamination peaks in the gas chromatographic trace of its procedural blank. The isolation procedure was carried out with 3-l resin columns as described by Thurman and Malcolm[24], with the exceptions that we used in-line glass-fibre filters (0.45 μm) in addition to the primary silver filters, and we required two recycling steps to concentrate the bulk humic isolate, which was not subsequently fractionated. By this method, 33.6–95.8 mg of humic material was isolated, corresponding to ~5–15% of the total dissolved organic carbon (DOC), assuming a DOC concentration of 0.8 mg l^{-1}. A procedural blank of 0.04 mg organic carbon was obtained for the entire isolation scheme, which corresponds to ~0.2% of the total organic carbon in the smallest humic isolate sample. Elemental compositions were determined in duplicate using a Carlo Erba Model 1106 CHN analyser. Stable carbon isotope compositions were determined in duplicate by Coastal Science Laboratories and are reported here in $\delta^{13}C$ notation, relative to PDB[25]. Cupric oxide lignin oxidation products were quantified as trimethylsilyl (TMS) derivatives by gas capillary chromatography[26] only after identities were verified against commercial standards by coinjection of TMS and methoxime derivatives[27], and by gas chromatography–mass spectrometry (GC–MS).

The average percentage of organic carbon in the humic isolates from the equatorial Pacific samples (50 ± 0.8%) agrees well with values previously reported for the open ocean[15] and the Amazon River[6,7], and reflects a low ash content. Atomic C/N ratios of the Pacific coastal and open-ocean humic isolates (32.4–37.2) are intermediate between reported ratios for open ocean (8.63; ref. 16) and Amazon (44.6 ± 5.2; refs 6, 7) isolates, but are significantly higher than the previously reported oceanic value. The mean H/C ratio for the ocean samples (1.58 ± 0.07) is similar to previously determined values for seawater humics (1.57 and 1.61; refs 18, 28), confirming the aliphatic nature of this material[17]. The somewhat lower H/C ratio of the coastal sample (1.27) is still higher than values reported for lake (1.2; ref. 14) and Amazon River (0.88–1.1; refs 6, 7) waters. All open-ocean H/C values are much higher than that of the polystyrene XAD-2 resin (1.09), indicating minimal sample contamination by the resin. The $\delta^{13}C$ values for the marine humic substances (−21.8 to −22.2‰) are within the range of values reported for humic isolates from coastal and open-ocean waters (−23.7‰ and −22.8‰, respectively)[16], and are also consistent with reported values for bulk DOC from the south (−19.9 to −22.2‰)[29] and north-east (−21.2 to −24.2‰)[30] Pacific Ocean. These $\delta^{13}C$ values for marine DOM are all more positive than reported values for humic substances from streams and rivers (−25.9 to −26.6‰)[14] and for bulk XAD-2 resin (−28.0‰), confirming the predominance of uncontaminated marine-derived material in the seawater humic isolates.

Gas chromatographic traces of the cupric oxide oxidation products for all Pacific samples (coastal and open-ocean) are remarkably similar and are dominated by non-lignin-derived compounds (Fig. 2). These traces have many peaks in common with the cupric oxide oxidation product mixtures of Amazon humic isolates[6,7], although some additional and as yet unidentified major peaks appear in the marine samples. For the coastal marine humic sample, all characteristic lignin oxidation products (aldehydic, ketonic and acidic forms of vanillyl and syringyl phenols, plus two acidic cinnamyl phenols) can be clearly identified by their mass spectra. In the open-ocean samples, neither syringaldehyde nor acetosyringone can be convincingly discriminated, and although the presence of acetovanillon is verified by GC–MS, it cannot be sufficiently separated from other compounds to be quantified in the gas chromatographic traces (Fig. 2).

In all five marine humic isolate samples, vanillyl phenols are the dominant lignin products, contributing an average 58 ± 5% to the total definable lignin yield. The S/V and C/V weight ratios of the coastal marine sample (0.21 and 0.10, respectively)

Table 1 Elemental and lignin compositions of humic substances isolated from coastal and open-ocean waters

Station	Depth (m)	%OC	C/N	H/C	Λ	$(Ad/Al)_V$	$\delta^{13}C$ (‰)
SJF	100	45.0	34.5	1.27	0.19	1.3	−22.2
EEP-1	5	49.9	32.4	1.65	0.16	1.3	−22.2
EEP-1	150	50.0	37.2	1.55	0.11	2.1	−21.8
EEP-2	5	51.1	35.7	1.57	0.12	1.1	−22.0
EEP-2	150	51.5	35.8	1.56	0.11	1.5	−22.2

SJF, Strait of Juan de Fuca sample, 48°13.2′ N, 123°21.1′ W; EEP-1, eastern equatorial Pacific station 1, 2°06.1′ N, 110°09.9′ W; EEP-2, eastern equatorial Pacific station 2, 5°00.9′ S, 124°58.4′ W; %OC, weight per cent organic carbon of freeze-dried humic isolates (uncorrected for ash); C/N and H/C, atomic ratios of freeze-dried isolates; Λ, sum of the eight lignin oxidation products in mg per 100 mg organic carbon; $(Ad/Al)_V$, weight ratio of vanillic acid to vanillin; $\delta^{13}C$ of freeze-dried humic isolates is given relative to PDB standard.

are very close to the values for the Amazon River system (S/V = 0.22–0.47; C/V = 0.01–0.10)[6,7]. The $(Ad/Al)_V$ ratios of all the marine humic isolates (1.1–2.1) also lie within the range for dissolved humic substances from the Amazon River system (1.1–2.2; refs 6, 7) but are, on average, higher than values reported for dissolved humic isolates from temperate freshwaters (0.79–0.98; ref. 22). The similar high $(Ad/Al)_V$ ratios for the marine and Amazon humic isolates reveal extensive oxidative biodegradation of the component lignin structural units. In all five marine samples, *p*-hydroxyl phenols are abundant relative to vanillyl compounds and *p*-hydroxyacetophenone is depleted, indicating a predominantly non-lignin source[6,7].

Because the relative yields of lignin oxidation products from the oceanic humic isolates are low, their quantification by means of gas chromatographic integration is crude. However, we obtain yields of total lignin phenols normalized to 100 mg of organic carbon (Λ) for open ocean humic materials that are uniformly near 0.14 (Table 1). These Λ-values are low compared with those reported for lake (2.5–3.4; ref. 22) and Amazon (0.90–2.1; refs 6, 7) humic isolates, and correspond to only 0.2% of the bulk humic carbon present as lignin structural units. Thus, the concentration of chemically recognizable lignin present in these marine humic substances is too low to account for a significant fraction of the aromatic carbon indicated by previous spectroscopic studies[17,18]. Assuming that the lignin content of riverine humic substances is unaltered at sea, the ratio $\Lambda_{ocean}/\Lambda_{Amazon}$ (0.14/1.2; refs 6, 7) provides a crude estimate that approximately 10% of open-ocean humic material is terrestrially derived. At the minimum (assuming all terrestrially derived material is confined to this 10% humic-fraction of DOC) this corresponds to roughly 1% of the bulk DOC, with a probably upper limit of 10%, if the resin-isolated material is typical of DOC in general.

With regard to the global carbon cycle, further data is necessary to better quantify the terrestrial contribution to oceanic DOM. Additional investigations of lignin-derived phenols from various ocean-water masses and geographical locations may provide compositional trends related to locations, patterns and rates of lignin removal as well as information applicable to oceanic mixing processes.

We thank J. Ertel for advice and consultation; T. Bates and P. Murphy (PMEL/NOAA) for providing cruise equipment and GC–MS use; E. M. Thurman for instruction on XAD use; B. Clark (NWFC/NOAA) for logistical support; Rainier Brewing Company for donating kegs which were crucial to our work; and the officers and crew of the NOAA ship *Discoverer* for cooperation and help. This research was supported by NSF grants OCE-821-9294 and OCE-842-1023. This is contribution no. 1613 from the School of Oceanography, University of Washington.

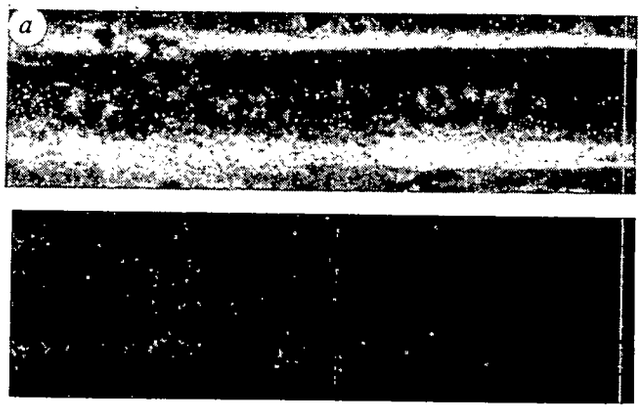
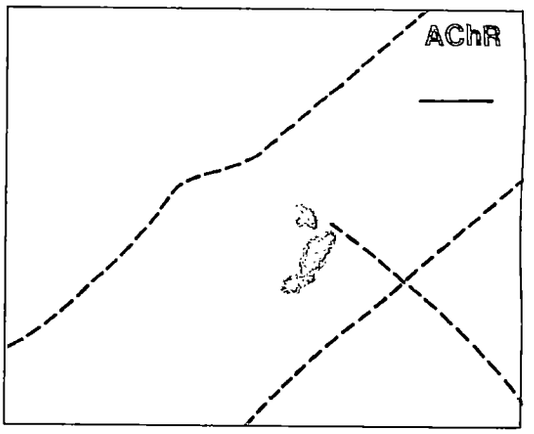
Fluorescently labelled Na^+ channels are localized and immobilized to synapses of innervated muscle fibres

Kimon J. Angelides*



Department of Neuroscience and Center for Neurobiological Studies, University of Florida College of Medicine, Gainesville, Florida 32610, USA

Segregation of voltage-dependent sodium channels to the hillock of motoneurones and nodes of Ranvier in myelinated axons is crucial for conduction of the nerve impulse[1,2]. Much less is known, however, about the distribution of voltage-dependent Na^+ channels on muscle fibres. Recently, Beam *et al.*[3] have shown that Na^+ channels are concentrated near the neuromuscular junction. To determine the topography and mechanisms governing the distribution of voltage-dependent Na^+ channels on muscle, microfluorimetry and fluorescence photobleach recovery (FPR) have now been used to measure the density and lateral mobility of fluorescently labelled Na^+ channels on uninnervated and innervated muscle fibres. On uninnervated myotubes, Na^+ channels are diffusely distributed and freely mobile, whereas after innervation the channels concentrate at neuronal contact sites. These channels are immobile and co-localize with acetylcholine receptors (AChRs). At extrajunctional regions the Na^+ channel density is lower and the channels more mobile. The results suggest that the nerve induces Na^+ channels to redistribute, immobilize and co-localize with AChRs at sites of neuronal contact.



Sodium channels were fluorescently labelled by exploiting the high affinity of fluorescent derivatives of toxin V from *Leiurus quinquiestriatus* (Lqq V), toxin II from *Centruroides suffusus* (Css II) and tetrodotoxin (TTX)[4–6]. Topographical mapping and lateral diffusion coefficients (D_L) of labelled Na^+ channels on aneurally cultured embryonic chick myotubes, chick spinal cord neurone–muscle co-cultures and mouse diaphragm muscle were measured using the spot photobleaching technique[7].

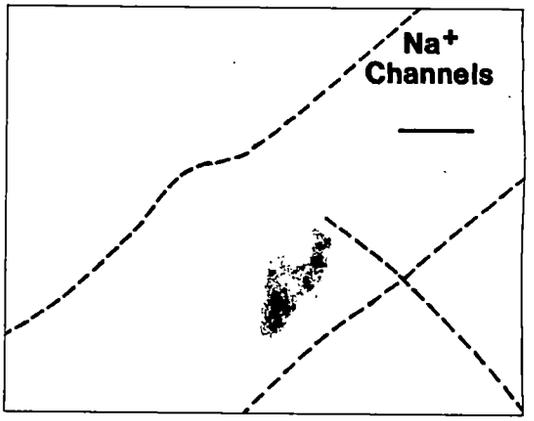


Figure 1 shows the fluorescence labelling of voltage-dependent Na^+ channels by 5-(6-)carboxytetramethylrhodamine-Lys-Lqq V) (TmRhd-Lqq V) on aneurally cultured chick myotubes and myotubes co-cultured with spinal cord neurones. Fluorescence staining of non-innervated myotubes was faint and diffusely distributed over the cell surface (Fig. 1*a*) whereas in the nerve–muscle co-cultures (Fig. 1*b*), more localized and patchy fluorescence was observed at regions which appeared morphologically identifiable as neuronal contact regions and which coincided with fluorescein 5-isothiocyanate (FITC)-α-bungarotoxin fluorescence[8,9]. Comparison of Na^+ channel and AChR distribution showed that the two channels occupy contiguous regions (lower panel to Fig. 1*b*). In most fibres, Na^+ channel and AChR staining appeared as single fluorescent patches that co-localized at neuronal contact sites, although Na^+ channel fluorescence was characteristically less intense than the AChR fluorescence. AChR patches were occasionally found in regions not associated with the neurite. Patches of fluorescently labelled Na^+ channels did not co-localize with these neurite-free AChR clusters.

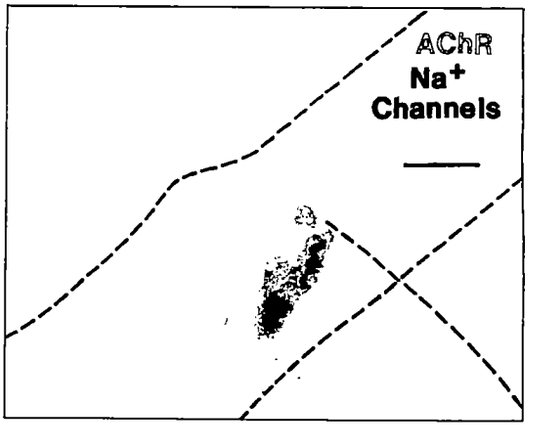

Fig. 1 Fluorescence labelling of Na^+ channels by TmRhd-Lqq V in 11-day-old chick myotubes (*a*) and chick myotubes innervated by spinal cord neurones (*b*). TmRhd-Lqq V binds reversibly to these cells with a K_d of 16 nM. The half-time for dissociation is 65 min at 22 °C. The upper micrographs are phase-contrast images of portions of the TmRhd-Lqq V-labelled myotubes and spinal cord neurone–muscle cell co-cultures. The lower micrograph is fluorescence labelling of Na^+ channels on 11-day-old chick myotubes. In *b* AChRs were visualized on the same fibre after labelling with 10^{-7} M FITC–α-bungarotoxin followed by washing. The bottom panel in *b* is a colour overlay of the AChR and Na^+ channel staining patterns on the same fibre. Scale bar, 10 μm. **Methods.** The cells were incubated with 40 nM TmRhd-Lqq V for 30 min at 22 °C in a buffer composed of 130 mM choline chloride, 50 mM HEPES adjusted to *p*H 7.4 with Tris base, 5.5 mM glucose, 0.8 mM $MgSO_4$, 5.4 mM KCl, to which 2 μM TTX was added to block any ion movement through the Na^+ channels that would lead to membrane depolarization and dissociation of TmRhd-Lqq V (ref. 4). The cultures were rapidly washed five times with ice-cold buffer before photography. Nonspecific binding of ^{125}I-Lqq V to these cells was 15% after depolarization by replacing the external medium with 150 mM external K^+ or by competitive displacement with 200 nM unlabelled Lqq V. The photographs were taken on Ektachrome film pushed to 1,200 ASA using a Nikon UFX automatic exposure attachmeent through a ×40 water immersion, 0.75 numerical aperature objective or a ×100 glycerin immersion, 1.4 numerical aperature objective.

To obtain a detailed profile of Na^+ channel distribution, fluorescently labelled Na^+ channels were mapped with a laser microbeam at various distances from the site of nerve contact using the AChR cluster identified by FITC–α-bungarotoxin as the origin. Figure 2 shows the distribution of these channels. Na^+ channel density in such cultures is much higher at the site of innervation. Within 20 μm of this region the fluorescence intensity doubles and at 200 μm it falls to ~15% of that of the synaptic region. Examination of AChR distribution shows that within the same region the drop in FITC–α-bungarotoxin fluorescence is three- to fivefold greater than the drop in TmRhd-Lqq V fluorescence. When FITC–succinyl concanavalin A (FITC–sCon-A) or tetramethylrhodamine phosphatidylethanolamine (TmRhD-PE) receptors were examined, no pattern in the fluorescence intensities was observed, indicating that the steep gradient observed for Na^+ channels is not due to local invaginations of the membrane at the nerve–muscle junction. Furthermore, this suggests that, compared with the Na^+ channel protein, the general classes of phospholipids and glycoproteins are more homogeneously distributed on the muscle cell surface. The absence of patches or a steep concentration gradient of FITC–sCon-A receptors co-localizing with Na^+ channels or AChRs shows that the innervated sarcolemma forms and maintains a distinct distribution of different membrane proteins. Beam *et al.*[3] and Roberts and Almers[10] have shown that on adult innervated skeletal muscle fibres, Na^+ channels congregate at the neuromuscular junction. Using the loose patch-clamp technique, they observed that immediately adjacent to the endplate the Na^+ current density, which they associated with voltage-dependent Na^+ channels, was 5–10-fold higher than at regions away from the endplate. Although the increased Na^+ conductance at the synapse could arise from channels possessing a high single-channel conductance, this now seems unlikely because our independent measurements by fluorescence methods using probes specific for the voltage-dependent Na^+ channel confirm that Na^+ channels are concentrated at synapses.

To gain insight into the mechanisms that organize Na^+ channels at the synapse and the elements maintaining this distribution, the lateral mobility of fluorescently labelled Na^+ channels was measured by FPR at several locations on the muscle cell. Figure 3 shows representative fluorescence recovery curves obtained from uninnervated myotubes (Fig. 3*a*) and myotubes

$<D_L>$, Lateral diffusion coefficient $\pm D_L$, s.d.; $<f>$, mobile fraction $\pm f$, standard deviation. IM, immobile on FPR timescale, $D \leq 10^{-12}$ cm^2 s^{-1}. N, number of measurements.

* Measured with TmRhd-Lqq V, unless otherwise noted using NBD-TTX or TmRhd-Css II.

innervated by spinal cord neurones (Fig. 3*b*, *c*). The recovery curves show that on uninnervated myotubes all Na^+ channels are relatively unrestricted in their lateral mobility, with diffusion coefficients of 8.9×10^{-10} cm^2 s^{-1} (Fig. 3*a*) whereas Na^+ channels clustered at synapses are immobilized, with diffusion coefficients of $\leq10^{-12}$ cm^2 s^{-1} (Fig. 3*b*). However, not all Na^+ channels are immobile. For example, at 240 μm from the site of neuronal contact, which is a region of lower channel density, 40% of the Na^+ channels are mobile, with lateral diffusion coefficients of 2.3×10^{-10} cm^2 s^{-1} (Table 1).

A general trend emerged from these experiments. Those channels located at and close to neuronal contact sites are immobile, while the rate of lateral motion and fraction of Na^+ channels able to move increase with increasing distance from the synapse. Similar observations were made on adult mouse diaphragm muscle, so these observations do not seem to be restricted to the culture system. The use of three Na^+ channel probes which bind to the Na^+ channel protein at independent and topologically remote sites[4–6], and the demonstration that the diffusion coefficients are independent of the probes themselves, eliminate any biasing or artefactual contribution from the probes. As an additional control, the fluorescent phospholipid derivative TmRhd-PE diffuses freely in all membrane regions with diffusion coefficients of $7\text{–}10\times10^{-9}$ cm^2 s^{-1} (Table 1). *t*-tests of the data show that there is no statistical difference between these regions. Therefore, inhomogeneities in membrane lipid viscosity cannot account for the different channel diffusion rates observed at locations on and away from the neuronal contact site.

Although the diffusion coefficient for FITC-sCon-A receptors does not change over the muscle cell surface, the mobile fraction increases somewhat in parallel with the Na^+ channel distribution (Table 1). The immobility of many FITC-sCon-A receptors at the synapse may be due in part to the high density of AChRs and Na^+ channels, both of which are glycoproteins and sCon-A receptors[11–13]. However, this region contains a small but important group of sCon-A receptors, besides AChRs or Na^+ channels, which are mobile. This indicates that not all proteins in this region are immobile and that Na^+ channels experience still stronger restrictions in lateral mobility.

The results using these probes demonstrate that the heterogeneous distribution and differential mobility of Na^+ channels are not a characteristic of all sarcolemmal proteins, the result of differences in membrane fluidity created by partitioning of particular phospholipids[14], or domains created by the aggregation and clustering of general classes of intrinsic membrane proteins. Our FPR results using nerve–muscle cocultures and Na^+ channel-specific fluorescent probes differ slightly from those of Stuhmer and Almers[15], for they found, using ultraviolet photobleaching and electrophysiological techniques, that on frog muscle all Na^+ channels were immobile.

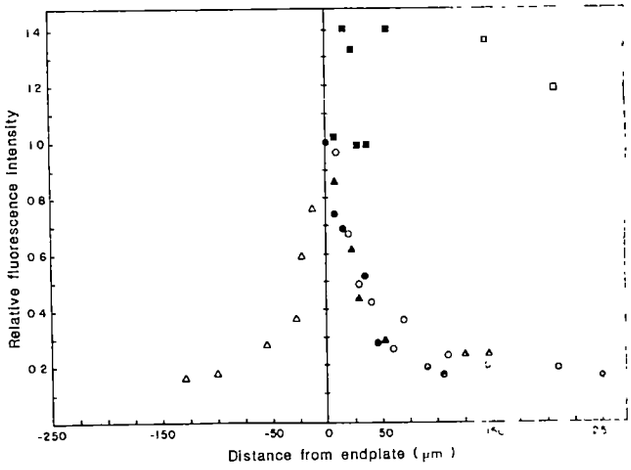

Fig. 2 Profile of fluorescently labelled Na^+ channel (●, ○, △, △) and FITC-sCon-A receptor (■) distribution on myotubes innervated by spinal cord neurones *in vitro*. Typically, a nerve process from a large multipolar neurone was visualized as it passed on top of, adjacent to, or terminated on the muscle fibre by phase or interference contrast illumination. Regions which appeared morphologically identifiable as neuronal contact sites were then examined for the localization of AChRs with FITC-α-bungarotoxin[8,9]. The monitoring beam of an argon ion laser was used to excite a small spot (1.7 or 3.6 μm diameter) on the cell membrane at various regions of the muscle and the fluorescence was accumulated at a photon counting interval of 40 ms. The beam diameter and a reticuled eyepiece were used to record the position of the microbeam relative to the nerve–muscle junction. Within each experiment no change in neutral density filters or in the optical arrangement was made. The neurite-associated ACh receptor patch at the junctional region was defined as the origin (zero distance). Photon counts were normalized to the value obtained at the neurite-associated ACh receptor patch at the junctional region, which was 1,254 counts per 40 ms for specific TmRhd-Lqq V binding and 990 counts per 40 ms for FITC-sCon-A. The absolute photon count levels, however, cannot be compared between FITC-sCon-A and TmRhd-Lqq V because a higher neutral density was required to reduce FITC-sCon-A pre-bleaching. Four representative muscle fibres are shown by the open and closed circles and triangles. The nonspecific binding was measured by displacing TmRhd-Lqq V with 200 nM unlabelled Lqq V and re-measuring the fluorescence intensities under identical counting conditions. The nonspecific binding (15%) was subtracted from the total binding to yield the specific binding to Na^+ channels[4]. The absence of a steep gradient in the fluorescence profile of FITC-sCon-A receptors demonstrates that the high fluorescence intensity observed for Na^+ channels is not due to localized foldings of the membrane which could enhance the fluorescence intensity by increasing the effective surface area.

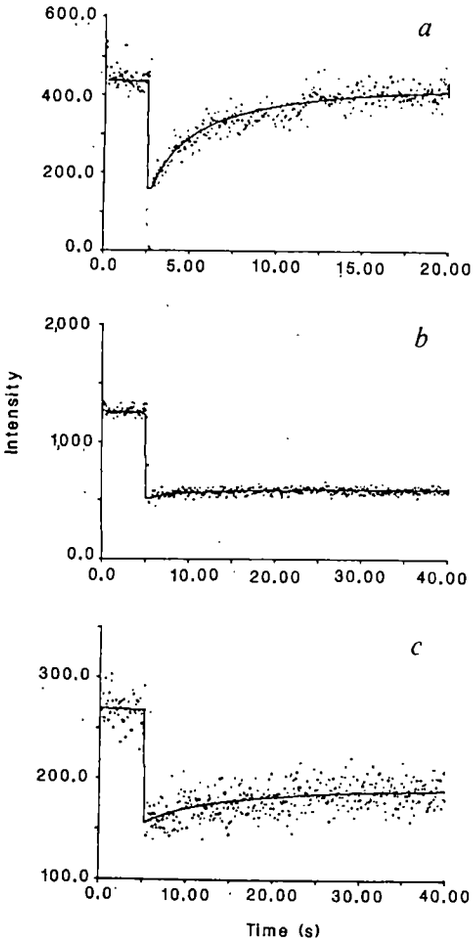

Fig. 3 Typical fluorescence recovery curves demonstrating Na^+ channel mobility on myotubes (*a*), immobility at the neuromuscular junction (*b*) and slow mobility 240 μm from the neuromuscular junction (*c*) in spinal cord neurone–muscle co-cultures. Curves *b* and *c* were obtained on the same muscle fibre. D_L and *f* were determined by curve-fitting procedures[7]. Values for D_L ($cm^2\ s^{-1}$) were determined using the expression $w^2/4T_D$ in which *w* is the e^{-2} radius of the beam profile and T_D is the half-time for recovery. Incomplete fluorescence recovery was interpreted as an indication that a fraction of labelled channels is immobile on the timescale of the experiment; $D_L \leq 3\times10^{-12}\ cm^2\ s^{-1}$ was considered to indicate immobility. The radius of the bleaching spot for the ×100 oil immersion objective used in this figure was 0.85 μm. Analysis of the curve in *a* yields a diffusion coefficient of $8.9\times10^{-10}\ cm^2\ s^{-1}$ and a recoverable fraction of 1.00. In *b*, $D_L \leq 10^{-12}\ cm^2\ s^{-1}$, and in *c*, $D_L = 2.3\times10^{-10}\ cm^2\ s^{-1}$ and $f = 0.37$.

In addition to the possibility of species differences, differences in the maturity of the tissue may contribute to the results observed. The nerve–muscle cultures may be at a stage early in development in which channels at extrajunctional regions still have some lateral mobility.

The sequelae of Na^+ channel accumulation at newly formed synapses is reminiscent of AChR cluster formation, where diffusely distributed AChRs cluster and become immobilized to the neuromuscular junction[16]. However, in contrast to AChRs, there do not appear to be regions of preexisting, dense, immobile Na^+ channel patches on uninnervated myotubes. Rather, all Na^+ channels are diffusely distributed and very mobile before innervation. The factors that specifically control the reorganization and subsequent immobilization of Na^+ channels are unknown. Apparently AChR clustering *per se* does not induce Na^+ channel clustering. Further, the specific recruitment of Na^+ channels and the conspicuous absence of Na^+ channels co-localizing with all AChR hotpsots suggest that the factors governing Na^+ channel cluster formation show some degree of temporal and molecular specificity. However, it is not clear whether the redistributed Na^+ channels originate from areas of diffuse Na^+ channel distribution on the uninnervated myotube or from an endogenous intracellular pool of newly synthesized Na^+ channels which preferentially appear at the synapse during the time of neuronal contact.

The localization and immobilization of Na^+ channels to the synapse is unexpected, for in muscle the action potential is propagated throughout the length of the fibre. The functional role of the high Na^+ channel density at the synapse is unclear but it has been proposed to raise the safety factor for impulse transmission[3]. Further experiments are required to elucidate the mechanisms by which the nerve induces the redistribution of Na^+ channels and the specific intra- and extracellular elements that maintain the elevated Na^+ channel density at the synapse.

I thank Dr Elliot Elson and David Loftus for use of the FPR equipment and for helpful discussions, the laboratory of Dr G. Fischbach, Washington University, for supplying some of the co-cultures, and Dr John Caldwell for careful reading of the manuscript and for invaluable comments. This work was supported by grants from the NIH (NS 18268) and the Muscular Dystrophy Association.

Single cyclic GMP-activated channel activity in excised patches of rod outer segment membrane

L. W. Haynes, A. R. Kay & K.-W. Yau

Department of Physiology and Biophysics, University of Texas Medical Branch, Galveston, Texas 77550, USA

The plasma membrane of retinal rod outer segments contains a cyclic GMP-activated conductance[1–6] which appears to be the light-sensitive conductance involved in phototransduction[7]. Recently, it has been found that this conductance is partially blocked by Mg^{2+} (refs 3, 8, 9) and Ca^{2+} (refs 3, 4, 8–11) at physiological concentrations, thus possibly accounting for the absence of observable single-channel activity in excised membrane patches[1,3,8] and for the unusually small apparent unit conductance deduced from noise measurements on intact cells[4,10,12,13]. We now report that, as expected from this idea, single cGMP-activated channel activity can be detected from an excised rod membrane patch in the absence of divalent cations. The most prominent unitary current had a mean conductance of ~25 pS. Both individual channel openings (mean open time ~1 ms) and short bursts of openings (mean burst duration of about a few milliseconds) were observed. In addition, there were smaller events which probably

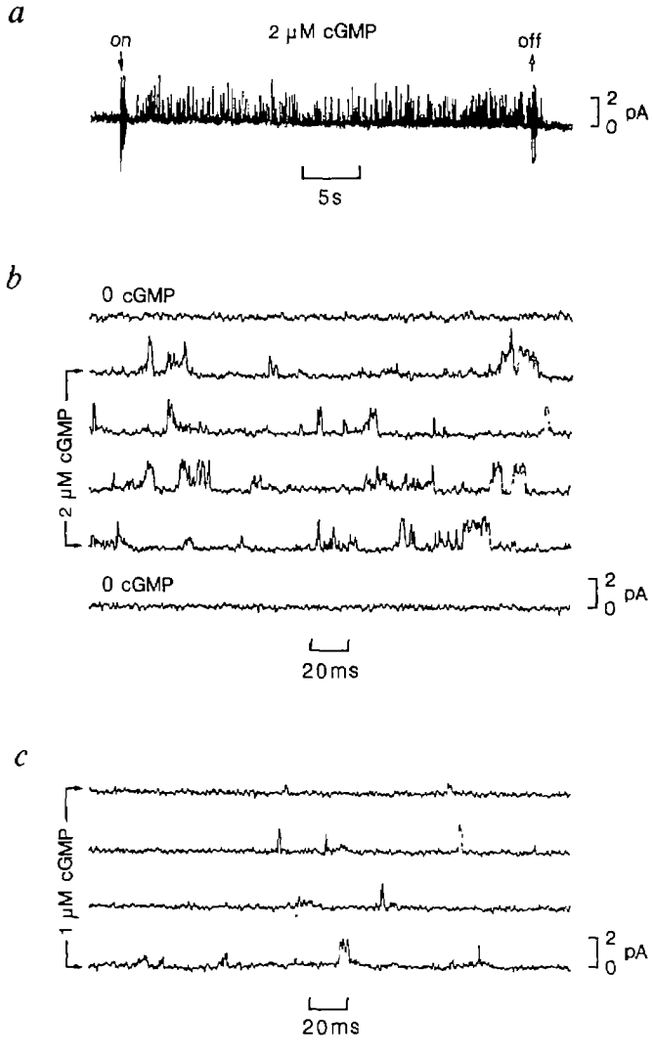

Fig. 1 Single cGMP-activated channels recorded from an inside-out membrane patch excised from a toad rod outer segment (ROS). Isotonic NaCl solution (118 mM NaCl, 0.1 mM Na-EGTA, 0.1 mM Na-EDTA, 5 mM Na-HEPES, *p*H 7.6) was present on both sides of the membrane. The holding potential was +60 mV (that is, interior of pipette being negative). All records were low-pass-filtered at 2 kHz (8-pole Bessel). *a*, Activation of single-channel activity by 2 μM cGMP. The 'on' and 'off' arrows indicate the times when tap movements were made to admit cGMP into the bath and to remove it. The ringing transients immediately following the on and off time markers were caused by vibrations from the tap movements. *b*, Samples of the same recording shown at a higher time resolution. Top trace, control recording before the admission of cGMP; bottom trace, control recording after removal of cGMP. The middle four traces, obtained in the presence of 2 μM cGMP, were not continuous in time, but were selected to illustrate various features associated with openings and closings of the cGMP-activated channels (see text). *c*, Recordings from the same patch at 1 μM cGMP.

Methods. All experiments, except for that in Fig. 4, were performed on ROS from the toad, *Bufo marinus*. The experiment in Fig. 4 was performed on a rod from the larval tiger salamander (*Ambystoma tigrinum*), simply because for a time we failed to obtain stable gigaohm seals from toad rods; other control experiments have indicated that the cGMP-activated channels in the salamander rod have properties similar to those in the toad rod. A piece of retina from a dark-adapted animal was incubated in the dark for 1 h in Ringer's solution containing 1 mg ml^{-1} hyaluronidase (Sigma type I-S), then finely chopped to yield many isolated rod outer segments[8]. The outer segments were then transferred to the experimental chamber and washed thoroughly with isotonic NaCl solution (see above) before recordings began. All recordings were made in visible light at room temperature (23–25 °C). The patch pipette, containing isotonic NaCl solution, was made of thick-walled borosilicate glass capillary and had a lumen diameter at the tip of ≤0.5 μm. The exterior of the pipette tip was coated with Sylgard to reduce electrical noise[30]. Current was measured with a List EPC-7 patch-clamp system in the voltage-clamp mode. Gigaohm seals were made on the plasma membrane of an outer segment near its tip, and the patch was then excised in the inside-out configuration by a gentle tap on the micromanipulator supporting the pipette[2,3,8]. The signals were stored on analog tape and subsequently digitized for analysis.

represented other states of the conductance. The mean current increased with the third power of cGMP concentration, suggesting that there are at least three cGMP-binding sites on the channel molecule. With 0.2 mM Mg^{2+} in the cGMP-containing solution, a flickering block of the open channel was observed; the effect of Ca^{2+} was similar. The results resolve a puzzle about the light-sensitive conductance by demonstrating that it is an aqueous pore rather than a carrier.

All experiments were done in visible light, with an isotonic NaCl solution (see Fig. 1 legend) present on both sides of the membrane. Figure 1*a* shows the current recorded from an excised, inside-out rod membrane patch held at +60 mV. With 2 μM cGMP in the bath, there were fluctuations which resembled the openings and closings of individual ion channels. The effect of cGMP was rapidly reversible. Figure 1*b* shows sample records at a higher time resolution. The most prominent unitary currents, which occurred both singly and in short bursts, had a mean amplitude of ~1.5 pA (see Fig. 2*a*), corresponding to a conductance of ~25 pS. Apart from the large unit currents there were also small events, but these were more difficult to analyse because their amplitudes were not significantly above background noise. The relationship between the small and the large events is not clear at present, though they probably represent different states of the same conductance. In Fig. 1*c*, the same patch was exposed to a lower concentration of cGMP: the frequency of events was lower, and the bursts of openings also seemed to be briefer.

Figure 2*a* shows probability density histograms of current amplitude obtained from the recordings illustrated in Fig. 1*a* and *b*. The solid profile is the histogram obtained in the presence of 2 μM cGMP, while the dashed profile is the control histogram scaled to the same height. The former histogram has two identifiable peaks: one centred at zero and the other at ~1.5 pA. As judged from the raw records, the non-zero peak appears to correspond to the mean amplitude of the large unitary events. The distribution centred at 0 pA overlapped with the control histogram quite well at negative current values, but at positive values there was excess probability density which reflected the contribution of the small events. From the histogram, we estimated that the probability of occurrence for the small events was roughly the same as that for the large events.

We have examined the kinetics of large events selected by a window, as indicated by the arrows in Fig. 2*a*. The open times of the events (low-pass-filtered at 1 kHz; see Fig. 2 legend) showed a roughly exponential distribution, with a time constant of 1.5 ms (Fig. 2*b*, left); the true value, however, was estimated to be ~1.0 ms after correcting for low-pass filtering[14]. The burst times (Fig. 2*b*, right) were also roughly exponentially distributed, with a time constant of 3.3 ms. A similar analysis of the single-channel activity at 1 μM cGMP (that is, Fig. 1*c*) gave a comparable channel open time (uncorrected time constant = 1.3 ms) but a shorter burst time (time constant = 2.4 ms). The significance of this concentration-dependent difference is unclear. It should be emphasized that even though there was little stacking of events at the low concentrations of cGMP used, the successive events did not necessarily reflect activity from the same channel molecule, because many channels were gen-

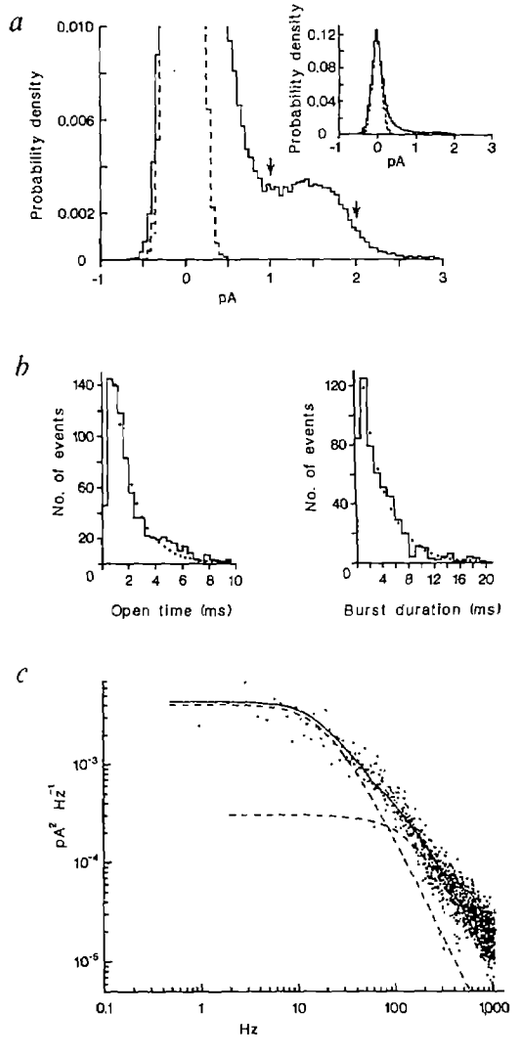

Fig. 2 Analysis of the single-channel records illustrated in Fig. 1*a* and *b*. The automated single-channel analysis program of Sachs *et al.*[31], implemented by Lingle (Florida State University) for the IBM PC, was used to produce the plots shown in *a* and *b*. Before analysis, the data were first filtered at 2 kHz with an 8-pole Bessel filter and digitized at 5 kHz, then further filtered at 1 kHz with a digital Gaussian filter to reduce background noise. *a*, Probability density histrogram of current amplitude (continuous profile) in the presence of 2 μM cGMP. The dashed profile indicates the control histogram obtained after the removal of cGMP; it has been scaled to the same height as the one with cGMP. To compute each histogram, the entire stretch of recording was divided into consecutive sections each 102.4 ms long. The baseline for each section (corresponding to 0 pA on the histograms) was located using an algorithm that maximizes the number of crossings through a horizontal line, and the probability density distribution (bin width 0.05 pA) was then determined. The control histogram was fitted well by a Gaussian distribution with a standard deviation of 0.12 pA. A similar control histogram obtained before the application of cGMP was also fitted by a Gaussian distribution with a standard deviation of 0.15 pA. The non-zero peak of the histogram obtained at 2 μM cGMP is situated at −1.5 pA, and corresponds to the mean amplitude of the large unitary events (see text). The arrows indicate the amplitude window used for computing the time histograms for the large events (see *b*). Inset, the same plots at reduced scales. The probability density histogram for the recordings at 1 μM cGMP (that is, Fig. 1*c*) was similar to the histogram for 2 μM shown here; the non-zero peak was in the same place, but the overall probability for non-zero amplitudes was less, as expected from the relative paucity of events. *b*, Histograms of open times and burst durations for the large events. The amplitude window chosen for analysing these large events (1.0–2.0 pA) also served to minimize the inclusion of stacked events. A burst was defined as either a single-channel opening or a collection of consecutive openings separated by closed periods ≤2 ms. This value was deduced from the closed-time distribution, which could be fitted by the sum of two exponentials, with the shorter time constant (~2 ms) representing the intra-burst closures. The dots in each plot indicate a single exponential fitted to the histogram. The time constant was 1.5 ms for the open time distribution and 3.3 ms for the burst-time distribution. The fall in probability density for short times in each histogram was due to low-pass filtering. *c*, Power density spectrum for the records in Fig. 1*b*. The raw records in this case were low-pass-filtered at 1 kHz (8-pole Butterworth) and digitized at 2 kHz. The control spectrum obtained in the absence of cGMP has been subtracted. The dashed curves indicate Lorentzians with corner frequencies of 20 Hz and 150 Hz respectively, corresponding to time constants of 8 and 1 ms. The continuous curve is the sum of the two Lorentzians.

erally present in a patch (see below). Therefore, the closed-time distribution was of limited usefulness and will not be described here.

Figure 2*c* shows the power spectrum for the current records at 2 μM cGMP. It can be fitted approximately by the sum of two Lorentzians, with characteristic time constants of ~1 ms and 8 ms respectively. The short time constant is comparable in value to the mean open time of the large events, while the long time constant is probably related to the burst times. Interestingly, the short time constant is rather similar to values obtained by others from noise measurements on intact cells[4,10,12,13]. It is difficult, however, to make an exact comparison between the power spectral analysis and the kinetic analysis because, among other reasons, both large and small events contributed to the power spectrum.

An analysis similar to those in Fig. 2*a*, *b*, performed on data from three other patches (all at +60 mV and 1–2 μM cGMP), gave comparable mean unit amplitudes (1.4–1.5 pA) and time constants (event open time 1.4–1.6 ms, burst duration 1.6–3.3 ms, 1-kHz filter). As a comparison, the power spectra obtained from four experiments (1–5 μM cGMP, +60 mV) gave a short time constant of 0.9–1.5 ms and a long time constant of 7–11 ms. At frequencies ≥1 kHz, the power spectra often showed some residual power density which could not be accounted for by just two Lorentzians. In experiments where channel openings were also studied at −60 mV (see, for example, Fig. 3*c*), the events were inverted in polarity and had shorter open times (see legend to Fig. 3*c*). Nevertheless, the latter events had amplitudes similar to those at +60 mV. Thus, the current-voltage relation for the unitary conductance seems to be roughly linear, which agrees with our previous conclusion from macroscopic current measurements—that is, a large part of the outward rectification observed in physiological solutions is the result of a voltage-dependent block by divalent cations[3,8,9].

One advantage of removing divalent cations from the solutions is that a much larger cGMP-induced current is obtained[3,8,9]; this permits the activation of current by cGMP to be studied at very low concentrations of the activator. Figure 3*a* shows one such experiment performed at −30 mV. As the cGMP concentration increased, the single-channel events gradually summed to give a noisy, steady current. No obvious desensitization was evident even after prolonged (>1 min) applications of cGMP. The large amplitude of the saturated current compared with the single-channel current indicated that many channels must be present in the membrane patch, a conclusion arrived at for all the experiments that we analysed. We have attempted to estimate the channel density on the membrane, but this was complicated by the finding that the saturated current amplitude showed large variations (up to almost 100-fold) in different experiments, with little correlation to the apparent patch size (as judged visually). Assuming an average patch size of 0.2 μm^2 (as estimated from the pipette tip lumen) and assuming that at saturating cGMP concentrations each channel molecule is conducting current about half the time, the high and low estimates for the channel density would be 3,000 and 30 μm^{-2}, respectively (average ~1,000 μm^{-2}, 18 patches). Taking a rhodopsin density on the surface membrane of 30,000 molecules μm^{-2}, the channel/rhodopsin mole ratio

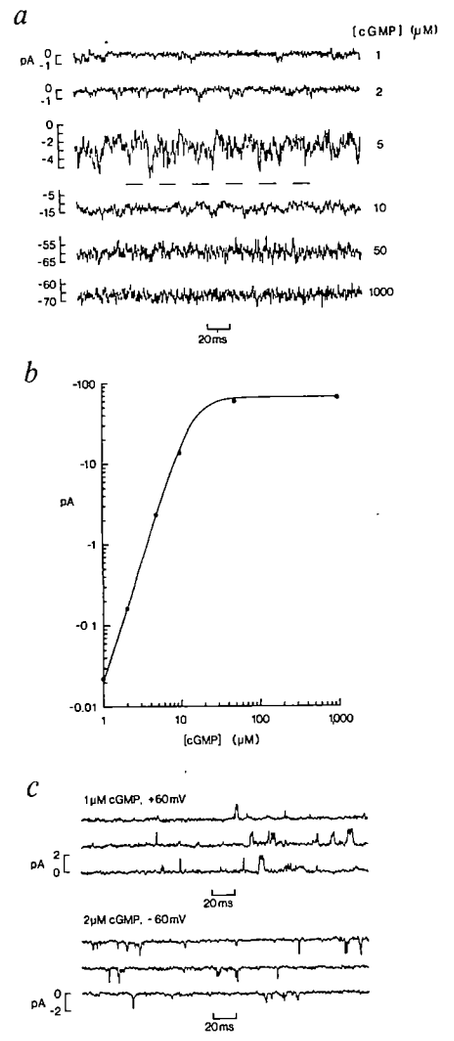

Fig. 3 *a*, Activation of current in toad rod patch at different concentrations of cGMP. Holding potential −30 mV. Records were filtered at 1 kHz. The top three and bottom three traces have different amplitude scales. Note the sustained current fluctuations even at a saturating cGMP concentration. In addition, at 50 μM and 1,000 μM cGMP, there were also slow fluctuations which are not apparent in the records shown here because of the fast time scale. Total current variances (d.c. to 1 kHz) at the different cGMP concentrations were: 0.01 pA^2 (1 μM), 0.08 pA^2 (2 μM), 1.15 pA^2 (5 μM), 6.33 pA^2 (10 μM), 14.56 pA^2 (50 μM) and 13.60 pA^2 (1 mM). *b*, log–log plot of mean current against cGMP concentration. The mean currents were computed from the records shown in *a*. Smooth curve is drawn according to the Hill equation: $j(C) = -67\ pA \times [C^3/(C^3+15^3)]$, where C is the cGMP concentration mean current. *c*, Effect of membrane potential on current activation by cGMP. Different toad rod patch from that in *a* and *b*. Only sample records are shown. Low-pass-filtered at 2 kHz. Analysis of the complete recordings indicated that the frequency of channel activation was about 2.5 times higher for 1 μM cGMP/+60 mV than for 2 μM cGMP/−60 mV. Open time constant (1-kHz filtering) was 1.4 ms at +60 mV and 0.8 ms at −60 mV.

would be between 1:10 and 1:1,000 (average ~1:30). The wide range of channel density estimates suggests that there may be a local clustering of channels on the plasma membrane. Previous estimates based on noise measurements from intact cells were between 100 and 200 channels per μm^2 (refs 10, 13). It is interesting that the current fluctuations remained high even at saturating cGMP concentrations (Fig. 3*a*); this perhaps suggests that the binding of cGMP molecules to the channel is an event separate from (though causally related to) the opening and closing of the channel. In other words, a channel molecule can

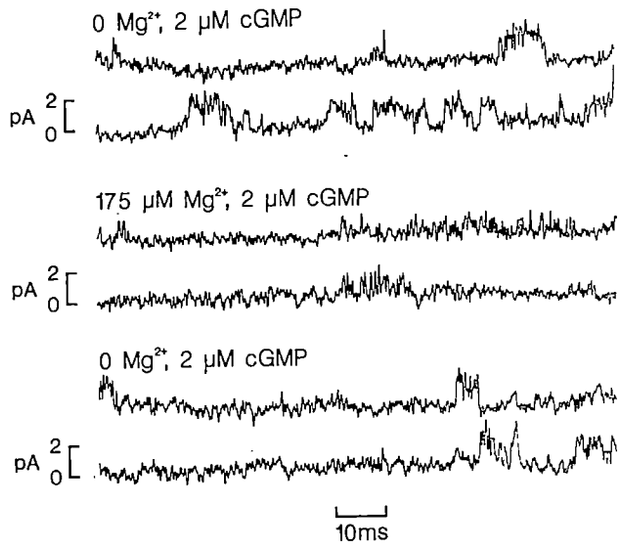

Fig. 4 Flickering block of the open-channel current by Mg^{2+}. Mg^{2+} was added only to the cGMP-containing solution in the bath, while the pipette solution still contained no divalent cations. Holding potential +60 mV, salamander rod patch (see Fig. 1 legend). Top two and bottom two traces were obtained with 0 Mg^{2+}; middle two traces with 175 μM $MgCl_2$ (no Na-EGTA or Na-EDTA; see Fig. 1 legend). To show the flickering blockade more clearly, the records have been low-pass-filtered at 5 kHz instead of the usual 2 kHz.

open and close repeatedly while still binding cGMP; this same mechanism may also explain the burst phenomenon[15]. Figure 3*b* shows the relation between mean current and cGMP concentration based on the records of Fig. 3*a*. The current increased with the third power of cGMP concentration (that is, the Hill coefficient, n, was 3), with a half-saturating cGMP concentration ($K_{1/2}$) of ~15 μM. Collected results gave an n of 2.9 ± 0.4 (mean ± s.d., 15 experiments) and $K_{1/2}$ of 14–45 μM at −30 mV (6 experiments). The n value here is higher than previous measurements made in the presence of divalent cations[1,3,6,7], but is probably more reliable because the current could be resolved down to lower cGMP concentrations. Still, an influence of divalent cations on the Hill coefficient cannot be ruled out. The $K_{1/2}$ values, on the other hand, are broadly consistent with previous measurements[1,3,6,7]. There was also an effect of membrane potential on current activation, in that at depolarizing voltages it took a lower concentration of cGMP to elicit a comparable frequency of events (Fig. 3*c*). This voltage effect, however, was not very large, with $K_{1/2}$ decreasing by only ~40% between −40 mV and +40 mV (2 experiments), or an estimated e-fold reduction over ~160 mV. The Hill coefficient, on the other hand, did not show any obvious voltage dependence. These observations are similar to previous results in cone patches[8].

Figure 4 shows an example of the effect of divalent cations on the current. With 175 μM Mg^{2+} in the bath, the prominent step changes in the current induced by cGMP were no longer observed. Instead, there were clusters of relatively high-frequency flickers, which most probably reflected blockage of the open channel[16]. In other experiments we found that Ca^{2+} had a similar effect, though a higher concentration was required (at least at depolarizing voltages). A flickering block by divalent cations has been observed previously for the glutamate-activated channel in mouse brain[17], as well as for the Ca-channel[18] in conditions where the current is carried by monovalent cations[19–21]. Indeed, the cGMP-activated (or light-sensitive) conductance has certain properties in common with Ca-channels, in that besides the blockade by divalent cations of current carried by monovalent cations, it is also highly permeable to divalent cations[22–28]. Both the blockade and the ion selectivity

can perhaps be explained, as has been proposed for the Ca-channel[21,29], by the presence of binding sites in the channel with different affinities for monovalent and divalent cations.

Thus our results demonstrate that the light-sensitive conductance is a pore rather than a carrier; this confirms a recent inference from noise measurements on intact cells[10]. As the Hill coefficient for current activation is near 3, there must be at least three cGMP binding sites per channel molecule. At present, however, we do not know the details of the kinetic scheme governing the channel activation by cGMP.

We thank Dr Kei Nakatani for invaluable help, Drs Philip Palade and Robert Wong for encouragement and for loaning equipment, and Drs Denis Baylor, Malcolm Brodwick and Philip Palade for discussions. Dr Chris Lingle provided us with an implementation (for the IBM PC) of the single-channel analysis program developed by Dr Frederick Sachs and co-workers. L.W.H. was supported in part by a Fight For Sight Inc. (New York) Research Fellowship; the work was supported by the US National Eye Institute and the Retina Research Foundation, Houston, Texas.

Cyclic GMP-sensitive conductance of retinal rods consists of aqueous pores

A. L. Zimmerman & D. A. Baylor

Department of Neurobiology, Stanford University School of Medicine, Stanford, California 94305, USA

The surface membrane of retinal rod and cone outer segments contains a cation-selective conductance which is activated by 3′,5′-cyclic guanosine monophosphate (cGMP)[1–4]. Reduction of this conductance by a light-induced decrease in the cytoplasmic concentration of cGMP appears to generate the electrical response to light (reviewed in refs 5, 6), but little is known about the molecular nature of the conductance. The estimated unitary conductance is so small[1,7–9] that ion transport might occur via either a carrier or a pore mechanism. Here we report recordings of cGMP-activated single-channel currents from excised rod outer segment patches bathed in solutions low in divalent cations. Two elementary conductances, of ~24 and 8 pS, were observed. These conductances are too large to be accounted for by carrier transport, indicating that the cGMP-activated conductance consists of aqueous pores. The dependence of the channel activation on the concentration of cGMP suggests that opening of the pore is triggered by cooperative binding of at least three cGMP molecules.

The cGMP-activated conductance of excised patches from salamander rod outer segments was greatly increased when both sides of the patch were bathed in solutions containing a very low concentration of divalent cations. For five patches in low concentrations of divalent cations (total less than 1 μM) the maximal agonist-induced conductance at +50 mV was 15.9 ± 2.1 nS (mean ± s.e.m.), while for 13 patches prepared similarly but studied in solutions with normal levels of divalent cations (external Mg^{2+} concentration ($[Mg]_o$) 6 mM; internal Mg^{2+} concentration ($[Mg]_i$) 3 mM; 1.5 mM $[Ca]_o$) it was 194 ± 27 pS. These results indicate that decreasing the concentration of divalent cations increased the cGMP-sensitive conductance by roughly two orders of magnitude.

Figure 1 shows dose–response relations for the cGMP-sensitive current of patches in 'low divalent' solutions. The cGMP-activated current of each patch is expressed relative to the maximal value; cGMP concentrations were normalized by the estimated half-saturating concentration, $K_{0.5}$, which ranged from 5.3 to 12 μM, with an average value of 9.6 μM. The solid curve was drawn according to the Hill equation: $r/r_{max} = G^3/(1+G^3)$, where r/r_{max} is the normalized response and G is the concentration of cGMP divided by $K_{0.5}$. This equation would apply if opening of a channel required the binding of at least three molecules of cGMP, and if the binding were strongly cooperative. The dashed curve, which gives a poorer fit, was drawn according to $r/r_{max} = (G/[1+G])^3$; this relation is expected if opening requires binding to three independent sites of equal affinity. Somewhat smaller power exponents have been reported from experiments with higher concentrations of divalent cations[1,3,10,11], where the smaller size of the agonist-induced currents prevented measurement of the foot of the dose–response relation.

Figure 2 shows the current obtained from an excised patch at a holding potential of +50 mV. Application of 0.5 or 1 μM cGMP to the cytoplasmic side of the patch caused outward current pulses, which were much more frequent at the higher dose. Removal of cGMP abolished the pulses, demonstrating that they did not result from disruption of the membrane or seal.

Selected records from the experiment of Fig. 2 are plotted on an expanded time base in Fig. 3*A*, which shows unitary outward currents with a mean amplitude close to 1 pA and widely variable durations. For the patch potential of +50 mV the underlying conductance change is 20 pS. In some traces there was a suggestion of smaller events of amplitude ~0.3 pA (conductance = 6 pS). Such smaller events are better resolved in the experiment of Fig. 4. Similar experiments on a total of nine patches gave, for the large and small transitions, mean conductance changes of 23.7 ± 4.1 and 7.7 ± 1.4 pS (mean ± s.d.), respectively. In one experiment the amplitude of the single-channel currents varied approximately linearly with holding potential between −100 and +50 mV.

Figure 3*B* presents further evidence for the quantal nature of the current transitions in the experiment of Fig. 2. The control amplitude histogram (Fig. 3*B*, *a*) is approximately gaussian, with a width at half height of 0.3 pA. The histogram for 0.5 μM cGMP (Fig. 3*B*, *b*) shows a small additional hump between 0.3 and 1 pA. In 1.0 μM cGMP (Fig. 3*B*, *c*) there are two peaks centred at amplitudes of 0 and 0.8 pA, with a smaller hump at ~1.6 pA. The form of the three histograms is consistent with quantal agonist-induced currents of ~0.8 pA, like those in

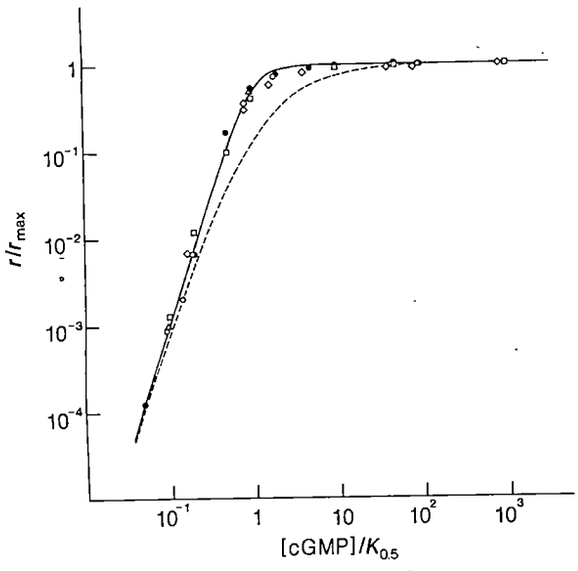

Fig. 1 Dose-response relation for activation of the cGMP-sensitive conductance of excised rod outer segment patches in low divalent solutions. Results from five patches, each plotted using a different symbol. The ordinate is the cGMP-activated current (r) relative to the maximal value (r_{max}), while the abscissa is the cGMP concentration relative to the estimated half-saturating concentration $K_{0.5}$. The curves were calculated from equations described in the text. Saturating currents and values of $K_{0.5}$ for each patch were as follows. ○: 1,021 pA, 5.3 μM; △: 116 pA, 10.5 μM; ◇: 834 pA, 12 μM; □: 774 pA, 10.0 μM; ●: 1,234 pA, 10.0 μM.

Methods. Patches were excised from the distal tip of isolated salamander rod outer segments, which were prepared in the light[1] and cleaned by exposure for 5 min to ~0.5 mg ml^{-1} hyaluronidase (Cooper, HSEP, 5474). Patches were studied in symmetrical solutions consisting of either nominally 0 divalent Ringer's, containing (in mM): NaCl 111, KCl 2.5, EDTA 0.02, *p*H 7.6 HEPES buffer 3.0, dextrose 10, sucrose 22.5 (solution A); or NaCl 128.5, *p*H 7.6 HEPES buffer 2.0, $MgCl_2$ 0.02, EDTA 0.20 (solution B), calculated to give a free Mg concentration of 10^{-7} M and a free Ca concentration $<10^{-7}$ M. cGMP was applied to the cytoplasmic side of the patches by perfusion through the recording chamber. The patch potential was held at +50 mV (cytoplasmic side positive), and the cGMP-activated current determined as the difference between the currents in the presence and absence of cGMP.

Fig. 3*A*. Analysis of histogram *c* in Fig. 3*B* showed that the valley between the main peaks was higher than expected from the summation of two gaussians, perhaps because of the presence of the smaller events. Furthermore, the histogram was not well fitted by a Poisson distribution constructed on the assumption that there were only large events and that they summed linearly; based on this model more samples are expected near an amplitude of $2 \times 0.8 = 1.6$ pA, given the small magnitude of the peak near 0 pA.

Analysis of the fluctuations in the macroscopic cGMP-activated current provided evidence that single-channel currents like those described above sum to produce the current at higher concentrations of cGMP. In four experiments the apparent single-channel current amplitude $\bar{a}$ was estimated from the slope of the relation between the mean response r and the scaled cGMP-induced variance, $\sigma^2 r_{max}/(r_{max} - r)$, which was determined over a bandwidth of only 100 Hz in order to minimize high-frequency noise arising from fast conductance fluctuations in activated channels. For values of r up to half-saturating, $\bar{a}$ was 0.46 ± 0.07 pA (mean ± s.d.) at +50 mV. This value of $\bar{a}$ falls between the mean amplitudes of the large and small transitions that were measured directly at low cGMP concentrations.

Single-channel currents of 0.3 or 1 pA are 100 times larger than those mediated by a variety of membrane carriers[12], sug-

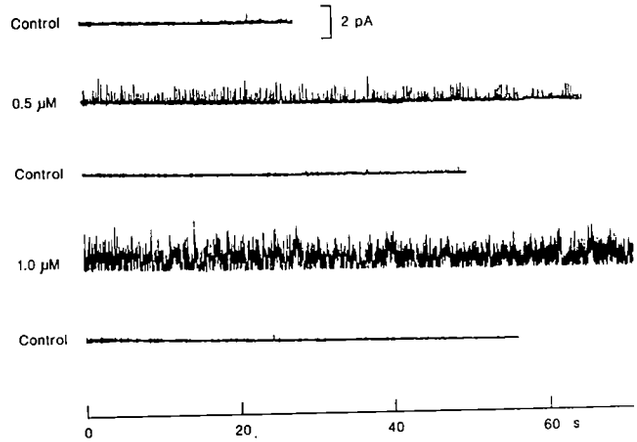

Fig. 2 Currents from an excised patch during application of low concentrations of cGMP to the cytoplasmic side. The patch was in the low divalent solution (A) of Fig. 1 legend. The recording is continuous except for interruptions at the ends of the traces, where the chamber was perfused for solution changes. Patch potential +50 mV, outward change in membrane current plotted upward. Bandwidth 0–100 Hz, temperature 21.8 °C, leakage resistance 10 GΩ.

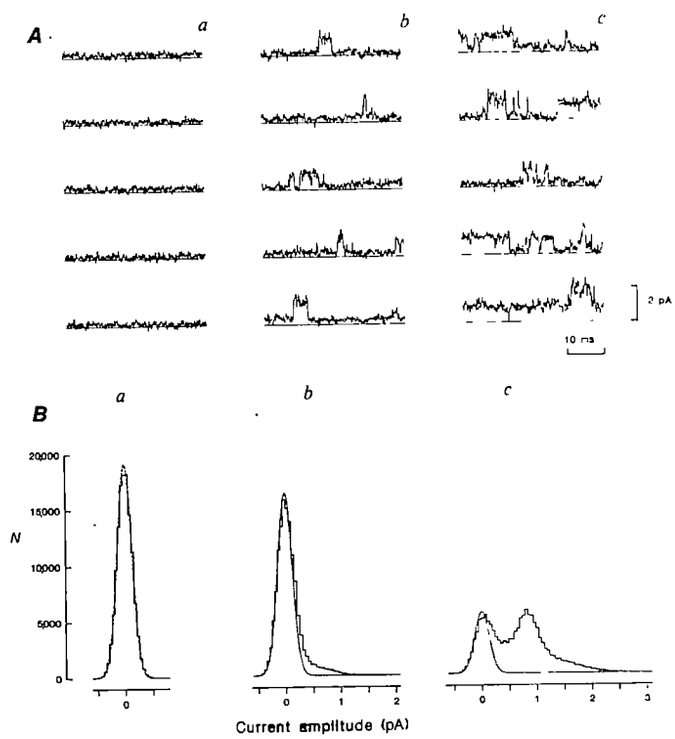

Fig. 3 Characteristics of the cGMP-induced patch currents from the experiment of Fig. 2. *A*, Sample patch currents from control, 0.5 μM cGMP and 1.0 μM cGMP runs (*a*–*c*, respectively). Lines beneath the traces were drawn at the same absolute current level. Recordings were high-pass-filtered with a single pole filter of time constant 10 s to remove a steady d.c. drift of 0.003 pA s^{-1}. Low-pass filtering was at 2 kHz (−3 dB point, 8-pole Bessel filter; Frequency Devices). Each sweep consists of 512 points acquired at a sampling rate of 10 kHz. *B*, Amplitude histograms from the experiment of Fig. 2 (*a*–*c* same as for *A*). Each histogram was prepared from 250 sweeps filtered and sampled as in *A*. The control histogram (*a*) was constructed from 50 sweeps from the initial control run and 100 sweeps from each of the later control runs of Fig. 2. Dashed curves are gaussian distributions with standard deviation $\sigma = 0.134$ pA, the measured value of r.m.s. noise in the control sweeps. The scaling of the gaussians corresponds to baseline probabilities, P_0, of 0.855 (0.5 μM) and 0.289 (1 μM). The average number of open channels, calculated from $-\ln P_0$, was 0.157 (0.5 μM) and 1.24 (1.0 μM).

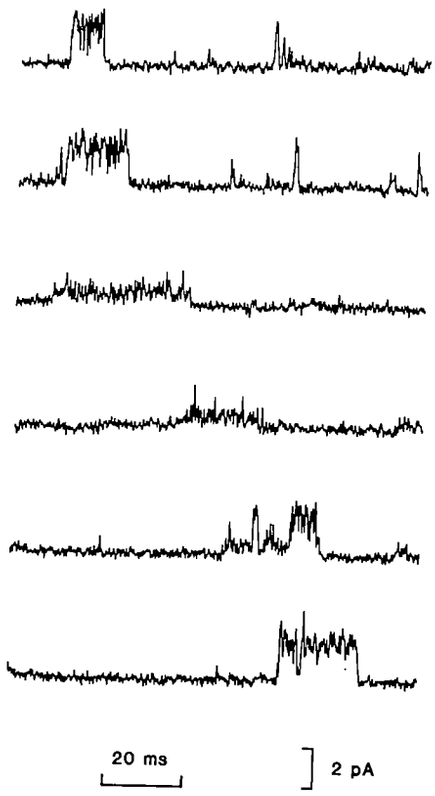

Fig. 4 Evidence for two activated states having different mean conductances. The currents are from an excised patch exposed to 0.5 μM cGMP; holding potential +75 mV, bandwidth 0–2 kHz, sampling rate 10 kHz. The patch was in solution B of Fig. 1 legend. Leakage resistance 10 GΩ.

gesting a pore mechanism of conduction. The effect of divalent cations in reducing the conductance might be explained by assuming that ions move through the channel in single file and encounter one or more binding sites with a high affinity for divalent cations. Divalent cations would pass through the channel[13–15], but with a long transit time, giving a very small time-averaged single-channel current under normal conditions[8].

The total number of channels in a patch can be estimated from the ratio of the current at saturating cGMP concentration to the single-channel current. In the experiments of Fig. 1, the saturating currents averaged 800 pA (range 116–1,234 pA). Taking the single-channel current as 1 pA and the patch area as roughly 2 μm^2, the apparent channel density is ~400 μm^{-2}. A channel density of 200 μm^{-2} was estimated from an analysis of the light-sensitive current noise of whole rods[9]. These rough estimates seem to be in satisfactory agreement, supporting the identity of the light-sensitive and cGMP-sensitive channels.

The large and small conductance states are illustrated in the records of Fig. 4, obtained from a patch held at +75 mV. The upper two traces show outward currents of ~1.9 pA mean amplitude (conductance 25 pS), while the middle two traces show smaller events with a mean amplitude of ~0.7 pA (conductance 9 pS). Both types of currents were noisy, suggesting that there were conductance fluctuations so fast that the method did not resolve them. The two lower traces in Fig. 4 illustrate events suggestive of transitions between the small- and large-conductance states: the highest current level is comparable to the large amplitude alone, rather than to the sum of the large and small amplitudes. It remains to be determined whether the two states have the same peak instantaneous conductance.

We conclude that the cGMP-activated channel of retinal rods is an aqueous pore which has a very small effective conductance in the presence of physiological concentrations of divalent cations. The small conductance is appropriate to give low quantizing noise in the small, stereotyped signals that encode photon absorption[16]. The cubic dependence of channel opening on cGMP concentration makes the channel an efficient molecular switch which is very sensitive to the local cGMP concentration.

We thank Dr K.-W. Yau for suggestions on divalent cation effects, Drs L. Stryer and R. Aldrich for discussions, and Mr R. Schneeveis for technical help. This work was supported by grant EY01543 from the National Eye Institute, USPHS.

Neural control of the forms of acetylcholinesterase in slow mammalian muscles

Josephine Lai*, Jolanta Jedrzejczyk†, John A. Pizzey‡, David Green & Eric A. Barnard§

Department of Biochemistry, Imperial College of Science and Technology, London SW7 2AZ, and MRC Molecular Neurobiology Unit, MRC Centre, Hills Road, Cambridge CB2 2QH, UK

The 'heavy', collagen-tailed form of acetylcholinesterase (AChE), having a $s^{\circ}_{20,w}$ of 16S in mammals, occurs at vertebrate muscle endplates and has been widely regarded as a marker of neuronal influence on muscle *in vivo*[1–5]. However, an interesting exception has been described by Bacou *et al.*, in a previous report in *Nature*[6]. They found, in a slow-twitch muscle of the rabbit, that after denervation the 16S form of AChE increases markedly, rather than disappearing. Such a phenomenon would modify current concepts of neuromuscular regulation. We report here, however, that this exception is apparent rather than real in terms of endplate AChE regulation.

The rabbit semimembranosus muscle was described by Bacou *et al.*[6] as containing an 'external region I' composed of fast-twitch glycolytic muscle (type IIB), surrounding an 'internal conoidal region II' containing only slow-twitch (type I) fibres. In fact, these prominent rabbit leg muscles have previously been named, respectively, as the semimembranosus accessorius (SA) and the semimembranosus proprius (SP) muscles[7,8]; the SA has been shown in rabbits to contain 86% type IIB, 12% type IIA and 2% type I fibres[9], while the SP contains 100% type I fibres. These values hold in our rabbits.

The AChE concentration in the normal rabbit SP (Fig. 1*a*) differs in our analyses from that reported[6]. The 16S form is major, not minor, and the light forms are mainly the 6S (dimeric),

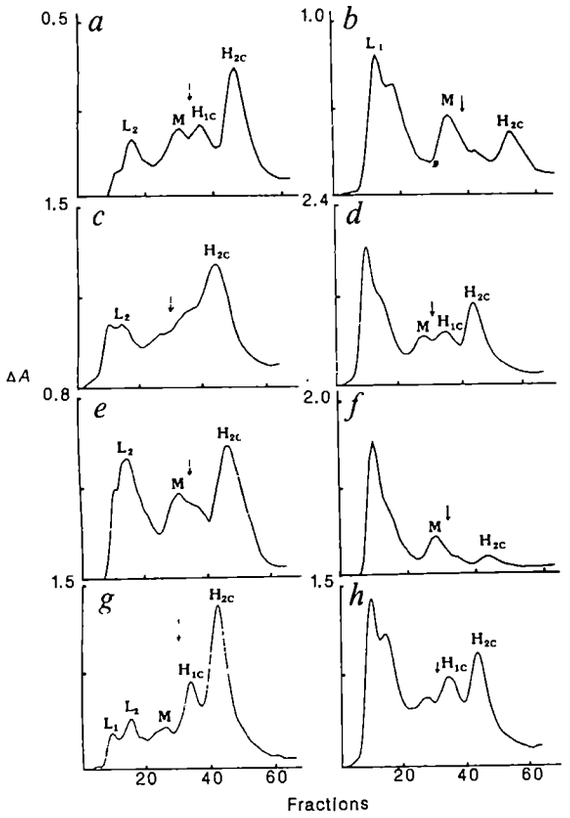

Fig. 1 Sucrose density gradient profiles of AChE in control and chronically denervated (4 weeks) muscles. Right-hand panels show denervated muscles, left-hand panels show control muscles. *a*, *b*, Rabbit SP; *c*, *d*, guinea pig SP; *e*, *f*, rabbit soleus; *g*, *h*, guinea pig soleus. The amounts of control tissue taken were 1.3–1.7 times those of the denervated tissues. M denotes the presumed tetrameric, globular form and H_{1c} the smaller collagen-tailed form, ~13S, which has fewer catalytic units than the maximum in the H_{2c} (~16S) form[1]. L_1 and L_2 denote, respectively, the ~4S and ~6S forms. AChE activity is in units of absorbance change (ΔA)[1] (note the different scales). The total centrifugal force used varied: arrows show the catalase (11.4S) internal marker.

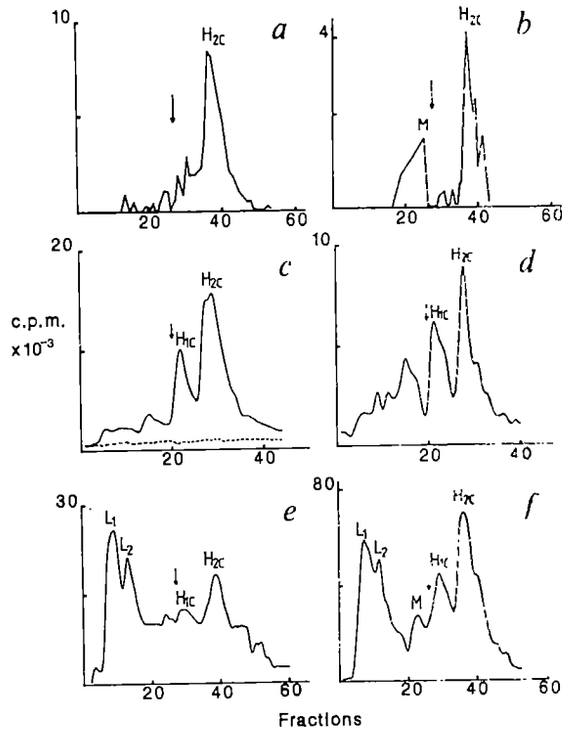

Fig. 2 Sucrose density gradient analysis of AChE (fractions assayed on ^{3}H-acetylcholine)[15] in the endplate (left-hand panels) and the non-endplate (right-hand panels) regions of slow-twitch muscles. *a*, *b*, Rabbit SP; *c*, *d*, guinea pig soleus; *e*, *f*, denervated guinea pig soleus. Endplates and non-endplate segments were microdissected[15] from the same fibres; 20–50 endplates (with the minimum of underlying fibre) or the same number of non-endplate segments (the latter about five times the length of an endplate and cut transversely across the whole fibre) were extracted for 60–90 min at room temperature in 0.25 ml of the extraction buffer described in Table 1 legend and all was applied. A blank was run in parallel with an identical extract, and was assayed in the presence of 10^{-4} M isooctamethyl pyrophosphoramide and 5×10^{-5} M BW284C51 (see ref. 15) to inhibit all cholinesterases: this is illustrated by the broken line in *c*, while in *a*, *b*, *e*, *f* the blank has already been subtracted throughout. The total force and the fraction size used varied, the arrow shows the catalase marker, and only the horizontal pairs can be compared in the amounts. Labelling of peaks is as in Fig. 1. Note that the smaller collagen-tailed form, H_{1c}, is also prominent in the guinea pig muscle both in and outside the endplate. Similar profiles were found when repeated on other guinea pigs and rabbits: see Table 1 for the means of the contributions of the L and H_{2c} peaks in all the experiments.

not the 4S (monomeric), AChE. Equivalent differences in the SA were also found (Table 1). We attribute these differences to our use of more antiproteases (see Fig. 1 legend) and to particularly rapid processing. When these precautions were relaxed, profiles similar to those reported[6] were obtained. High 4S AChE in mature muscles is generally a marker of proteolytic breakdown[1,4,10]. Hence, the starting concentration of SP 16S AChE was much higher than that (only 9.5% of the total AChE) found previously[6]. After complete denervation (see below) for 2–4 weeks, the contribution of the 16S form to the total AChE declined greatly in both muscles (Fig. 1*b*, Table 1). Similar behaviour was observed in other denervated slow-twitch muscles, that is, the SP of the guinea pig (which we have identified as being similar anatomically and in fibre types to rabbit SP), as well as rabbit and guinea pig soleus muscles (Fig. 1*c*–*h*).

It has been frequently reported that mammalian muscles lose nearly all of their 16S AChE when the maximum effect of denervation is attained[3,5,11]. We found, however, that although there was a decline in the 16S form, some persisted throughout, with higher concentrations remaining in certain slow-twitch muscles (Fig. 1, Table 1). Further, on chronic denervation, the AChE concentration (and the AChE content per entire muscle) may either decrease (the most usual case) or increase, depending on the species; rabbit[12] and chicken[10] were previously known to behave exceptionally in increasing their muscle AChE. We find that the guinea pig is also in that group. In those three species a long-lasting increase of severalfold occurred in the AChE concentration in both fast and slow muscles after denervation, and despite the muscle weight loss (to the order of one-half, at the maximum here) the total content of AChE per muscle did not decline but increased further. Nevertheless, the proportion of 16S AChE in the slow muscles was much reduced, while the 16S AChE per entire muscle remained about constant or again decreased (Table 1). The overall increase in AChE was contributed by the lighter forms. In the fast fibres the 16S AChE per entire muscle always declined greatly on denervation.

Another technical reason for the difference in findings may be the surgical procedure involved. We fully denervated both SP and SA, by cutting all relevant branches of the sciatic and obturator nerves (a branch of the latter giving an additional

Table 1 Changes in AChE activities in slow- and fast-twitch muscles on denervation

Species	Muscle	Control [AChE] (U g^{-1})	n	Ratio of denervated to control (basis)	all forms	L	16S	L (%)	16S (%)
Rabbit	SP (100% slow)	0.6±0.07	7	(total)	1.7±0.3	2.7	1.2	55(16)	19(54)
				(conc.)	4.4±0.7	7.0	3.0		
	Soleus (96% slow)	0.6±0.07	6	(total)	1.3±0.3	3.1	0.4	72(33)	10(42)
				(conc.)	2.5±0.4	5.8	0.7		
	SA (98%) fast)	0.5±0.03	7	(total)	1.6±0.1	4.4	0.3	73(26)	10(44)
				(conc.)	3.7±0.8	10.3	0.8		
Guinea pig	SP (100% slow)	0.7±0.04	5	(total)	1.7±0.2	3.0	1.0	48(27)	25(43)
				(conc.)	3.5±0.3	6.2	2.0		
	Soleus (100% slow)	0.5±0.05	6	(total)	1.5±0.3	2.0	0.7	44(17)	25(71)
				(conc.)	3.0±0.4	4.0	1.3		
	SA (99% fast)	0.6±0.01	5	(total)	1.2±0.1	2.8	0.4	60(32)	13(44)
				(conc.)	2.7±0.4	6.2	1.0		
	EDL (94% fast)	0.8±0.02	3	(conc.)	1.3±0.2	2.2	0.4	62(30)	14(51)

Values given are the ratios of the activity of specified AChE forms in the denervated muscles relative to that of the corresponding activity in the contralateral control muscles: the ratio of the activities is expressed either on the basis of per gram (wet weight) of muscle ('conc.') or (for the same specimens) on the basis of the entire muscle content ('total'). The mean ±s.e.m. for n denervated animals sampled is given for each muscle type. (Where s.e. is not shown, it was of the same relative order as given for that muscle or ratio.) The last two columns show the % of the muscle AChE of the denervated muscle (or, in parentheses, of the control muscle) contributed by all the L (~4S and ~6S) forms, or by the 16S form. The difference of their sum from 100% is all accounted for by the forms sedimenting in the region of the M (10S) and H_{1c} (13S) peaks (see Fig. 1), whose poor resolution frequently prevents accurate computation. The fibre typing noted shows the % of type I fibres (slow) or type II fibres (fast) in these muscles. The soleus or extensor digitorum longus (EDL) muscles of New Zealand White rabbits (~3 kg) or Dunkin–Hartley guinea pigs (2 months old) were denervated by sectioning the lower branch of the sciatic nerve. The SP of the rabbit was fully denervated by sectioning the branches of the sciatic nerve, the cutaneous caudal femoral nerve and the obturator nerve to that muscle[8]. Similarly, the guinea pig SP was denervated by cutting the branches of the sciatic nerve, the cutaneous caudal femoral nerve, the femoral nerve and the saphenous nerve to that muscle. The rest of the limb remained mobile in each case. The control (contralateral) and denervated muscles were analysed for their AChE content 4 weeks later. Changes in the same direction, but to a lesser extent, were seen in other cases analysed after 2 or 3 weeks of denervation. For AChE analysis, muscle crude extracts were processed rapidly at 4 °C: the entire muscle was carefully excised, weighed, minced rapidly, mixed and aliquots were homogenized in 10 vol. of 5 mM EGTA, bacitracin (1 mg ml^{-1}), benzamidine-HCl (2 mM), N-ethylmaleimide (5 mM), chicken ovomucoid inhibitor (0.2 mg ml^{-1}), soybean trypsin inhibitor (0.1 mg ml^{-1}), leupeptin (0.04 mg ml^{-1}) and pepstatin (0.02 mg ml^{-1}). The homogenates were centrifuged at 43,500g for 15 min, and aliquots of the extracts thus obtained were used immediately for sucrose density gradient analysis (Fig. 1) or AChE assays[1]. The proportions of the molecular forms were obtained from computer-assisted analysis of the peaks in the profile.

motor supply). Bacou *et al.*[6] cut only the sciatic nerve. When we did this, only partial denervation occurred; a twitch of the semimembranosus could still be elicited by stimulating the obturator nerve. Whether denervation was partial or total, the morphological changes were similar and as illustrated by Bacou *et al.*[6]: the SA was more affected than the SP muscle, with marked fibre atrophy in both, and similarly in other denervated slow muscles such as rabbit and guinea pig soleus. Despite the similar histology, partial denervation may produce increased activity or terminal sprouting[13].

Further, we localized the various AChE forms, using microdissection[14,15] of individual endplates (Fig. 2). In the innervated slow-twitch fibres, the endplate contained essentially only collagen-tailed (16S and a little 13S) AChE (Fig. 2*a*,*c*). However, the extrasynaptic regions of innervated slow-twitch muscles studied also contained most of their AChE in these heavy forms (Fig. 2*b*,*d*). Although at a much lower concentration than at the endplate, when summed over the very great total surface this forms a large contribution to the whole muscle AChE. This extrasynaptic collagen-tailed AChE (also seen in non-endplate segments of rat diaphragm[11], where 40% of fibres are type I, and in hamster slow-twitch fibres) is much lower or absent in fast-twitch fibres[4,14]. The microdissected extrasynaptic regions of the denervated slow-twitch fibres of the SP and soleus showed a large increase in the light forms but also clear retention of the heavy forms (Fig. 2*f*); their endplates showed much loss of the 16S and the appearance of 4S and 6S AChE (Fig. 2*e*).

We conclude that denervation always produces a decline in the proportion of the muscle collagen-tailed AChE and in its amount at the endplates. However, in slow-twitch fibres there is, interestingly, another population of extrasynaptic 16S AChE which does not require neural contact. In a few species where AChE production increases on denervation, this extrasynaptic 16S AChE increases with the rest; this gain is nevertheless balanced or exceeded by the loss from the endplates, and the percentage contribution of this form to the total AChE of the muscle invariably declines markedly.

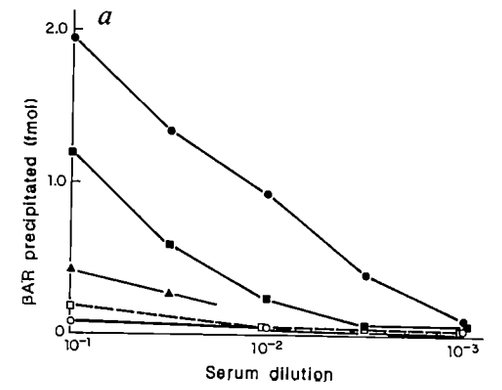
The adenylate cyclase system, which consists of a catalytic moiety and regulatory guanine nucleotide-binding proteins, provides the effector mechanism for the intracellular actions of many hormones and drugs[1]. The tissue specificity of the system is determined by the particular receptors that a cell expresses. Of the many receptors known to modulate adenylate cyclase activity, the best characterized and one of the most pharmacologically important is the β-adrenergic receptor (βAR). The pharmacologically distinguishable subtypes of the β-adrenergic receptor, β_1 and β_2 receptors, stimulate adenylate cyclase on binding specific catecholamines[1]. Recently, the avian erythrocyte β_1, the amphibian erythrocyte β_2 and the mammalian lung β_2 receptors have been purified to homogeneity and demonstrated to retain binding activity in detergent-solubilized form[1–5]. Moreover, the β-adrenergic receptor has been reconstituted with the other components of the adenylate cyclase system *in vitro*[6], thus making this hormone receptor particularly attractive for studies of the mechanism of receptor action. This situation is in contrast to that for the receptors for growth factors and insulin, where the primary biochemical effectors of receptor action are unknown. Here, we report the cloning of the gene and cDNA for the mammalian β_2AR. Analysis of the amino-acid sequence predicted for the βAR indicates significant amino-acid homology with bovine rhodopsin and suggests that, like rhodopsin[7], βAR possesses multiple membrane-spanning regions.

Hamster lung βAR was purified to homogeneity by sequential affinity chromatography and molecular-sieve HPLC as described previously[2,5]. The purified receptor bound ligand with theoretical specific activity and migrated on SDS-polyacrylamide gel electrophoresis as a single broad band at a relative molecular mass (M_r) of 64,000 (64K). Initial attempts to obtain N-terminal sequence data on intact βAR failed, presumably because the N-terminus of this protein was blocked. Therefore, peptide fragments generated by CNBr cleavage of pure βAR were isolated by reverse-phase HPLC.

Figure 1*a* (solid line) shows a peptide map generated from 1 nmol of pure receptor; the broken line shows the HPLC profile resulting from CNBr treatment of the detergent alone. The βAR-derived peptides produced at least nine specific absorbance peaks which were reproducibly observed in five separate βAR preparations. The most prominent of these peptides (marked with arrows in Fig. 1) were subjected to N-terminal sequence analysis, yielding the amino-acid sequences in Fig. 1*b*.

To confirm that the determined amino-acid sequences were those of the βAR polypeptide, we raised anti-peptide antibodies against peptide 7. Peptide 7 was expressed in *Escherichia coli* as a C-terminal peptide fused to the N-terminal domain of the yeast *RAS*^{sc1} protein SC1N (ref. 8). Rabbits injected with the isolated fusion protein produced antibodies which reacted with ^{125}I-labelled immunogen as well as pure ^{125}I-labelled βAR or pure ^{125}I-cyanopindolol-labelled (^{125}I-CYP) βAR. Figure 2*a* shows an immunoprecipitation titration curve of this antibody against ^{125}I-CYP-labelled solubilized βAR from hamster lung, hamster heart, A431 epidermoid carcinoma cells and turkey erythrocytes. No immunoprecipitation of counts above background was observed in control experiments when ^{125}I-CYP was incubated with the antibody in the absence of receptor.



Antibody to the hamster lung βAR-derived peptide was capable of recognizing the human βAR from the A431 line, albeit with a slightly lower sensitivity (50%) (Fig. 2*a*). The antibody also cross-reacted slightly with hamster heart βAR, a tissue containing a β_1 subtype of receptor, but did not immunoprecipitate the β_1AR of turkey erythrocytes. These differences in antibody sensitivity could reflect differences in either primary sequence or the conformation of this region of the protein within the various receptor subtypes and receptors from different species. To confirm that the antibody was recog-

Fig. 1 Amino-acid sequence of peptides derived from CNBr-treated β-adrenergic receptor. *a*, Absorbance profiles represent CNBr treatment of pure βAR (solid line) or digitonin (dashed line). The arrows indicate the peptides that were sequenced. *b*, Amino-acid sequences identified by HPLC following each cycle of the sequenator. Two of the four blank cycles (X) in the amino-acid sequence for peptide 2 are presumed to be due to *N*-linked glycosylation. Peptides 7 and 7a were located within the same peak. **Methods.** βAR was purified to homogeneity from hamster lung membranes by the method of Benovic *et al.*[5], using affinity chromatography followed by molecular-sieve HPLC. Binding of ^{125}I-CYP to intact cells or to solubilized βAR was determined according to Caron and Lefkowitz[22]. For peptide preparation, ~1 nmol of pure βAR was treated with CNBr (0.4 mM) in 70% formic acid at 23 °C for 20 h. After lyophilization, the sample was resuspended in 20 mM trifluoroacetic acid (TFA) and the peptides separated by reverse-phase HPLC on a Synchropak C-4 column, eluted with a 10–70% acetonitrile gradient containing 20 mM TFA. The N-terminal sequence analysis was performed by the method of Hewick *et al.*[23], using a gas-phase sequenator (Applied Biosystems). The phenylthiohydantoin (PTH) amino acids produced at each step were separated and quantitated by HPLC[24].

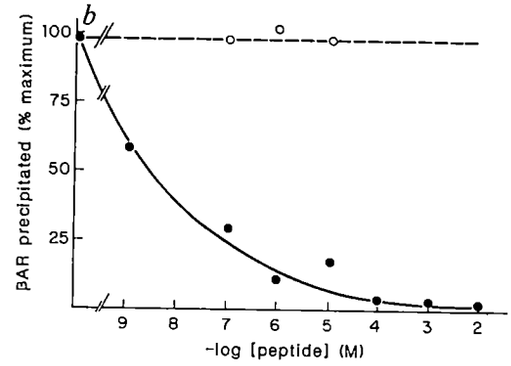

Fig. 2 Immunoreactivity of β-adrenergic receptor. *a*, Immunoprecipitation of ^{125}I-CYP-βAR from hamster lung (●), hamster heart (▲), A431 cells (■) or turkey erythrocytes (○) by serum from rabbits immunized with βAR peptide 7. □, Immunoprecipitation of hamster lung receptor by preimmune serum. *b*, Immunoprecipitation of ^{125}I-CYP-labelled hamster lung βAR with anti-βAR peptide 7 antibody following preincubation with a synthetic peptide containing a portion of the sequence for peptide 7 (●), or with an unrelated peptide, atrial natriuretic factor (○). *c*, Protein immunoblotting of the βAR. Protein samples were separated on a 10% polyacrylamide gel[25], transferred to nitrocellulose and treated sequentially with antibodies and ^{125}I-protein A (10^6 c.p.m. per 25 ml) as described elsewhere[26,27]. Lane 1, pure hamster lung βAR (5 pmol); lane 2, A431 cell lysate from 4×10^5 cells; lane 3, RPMI 1846 lysate from 10^5 cells.

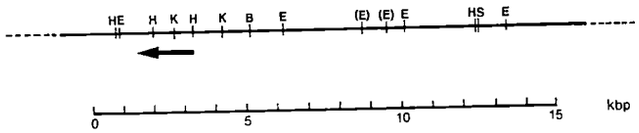
Methods. The immunogen for induction of anti-peptide antibodies was expressed in *E. coli*. Two oligonucleotides encoding the 19 amino acids of peptide 7 (QVAKRQLQKIDKSEGRFHS) were synthesized (see Fig. 1 legend), annealed and ligated[28] into the *Acc*I and *Hin*dIII sites of plasmid pSC1N[8] to give the plasmid pβP1. *E. coli* transformed with pβP1 overexpresses a protein of apparent M_r 23K, while *E coli* containing pSC1N overexpresses a protein of apparent M_r 21K (data not shown). This observed difference in relative molecular mass of the two proteins is consistent with the encoded fusion protein containing 19 additional amino acids. To prepare antigen, plasmid-containing cells were grown in L-broth containing ampicillin and isopropylthiogalactoside at 37 °C for 16 h, harvested by centrifugation, lysed by sonication and the soluble proteins removed by centrifugation at 40,000*g*. The cell pellet was seqentially extracted with 1 M NaCl, 1% Triton X-100 and 1.75 M guanidinium-HCl. The SC1N βAR fusion protein was extracted from the cells with 3.25 M guanidinium-HCl, dialysed against phosphate-buffered saline and used directly as an immunogen. Approximately 100 mg of fusion protein of 90% purity was obtained from 1 litre of starting culture. Antibodies were detected in serum from injected rabbits by incubation of the serum with ^{125}I-CYP-labelled soluble βAR in 10 mM Tris-HCl, 0.1 M NaCl, 0.1% digitonin, 0.5% bovine serum albumin (BSA) *p*H 7.4. After 2 h at 25 °C, the antibody was precipitated by addition of either $(NH_4)_2SO_4$ to 50% or *Staphylococcus aureus* protein A, followed by incubation in ice for 30 min. The precipitated protein was collected by centrifugation, and the radioactivity contained in the antibody pellet measured. For the peptide blocking experiment, the peptide YAKRQLQKIDKSEGR was synthesized[29] using a SAM II peptide synthesizer (Biosearch), and purified on a Whatman C-18 Magnum column in a H_2O/acetonitrile gradient containing 0.2% TFA. The resulting product was judged to be pure by amino-acid sequencing and mass spectral analysis. Increasing concentrations of this peptide were added to a 1:100 dilution of anti-peptide 7 antiserum and incubated for 2 h at 23 °C. The treated antiserum was then mixed with ^{125}I-CYP-labelled βAR and assayed as above.

nizing the amino-acid sequence of peptide 7, a chemically synthesized peptide was used as a specific inhibitor of antibody–receptor interactions. At concentrations ≥100 μM, this synthetic peptide completely prevented the immunoprecipitation of ^{125}I-CYP-labelled βAR by the antibody (Fig. 2*b*). An unrelated peptide, atrial natriuretic factor[9], had no effect on the immunoprecipitation.

The specificity of the antibody for the βAR was demonstrated further by protein immunoblotting. As shown in Fig. 2*c* (lane 1), the antibody reacted specifically with pure hamster lung βAR; a single protein of the same relative molecular mass (64K) was also observed in human A431 and hamster melanoma RPMI 1846 cells (Fig. 2*c*, lanes 2, 3), both of which were found to contain βAR on the basis of ^{125}I-CYP binding[10] (data not shown). This specific immunoreactive band was not observed on prior treatment of the antibody with the synthetic peptide and was not present when normal rabbit serum was substituted for the anti-peptide 7 antibody (data not shown).

To facilitate cloning of the βAR gene, oligonucleotides complementary to the DNA encoding the amino-acid sequence of peptide 7 were synthesized for use as hybridization probes (see Fig. 3 legend). In hybridization experiments performed at high stringency on blots of hamster genomic DNA, a single hybridizing band of 5.2 kilobases (kb) was observed in *Eco*RI digests and a band of 1.3 kb was observed in *Hin*dIII digests (data not shown). When a complete hamster genomic library was screened under the same conditions, five clones were isolated. Restriction analysis of the phage DNA revealed that all these clones contained a 1.3-kb *Hin*dIII and a 5.2-kb *Eco*RI fragment which hybridized to the probes (data not shown). Mapping of the phage DNA indicated that these clones overlap to give a total of 30 kb of contiguous genomic DNA. Figure 3 shows the restriction map of the genomic DNA containing the βAR-related sequences. Sequencing of the 1.3-kb *Hin*dIII fragment revealed a continuous open reading frame encoding 435 amino acids; the sequences of all the CNBr peptides shown in Fig. 1 were contained within this putative polypeptide.

Using the 1.3-kb *Hin*dIII gene fragment as a probe, seven clones were obtained from an unamplified hamster cDNA library (2×10^6 recombinants). Two of these cDNAs hybridized to oligonucleotide probes specific for the N-terminal, middle and C-terminal portions of the βAR gene. The nucleotide sequence of these two cDNA clones (Fig. 4) extends from 210 nucleotides (nt) 5′ to the open reading frame encoding the βAR



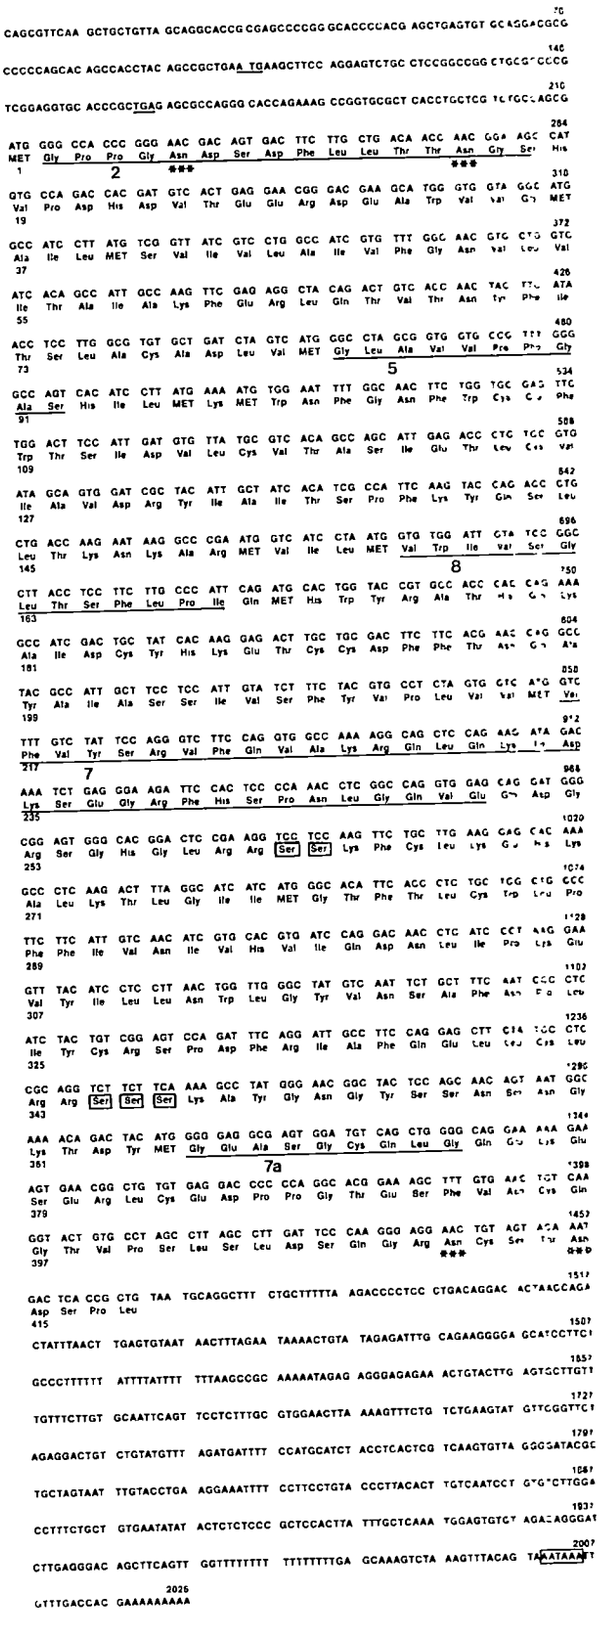


Fig. 3 Restriction map of the hamster βAR gene. A portion of the hamster DNA is shown. The 1.3-kb *Hin*dIII fragment which hybridizes to oligonucleotides specific for peptide 7, is underlined with an arrow indicating the direction of transcription of the βAR gene. The restriction enzyme sites are: B, *Bam*HI; E, *Eco*RI; H, *Hin*dIII; K, *Kpn*I; S, *Sal*I. Those sites shown in parentheses have not been unequivocally ordered.

Methods. All restriction enzymes, *E. coli* DNA polymerase I, T_4 DNA ligase and T_4 polynucleotide kinase were purchased from New England Biolabs. Radiolabelled nucleotides were purchased from Amersham. λ EMBL3A phage arms[30] and λ *in vitro* DNA packaging extracts were purchased from Vector Cloning Systems. Standard recombinant DNA and microbiological procedures were used throughout[28]. Genomic libraries were constructed using high-M_r genomic DNA isolated from hamster lung cells in the vector λ EMBL3 (refs 6, 30). Probes for peptide 7 coding sequences, oligonucleotides ON225(5′ pCTCCACCTGGCCCAGGTTGGG-AGAGTGGAACCTGCCCTCAGACTTGTCGAT) and ON229(5′ pAGGCAGCTGCAGAAGATCGACAAGTCTGAG) and ON168 (5′ pTTCCAGGTGGCCAAGCGGCAGCTGCAGAAGATCGA-CAA) and ON169(5′ pATGGTCTTTGTCTACTCCCGGGTCT-TCCAGGTGGCCAA), were synthesized on an Applied Biosystems Model 3A DNA synthesizer. The oligonucleotides were labelled by either a fill-in reaction (ON225, ON229) using Klenow DNA polymerase and all four [α-^{32}P]dNTPs[31] or by phosphorylation using T_4 polynucleotide kinase and [γ-^{32}P]ATP[28]. Phage libraries were screened by the method of Benton and Davis[32] using the hybridization conditions of Ullrich *et al.*[33]. DNA was isolated from CsCl-banded phage as described elsewhere[28]. For restriction analysis, DNA was digested with the appropriate enzyme and electrophoresed on 0.8% agarose gels. DNA was transferred to nitrocellulose by the procedure of Southern[34] and hybridized as above.

Fig. 4 (Right) Nucleotide and deduced amino-acid sequence of the βAR cDNA. The nucleotides are numbered on the right-hand side of each line beginning with the first nucleotide of the most 5′ cDNA clone. The translated amino-acid sequence is shown beneath the corresponding nucleotide sequence and is numbered to the left of each line. Underlined amino acids represent the CNBr peptides whose sequences are given in Fig. 1. All predicted amino acids agree with those determined by peptide sequencing, with the single exception of a cysteine for serine substitution in peptide 7a. All derived peptide sequences are preceded by a methionine, consistent with CNBr cleavage. The underlined nucleotides preceding the βAR sequences denote the first methionine codon and an in-frame termination codon. The boxed nucleotides at the 3′ end of the sequence represent the polyadenylation signal. Postulated glycosylation sites (Asn-X-Ser/Thr) are indicated by asterisks. Putative protein kinase A phosphorylation sites are boxed.

Methods. Reverse transcriptase was purchased from Seikagaku-America. RNase H was from Pharmacia and λ gt10 arms were from Vector Cloning. Total cellular RNA was isolated from growing cultures of DDT1-MF2 cells by the guanidinium isothiocyanate–CsCl method[47]. Poly(A)$^+$ RNA was purified by chromatography on oligo(dT)–cellulose. Double-stranded cDNA was synthesized by oligo(dT)-primed reverse transcription of the poly(A)$^+$ RNA, followed by treatment with *E. coli* DNA polymerase and RNase[48]. The ends of the cDNA were blunted with T_4 DNA polymerase[28]. Following protection of the *Eco*RI sites with *Eco*RI methylase, *Eco*RI linkers were added[28]. *Eco*RI-digested cDNA was size-fractionated by agarose gel electrophoresis to obtain cDNAs between 2 and 7 kb long. The cDNA was ligated to the vector λ gt10 (ref. 49) and packaged *in vitro*. The resulting library was screened unamplified as described in Fig. 3 legend. The 1.3-kb *Hin*dIII fragment was labelled using [α-^{32}P]dCTP by nick-translation for use as a hybridization probe[28]. The cDNA inserts contained in the positive phage were subcloned into pUC13 or M13 mp19 for DNA sequence analysis[35–37]. Both strands of the clones were sequenced with no discrepancies.

peptides to 560 nt 3′ to the termination codon. A hexanucleotide AATAAA occurs near the 3′ end, followed by a poly(A) stretch. The nucleotide sequence of the genomic clones is identical to that of the cDNA clones up to but not including the poly(A) tail. These data demonstrate an absence of introns within the coding and 3′-untranslated regions of the βAR gene but the possibility of introns in the untranslated region 5′ to the sequence isolated cannot be ruled out. While the lack of introns is unusual, it is not unprecedented in that sea urchin histone genes[38] and mammalian α- and β-interferon genes[39,40] are also uninterrupted. Previous studies with simian virus 40 and β-globin indicate that introns are necessary for efficient expression of those genes[41,42], so the lack of introns within the hamster βAR gene may account in part for its low level of expression.

Whereas most eukaryotic genes are translated using the first AUG encountered in the messenger RNA[43], the open reading frame (ORF) encoding the βAR peptides begins at the second AUG. The first AUG is followed by a termination codon after only 19 amino acids. This open reading frame is in-frame with the AUG codon beginning the βAR polypeptide. A similar situation has recently been reported for the oestrogen receptor, where the reading frame of that receptor is preceded by a short 20-amino-acid ORF[44]. Note that the DNA sequence around the AUG codon for the second ORF agrees well with the consensus eukaryotic translation initiation sequence[43] (CAGCGAUGG compared with CCGCCAUGG), whereas the sequence surrounding the first AUG does not.

Translation beginning with the second AUG as the initiation site would produce a polypeptide of 418 amino acids, with a M_r (46K) in close agreement with the apparent M_r of the deglycosylated βAR (49K)[11]. The protein sequence immediately following the initiator methionine residue is identical to the sequence determined for peptide 2. Apparently, like several other integral membrane proteins—for example, bovine opsin[45]—the βAR does not contain a cleavable signal sequence and may use internal signals for the insertion of the protein into the membrane. The receptor has been shown to have two sites of *N*-linked glycosylation (R.J.L. *et al.*, in preparation). Both sites are present in peptide 2, consistent with the results of peptide sequencing. The presence of two consensus protein kinase A and C sites[46] within the coding region (Fig. 4) agrees with *in vitro* phosphorylation results[20].

Hydropathicity profiles of the predicted βAR amino-acid sequence were produced using the analyses of Hopp and Woods[12] and of Kyte and Doolittle[13], with similar results. As shown in Fig. 5*a*, the βAR sequence should encode a largely hydrophobic polypeptide, with the N-terminal region of the receptor being predominantly hydrophobic and the C-terminal region of the molecule being hydrophilic. The βAR hydropathicity profile is remarkably similar to that of the rhodopsins (Fig. 5*b*), of which bacteriorhodopsin[7] is known to contain seven membrane-spanning helices. Not only does a similar pattern of repeating hydrophobic sequences 20–25 residues long occur in the predicted βAR sequence, but also the amino-acid composition of these postulated helices is similar to that of the rhodopsins, having a high proportion of proline and aromatic amino acids. The exact number of transmembrane regions remains to be determined. Amino-acid homology was apparent when the sequences corresponding to the postulated helices V, VI and VII of bovine opsin[14], which comprise the retinal binding site[15], were aligned with those for the analogous regions of βAR (Fig. 5*c*).

The sequence homology between βAR and rhodopsin parallels similarities in their function: both rhodopsin and βAR are involved in signal transduction mechanisms that involve interaction with the guanine nucleotide regulatory proteins transducin[16] and G_s (ref. 17), respectively. Moreover, it seems that phosphorylation has an important role in the regulation of both rhodopsin and βAR[18,19]. Rhodopsin is multiply phosphorylated at its C-terminus, which contains seven serine

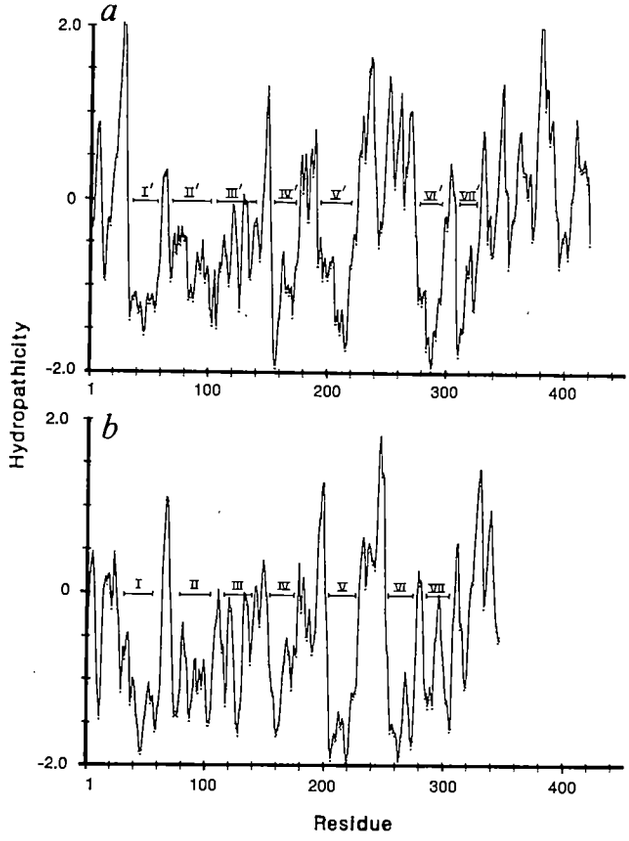

Fig. 5 Structure and sequence homology for hamster βAR and bovine opsin. Hydropathicity profiles are shown for hamster βAR (*a*) and bovine opsin[14] (*b*). Values were calculated by the method of Hopp and Woods[12]. Hydrophobicity increases with decreasing values. Horizontal lines indicate hydrophobic peptide regions 20–25 residues long. The putative transmembrane helices of bovine opsin are numbered as in ref. 14. We have designated the proposed transmembrane helices of βAR based on the analogous hydropathicity patterns of βAR and opsin. *c*, Amino-acid sequence homologies between the hamster βAR and bovine opsin (OPS). Positions of amino-acid identities are designated by asterisks. The underlined lysine residue (296) of bovine rhodopsin is involved in a Schiff base with retinal[15].

and threonine residues[18]. The C-terminus of the postulated sequence for βAR contains several serine and threonine residues that could serve as sites for phosphorylation[19].

The similarity in both the amino-acid sequence and proposed structure for the retinal binding site of rhodopsin and the analogous region in βAR suggests a specific mode of action for the ligands that modulate βAR function. We propose that these compounds interact with the βAR in a manner similar to that by which retinal interacts with opsin[21]; that is, they intercalate among the hydrophobic transmembrane helices and thereby determine whether the receptor is in its active or inactive conformation. According to this model, agonists and antagonists would mimic the action of photoactivated and native retinal. The generality of this hypothesis will be tested once the genes for similar membrane-bound receptors, such as those for leuko-

trienes, prostaglandins, dopamine and histamine, have been isolated. Our proposed model for the structure of βAR and its interaction with pharmacologically important ligands should, together with the biochemical and genetic studies now possible, provide a rational basis for a new approach to the development of more selective drugs.

We thank Lenora Davis, Jill D'Alonzo, Ester Hou, Tong Sun Kobilka, John Rodkey, Claudia Staniszewski, H. Vincent Strout Jr and Barbara Zemcik for technical assistance, Jeanne White and Lynn Tilley for manuscript preparation, and Drs Eugene Cordes, Ronald Ellis, Russell Kaufman, Paul Keller, Pete Kniskern, Richard Lebovitz, Mark Riemen and Michael Rosenblatt for helpful discussions. We particularly thank Dr Edward Scolnick for continued support and direction.

In vitro osteoclast generation from different bone marrow fractions, including a highly enriched haematopoietic stem cell population

Ben A. A. Scheven*, Jan W. M. Visser† & Peter J. Nijweide*

* Laboratory of Cell Biology and Histology, University of Leiden, Rijnsburgerweg 10, 2333 AA Leiden, The Netherlands

It is well established that the osteoclast is formed by fusion of post-mitotic, mononuclear precursors[1] derived from circulating progenitor cells[2]. However, the precise haematopoietic origin of the osteoclast is unknown. We have investigated this here by fractionating mouse bone marrow and isolating haematopoietic stem cells using a three-step method combining equilibrium density centrifugation and two fluorescence-activated cell sortings (FACS)[3], and have tested the ability of each bone marrow fraction, including highly purified haematopoietic stem cells, to generate osteoclasts during co-culture with preosteoclast-free embryonic long bones[4,5]. The osteoclast-forming capacity was found to increase with increasing stem cell purity. On the other hand, the culture time needed for osteoclast formation also increased with purification, suggesting the presence of progressively more immature progenitor cells. The pluripotent haematopoietic stem cell fractions with the highest purity needed preincubation with a stem cell-activating factor (interleukin-3) to activate the predominantly quiescent stem cells *in vitro*.

Embryonic long bones stripped of the endogenous osteoclast precursor pool (the periosteum) were used to induce the development of osteoclasts from different bone marrow cell populations. When stripped long bones are co-cultured with cell populations containing osteoclast progenitors, osteoclasts develop which thereby give rise to the formation of a marrow cavity. Culture of stripped bones alone does not lead to appearance of osteoclasts[4,5]. Total bone marrow cell population and both high-density ($1.100 < \rho < 1.078$ g cm^{-3}) and low-density ($\rho < 1.078$ g cm^{-3}) bone marrow fractions, obtained by equilibrium density centrifugation on a discontinuous metrizamide gradient, gave rise to osteoclast formation (Table 1). Autoradiography using continuous ^{3}H-thymidine labelling indicated that the osteoclasts were derived from progenitor cells which had proliferated during co-culture. The osteoclasts exhibited tartrate-resistant acid phosphatase activity, which is specific for these cells. Some mononuclear cells and an occasional multinucleated cell present in the plasma clot surrounding the bones also displayed this osteoclastic enzyme activity. Mature granulocytes accumulated in the developing marrow cavity following the invasion of osteoclasts. With time, other cell types such as megakaryocytes, macrophages and undifferentiated cells were observed in the expanded cavity.

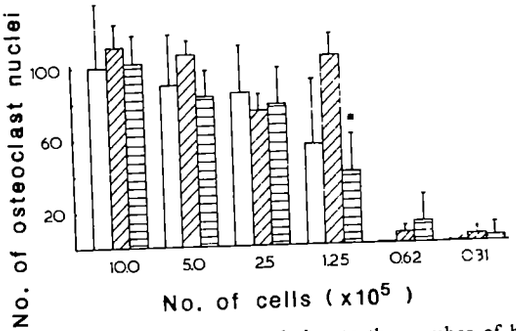

Fig. 1 Osteoclast formation in relation to the number of bone marrow cells (per plasma clot per bone) after 8 days of co-culture. Means ± s.d. of the number of osteoclast nuclei in five axial sections of four to six cultures are shown. □, Unfractionated bone marrow cells; ▨, low-density bone marrow cells; ▤, high-density bone marrow cells. Statistically significant ($P < 0.05$) compared with low-density cells.

Dilution experiments were performed to assess the relationship between the number of cells added to the bones and the

Table 1 Osteoclast formation from different bone marrow fractions

	No. of osteoclast nuclei per bone							
	0	1–5	6–20	>20	(n)	No. of cells added per bone ($\times 10^5$)	No. of day-12 CFU-S per 10^5 cells	Culture time (days)
Unfractionated bone marrow cells				26	26	2.5–10.0	51±5	7–8
Low-density cells				22	22	2.5–10.0	ND	7–8
High-density cells			5	17	22	2.5–10.0	ND	7–8
Total WGA^+ cells	2			12	14	2.0–3.0	ND	7
Total WGA^- cells	14	1			15	2.0–3.0	ND	7
WGA^+ low-density cells		1		4	5	0.40–0.50	ND	9–11
WGA^- low-density cells	8	1			9	0.40–0.50	ND	9–11
WGA^+ and H-$2K^+$ low-density cells (−SAF)	7	1			8	0.0125	690±840	14–17
WGA^+ and H-$2K^+$ low-density cells (+SAF)	1		1	10	12	0.0250	2,900±510	2+8

Metatarsal bones of 17-day-old mouse embryos were dissected and stripped of surrounding periosteum using the collagenase and mechanical treatment of Burger *et al.*[4]. The stripped cartilaginous bone rudiments consisted of a central calcified area (without (pre)osteoclasts and marrow cavity) with a thin bone collar and two uncalcified epiphyses. The bone marrow cell preparation and separation procedures were performed as described elsewhere[3]. The cells were first separated by density using a discontinuous metrizamide gradient and simultaneously labelled with WGA and fluorescein isothiocyanate (FITC), and then collected at the interfaces between the 1.100 and 1.078 g cm^{-3} solutions (high-density fraction) and the 1.078 and 1.055 g cm^{-3} solutions (low-density fraction). Cells from unfractionated bone marrow and the low-density cells were analysed for WGA–FITC binding by a modified fluorescence activating cell sorter (FACS II, Becton Dickinson). All WGA–FITC-positive cells with medium forward light scatter and low perpendicular light scatter were sorted. WGA–FITC was removed from the sorted cells by treatment with 0.2 M *N*-acetyl-D-glucosamine for 15 min at 37 °C. The cells were then labelled with biotinylated anti-H-2K followed by avidin–FITC. The most brightly fluorescent cells were selected by FACS. The low-density cells comprised ~15% of all nucleated bone marrow cells. About 30–40% of the total bone marrow was WGA^+, compared with about 4–6% of the low-density cells. The H-$2K^+$ fraction comprised ~0.3% of all nucleated bone marrow cells. SAF (10 U) was used for preincubation of the isolated H-$2K^+$ cells for 2 days before co-culture with stripped embryonic bones. 1 U of SAF is the amount needed for 50% proliferation of the interleukin-3-dependent cell line DA-1. The isolated cell suspensions of known cell number were diluted with 10% rat serum and 10% chicken embryo extract in HEPES-buffered Hanks' balanced salt solution and centrifuged to collect the cells. Then 10 μl of cock plasma was added to the cells to make a weak plasma clot. The clot was divided into equal parts of ~1 mm^3 and placed along both sides of the stripped bones. Co-culture was performed on a semi-solid medium, composed of 60% Eagle's α-minimal essential medium, 10% rat serum, 10% chicken embryo extract and 20% cock plasma, at 37 °C in a humidified 5% CO_2 atmosphere. The numbers of osteoclast nuclei in the marrow cavity were counted in five axial histological sections of bone rudiments. Recipient mice for the CFU-S assay[10] received 9.5 Gy total body irradiation (^{137}Cs, 0.85 Gy min^{-1}) 4–6 h before transplantation. Spleen colonies were counted on day 12. ND, not determined.

number of osteoclasts formed, and to determine the minimum number of cells needed for osteoclast formation (Fig. 1). At high cell concentrations the number of osteoclast nuclei reached about the same plateau level for all three bone marrow fractions. However, at a cell dose of 1.25×10^5 cells per clot, the low-density cells showed a significantly greater potency for osteoclast formation than the unfractionated and high-density bone marrow cells. The experiments were repeated twice at this critical cell dose, resulting in 89.3±25.0 and 17.3±11.2 osteoclast nuclei for the low- and high-density cells, respectively (means±s.d. of five axial sections, $P < 0.001$, $n = 6$). Lower cell doses led to an abrupt decline in the number of osteoclasts developing during culture from these three fractions.

Examination of the co-cultures using a diavert microscope revealed that resorption of the calcified centre generally started earlier when the bones had been co-cultured with the high-density bone marrow cells than with the low-density cells. To quantitate this, osteoclastic mineral resorption was determined by measuring the release of ^{45}Ca from prelabelled bones during co-culture. These experiments were carried out using high cell doses so as to exclude possible cell concentration effects (Fig. 1). Figure 2 convincingly demonstrates that the high-density cells indeed gave rise to an initial, significantly higher release of ^{45}Ca. However, from day 6 onwards the relative ^{45}Ca release was equal in all groups.

Our results indicate that the different bone marrow density fractions contain subpopulations of osteoclast progenitor cells which differ in maturation stage. The low-density fraction apparently contains more immature progenitor cells which have a greater proliferation capacity (Fig. 1) but need a longer time to differentiate into mature, fusable preosteoclasts (Fig. 2). This is consistent with the finding that the primitive progenitors, type 1 granulocyte–macrophage colony-forming units (GM-CFU-1) and spleen colony-forming units (CFU-S), can be separated from the more mature haematopoietic cells by their low buoyant density[6–9]. At increasing buoyant densities the proliferation potency of the culture colony-forming units (CFU-C) decreases, whereas the maturation rate increases[7,8]. The earlier ^{45}Ca release induced by the high-density cells correlates with the earlier maturation of agar colonies from GM-CFU-2 and -3, while the late osteoclast formation from the low-density cells may be compared to colony formation from GM-CFU-1.

Sorting on the basis of labelling of unfractionated bone marrow cells by wheat germ agglutinin (WGA) resulted in a distinct separation between an osteoclast-forming (WGA^+) and a non-osteoclast-forming (WGA^-) fraction (Table 1). The total WGA^+ cell population comprised cells belonging to the granulocyte series, including the mature forms, immature cells of the monocyte–macrophage lineage and early haematopoietic progenitor and stem cells. The WGA^- cell population, on the other hand, consisted of erythrocytes, lymphocytes, megakaryocytes and their immediate precursors, and mature macrophages and osteoclasts.

The WGA^+ fraction of the low-density cells consisted mainly of early haematopoietic progenitor and stem cells with 60-fold enrichment of CFU-S[8]. Only the WGA^+ low-density cells were able to induce osteoclast development (Table 1). This, however, took a longer co-culture period (8–10 days) compared with the

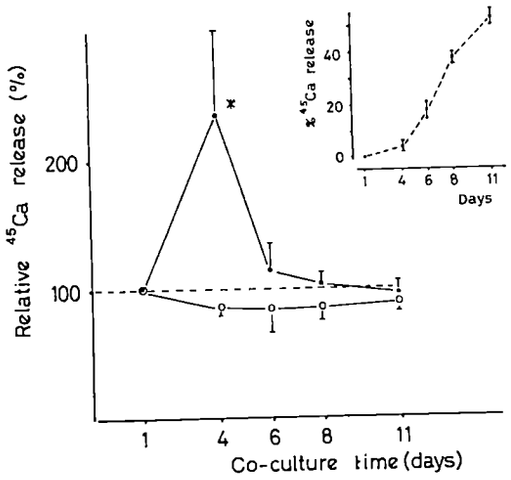

Fig. 2 Osteoclastic mineral resorption during co-culture with high (●)- or low (○)-density bone marrow cells. At each time point the release of ^{45}Ca from prelabelled metatarsal bones is expressed as a percentage of the average ^{45}Ca release obtained during co-culture with unfractionated cells. Inset, cumulative release of ^{45}Ca during co-culture with unfractionated bone marrow cells shown as a percentage of total incorporated ^{45}Ca per bone.
Methods. Pregnant mice were injected with 50 μCi ^{45}Ca on day 16 of gestation. The next day the ^{45}Ca-labelled metatarsal bones were dissected, stripped, explanted on a semi-solid medium and co-cultured with clots containing unfractionated, low-density or high-density bone marrow cells (see Table 1 legend). Medium was changed after 1, 4, 6 and 8 days. After a total culture period of 11 days the co-cultures were fixed in a mixture of 5% glacial acetic acid, 85% ethanol and 10% formaldehyde for 24 h, then decalcified in a 5% formic acid/5% formaldehyde solution. The semi-solid media were digested overnight with 0.1% trypsin and the digested culture media, fixation and decalcification fluids analysed for ^{45}Ca radioactivity on a Beckman LS 1800 liquid scintillation counter. The release of ^{45}Ca during the first culture day, which represents physicochemical exchange, was discarded. The values shown are means ± s.e.m. of seven or eight co-cultures. * Statistically significant ($P < 0.05$) compared with low-density cells.

cell populations described above. This phenomenon is probably due to the lower number of cells per bone and the occurrence of predominantly very immature cells in this fraction which needed more time to mature into preosteoclasts.

H-2K sorting of the WGA$^+$ low-density fraction produced a highly enriched pluripotent haematopoietic stem cell population. Intravenous injection of 100 sorted cells per lethally irradiated mouse resulted in 6.9–9.3 colonies per spleen 12 days later (day-12 CFU-S; refs 3, 10). As the seeding efficiency of transplanted haematopoietic stem cells to the spleen is between 0.05 and 0.10 (refs 3, 11, 12), this indicates that at least 69–93% of the sorted cells were pluripotent stem cells.

The osteoclast-forming capacity of these sorted cells, however, was minimal (Table 1), perhaps because of the lower number of cells present per clot and/or the absence of suitable factors for activating the mainly quiescent stem cells. A stem cell-activating factor (SAF = interleukin-3)[13] was therefore used to stimulate the sorted stem cells. Preincubation of cells with 10 U SAF for 2 days resulted in a doubling of the total number of cells, concomitantly with maintenance of day-8 CFU-S and a slight decrease in the number of day-12 CFU-S per culture. Subsequent co-culture with stripped metatarsal bones led to a burst of haematopoietic cell growth (granulocytes and macrophages) and abundant osteoclast formation. This indicates either that SAF triggers the pluripotent haematopoietic stem cells into a state in which they are responsive to the growth factors in the plasma clot, or that the pluripotent stem cells, because of SAF, differentiate into committed progenitors which are then stimulated by the clot. The plasma clot itself apparently does not contain SAF. When, in another experiment, we added recombinant SAF (10 U ml^{-1}) to a co-culture of purified stem cells and stripped metatarsal bones on day 0 and removed the SAF on day 2 by washing, we observed extensive haematopoietic cell growth and abundant osteoclast formation similar to that in the above experiment. Without SAF no osteoclast formation was observed in this experiment either.

Our results with purified stem cells provide direct, although not yet conclusive, evidence for the hypothesis that osteoclasts are derived from the pluripotent haematopoietic stem cell[14–17]. In addition, the data indicate that SAF is needed to initiate the proliferation and differentiation of the pluripotent stem cell. The evidence presented cannot exclude the possibility that the osteoclast progenitor co-purifies with the CFU-S population, although we consider this highly unlikely. It is not very probable that a distinct osteoclast stem cell would behave exactly like the haematopoietic stem cell during the isolation procedure, causing a >100-fold enrichment of the latter cell, for it would mean the possession of similar cytochemical (WGA, H-2K) and physical (density, light-scattering) properties, and the ability to react in a similar manner to SAF.

The first part of the pathway along which osteoclasts differentiate may very well coincide with the monocyte differentiation lineage, as granulocyte and macrophage precursors are also found among the WGA$^+$ bone marrow cells[18]. However, as we have shown earlier[19], the direct precursors of the osteoclast are not monocytes. The formation of osteoclasts from isolated haematopoietic stem cells in the *in vitro* model used here should facilitate the elucidation of the osteoclast differentiation lineage and its relation to other blood cell lineages.

We thank Dr L. Dorssers for supply of (recombinant) SAF, Mrs A. M. Wassenaar, E. W. M. Kawilarang-de Haas and M. Hogeweg-Platenburg for technical assistance and Professor J. P. Scherft for critically reading the manuscript. This study was supported by the J. A. Cohen Institute, IRS, Leiden.

Epidermal growth factor-dependent phosphorylation of lipocortin

R. Blake Pepinsky & Lesley K. Sinclair

Biogen Research Corporation, 14 Cambridge Center, Cambridge, Massachusetts 02142, USA

Lipocortin-like proteins are a family of steroid-induced inhibitors of phospholipase activity with potential anti-inflammatory activity (for reviews see refs 1, 2). Related proteins have been detected in a variety of tissues and species[3–7]. The best characterized form is a protein of relative molecular mass (M_r) ~ 40,000 (40K), which is phosphorylated *in vivo* by protein tyrosine kinases and by protein

serine-threonine kinases[8,9]. It has been proposed that the phospholipase inhibitory activity of lipocortin can be regulated by its phosphorylation[5]. In the A431 cell line, a protein of ~35K is phosphorylated by the protein tyrosine kinase activity of the epidermal growth factor (EGF) receptor[10]. Here we report that human lipocortin is phosphorylated near its amino terminus by the EGF receptor/kinase. By peptide mapping and immunological analyses, we show that lipocortin and the endogenous 35K substrate for the EGF receptor/kinase from A431 cells are the same protein.

Recently, the human gene for lipocortin was cloned and expressed in *Escherichia coli*[11]. The gene encodes a 38.5K protein that inhibits phospholipase A_2 activity. The inhibitory activity was readily detected in crude bacterial lysates, but only from cells transformed with the human gene. Lipocortin was found in cell types of diverse origin, including macrophages, fibroblasts and epithelial cells[4], and levels of expression in these preparations represented 0–0.5% of total cell protein. Figure 1 shows the results of gel filtration analysis of the recombinant human protein. On chromatography, the inhibitor yields a single peak with an apparent M_r of ~40K. The elution profile of phospholipase A_2 inhibitory activity (Fig. 1*A*) and the profile of the protein when subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) (Fig. 1*B*) coincide exactly. The inhibitory activity is trypsin-sensitive, destroyed by boiling and inactivated by treatment with heparin (not shown). Like natural lipocortin, the recombinant protein has a specific activity of 6,000–10,000 units per mg of protein, where 1 unit inhibits 15 ng of phospholipase A_2.

The EGF receptor (170K) is a protein tyrosine kinase that is activated by EGF[12,13]. The enzyme is membrane-associated and retains its activity in preparations of isolated cell membranes[14,15]. Two prominent phosphorylation products of the EGF-dependent kinase are the receptor itself and an endogenous 35K substrate. In the A431 cell line the receptor/kinase is overproduced[16], leading to the frequent use of this human line as a source of the kinase. When membranes from A431 cells are incubated with [γ-^{32}P]ATP and the phosphorylated products analysed by SDS-PAGE, the receptor and the 35K protein are both phosphorylated[14,15]. The degree of phosphorylation is greater if the kinase is prepared from EGF-treated cells. Using the A431 membrane-derived kinase activity, we observed similar results: both the receptor and the endogenous 35K protein were prominent phosphorylation products in the sample derived from EGF-treated membranes (Fig. 2*b*) and were present as minor species in the corresponding untreated sample (Fig. 2*a*).

When membranes from A431 cells were first treated with lipocortin and then subjected to phosphorylation and SDS-gel analysis, the recombinant protein was phosphorylated (Fig. 2*c, d*). Whereas in the absence of EGF, lipocortin was barely detected (Fig. 2*c*), it was the major phosphorylated protein in the EGF-treated preparations (Fig. 2*d*). The incorporation of phosphate into lipocortin varied as a function of the concentration of protein added (Fig. 2*e–h*). The dilution series tested ranged from concentrations where no effect was observed (5 nM lipocortin, Fig. 2*e*) to those where the phosphorylation reaction was saturated (5 μM lipocortin, Fig. 2*h*). The increase in phosphorylation of lipocortin coincides with a decrease in phosphorylation of the EGF receptor. We found that human lipocortin and the endogenous 35K substrate have similar electrophoretic mobilities by SDS-gel electrophoresis. The 4K discrepancy between the predicted and apparent M_rs for lipocortin presumably results from its unusually charged amino-acid composition, as charged amino acids affect the electrophoretic mobility of proteins in SDS-gels[17].

We have shown by peptide mapping analysis that lipocortin and the endogenous 35K protein from A431 cells are the same protein. We incubated gel slices containing phosphorylated lipocortin and phosphorylated 35K protein with CNBr, then separated the cleavage products by SDS-PAGE. Radioactive products were visualized by autoradiography. As shown in

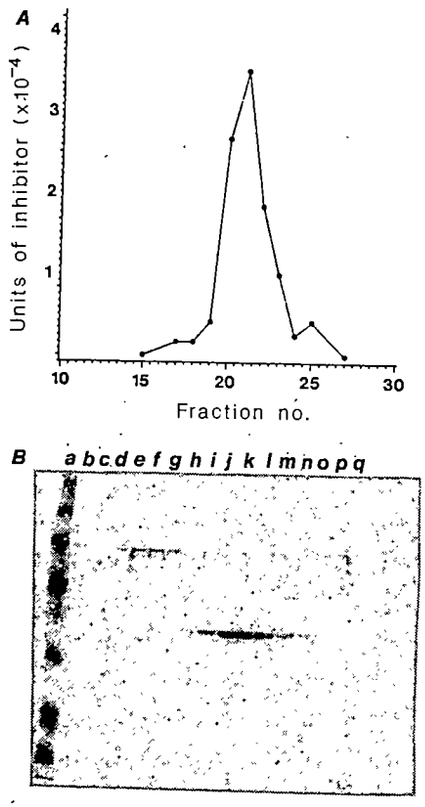

Fig. 1 Gel filtration analysis of recombinant lipocortin. Recombinant human lipocortin produced in *E. coli* was chromatographed on a P150 column (2.5 cm diameter × 45 cm). Aliquots from each 5-ml fraction collected were analysed for phospholipase A_2 inhibitory activity (*A*) and by SDS-PAGE (*B*). Proteins were separated electrophoretically in SDS-gels (15% acrylamide, 0.18% methylene bisacrylamide)[25] and stained with Coomassie brilliant blue R-250. Stacking gels contained 7.6% acrylamide and 0.21% bisacrylamide. *a*, Pre-stained M_r markers (BRL): myosin, 220K; phosphorylase B, 100K; bovine serum albumin, 65K; ovalbumin, 47K; α-chymotrypsinogen, 30K; β-lactoglobulin, 18K; lysozyme, 15K. Lanes *b–q* correspond to column fractions 10, 12, 14, 16–27 and 29, respectively. For inhibitory activity, samples were assayed with porcine pancreatic phospholipase A_2, using autoclaved ^{3}H-oleic-acid-labelled *E. coli* as substrate[4].

Fig. 3*b, c*, phosphate-labelled CNBr fragments from the two protein preparations were identical. The six phosphorylated fragments formed a distinct subset of the total digestion products of lipocortin, which consists of 22 fragments (Fig. 3, lane *a*). This series of fragments is a mixture of complete and partial cleavage products, which we have characterized by CNBr mapping analysis. Although the relative intensities of the cleavage products vary as a function of the CNBr concentration, no additional products were generated when preparations were treated with CNBr at 7–21 mg ml^{-1}, spanning the range of concentrations used routinely for analysis of lipocortin.

To localize the site of phosphorylation within lipocortin, we first identified the fragment composition for each of its 22 digestion products by CNBr mapping and then used this information to identify the subset of fragments that were phosphorylated. This type of procedure has been described in detail previously[18,19] and is based on the fact that each CNBr fragment is represented by a distinct subset of the digestion products. The mapping information for lipocortin is summarized on the left of Fig. 3; however, the actual cleavage maps will be presented elsewhere. Based on the map of lipocortin, the pattern of phosphorylated fragments suggests a modification within fragment 1. The series of radioactive spots corresponds to fragment 1 and each of the fragment 1-containing partial digests. Thus, the

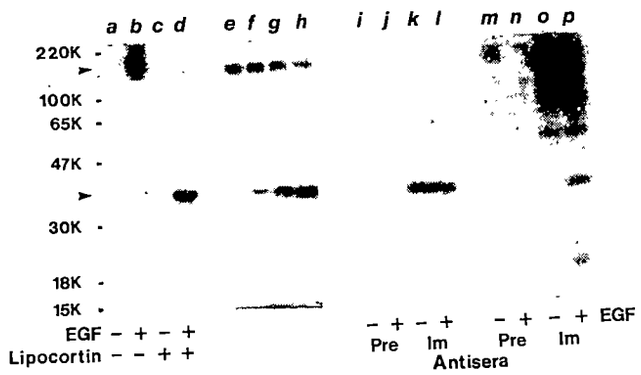

Fig. 2 EGF-dependent phosphorylation of lipocortin. A431 cells were grown at 37 °C in Dulbecco's modified Eagle's medium supplemented with 10% calf serum. *In vitro* phosphorylation reactions using isolated A431 cell membranes (lanes *a–h*) and immune precipitations from metabolically labelled cells (^{35}S-methionine-labelled, lanes *i–l*; ^{32}P-phosphate-labelled, lanes *m–p*) were analysed by SDS-PAGE and radioactive products visualized by autoradiography. Arrowheads denote the positions of the EGF receptor and the 35K protein. *e–h*, *In vitro* phosphorylation products generated when membranes from EGF-treated cells were treated with various concentrations of lipocortin: 0.2, 2, 20 and 200 μg ml^{-1} of lipocortin, respectively.

Methods. For *in vitro* phosphorylation reactions, confluent monolayers of A431 cells in T75 flasks were washed with Dulbecco's medium without serum and incubated at 37 °C for 1 h in 7 ml of serum-free medium without (−) and with (+) 200 ng ml^{-1} EGF (Sigma). Monolayers were rinsed with 2.5 ml of ice-cold hypotonic buffer (10 mM HEPES *p*H 7.5, 0.5 mM $MgCl_2$) and the cells scraped into 1.5 ml of the same buffer. After 30 min on ice, the cells were disrupted with a Dounce homogenizer (20 strokes with a type A pestle), and large particulate debris was removed by centrifugation (2,000*g*, 5 min). The resultant supernatants were centrifuged at 10,000*g* for 10 min and the membranous pellets suspended in 300 μl of phosphorylation buffer (20 mM HEPES *p*H 7.5, 2 mM $MgCl_2$, 10 μM ammonium vanadate). EGF-treated membranes were suspended in buffer plus 2 μg ml^{-1} EGF. 60-μl reactions, each containing 30 μl of a given membrane preparation, were held on ice for 10 min in the presence of 30 μCi [γ-^{32}P]ATP per tube. Reactions were stopped by adding 20 μl of 5× electrophoresis sample buffer. Samples were heated at 55 °C for 10 min, and then subjected to SDS-gel analysis. For the metabolic labelling experiments, A431 cells were grown in 6-well microtitre dishes. Cells were labelled with ^{35}S-methionine (100 μCi per well) in methionine-free medium and with ^{32}P-phosphate (1 mCi per well) in phosphate-free medium. In both cases cells were cultured for 4 h in serum-free medium without and with 200 ng ml^{-1} EGF. Labelled cells were disrupted with 1 ml of lysis buffer (50 mM NaCl, 20 mM Tris-HCl *p*H 7.3, 0.5% Nonidet P-40, 0.5% sodium deoxycholate, 4 mM iodoacetic acid, 1 mM ammonium vanadate), and lysates were subjected to vortex mixing for 30 s and clarified by centrifugation for 5 min in an Eppendorf centrifuge. The appropriate antisera were added (Pre, preimmune serum; Im, immune serum) and the samples were incubated for 2 h at 4 °C. The immune complexes were collected by adsorption to protein A–Sepharose for 1 h at 4 °C with continuous mixing. The adsorbed immune precipitates were washed four times (each with 0.5 ml lysis buffer), suspended in 50 μl of electrophoresis sample buffer, heated at 60 °C for 10 min, and subjected to SDS-PAGE. To prepare anti-lipocortin serum, rabbits were immunized with recombinant human protein produced in *E. coli*. Native protein was emulsified with Freund's complete adjuvant and administered by intramuscular injection; 5 weeks after the primary injection, the rabbits received a booster injection of protein emulsified with incomplete adjuvant.

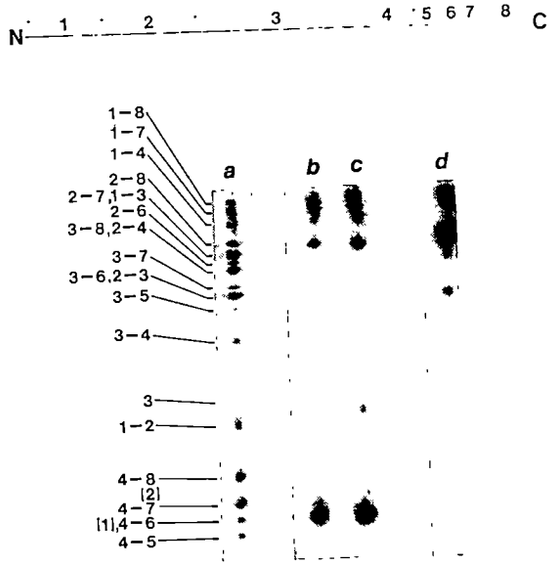

Fig. 3 Cyanogen bromide mapping of phosphorylated lipocortin. *a*, Unlabelled lipocortin; *b*, phosphorylated lipocortin (EGF receptor/kinase); *c*, phosphorylated endogenous 35K protein (EGF receptor/kinase); *d*, phosphorylated lipocortin (protein kinase A). Numbers on the left correspond to CNBr fragments of lipocortin: fragment 1 refers to the amino-terminal fragment and fragment 8 the carboxy-terminal fragment. The distribution and relative sizes of all the fragments are indicated in the schema shown at the top. The fragmentary compositions of cleavage fragments are based on CNBr mapping[18]. Although fragments 1 and 2 are not visualized by this particular silver staining procedure[26], their positions in cleavage profile are indicated. Other cleavage products were not identified because either they were below the size limit of detection of this particular gel system or they were minor cleavage products and could not be analysed.

Methods. Gel slices containing either unlabelled lipocortin or *in vitro* phosphorylated products were incubated with CNBr (10 mg ml^{-1}) for 1 h at room temperature in 0.1 M HCl plus 0.1% 2-mercaptoethanol. The CNBr-treated gel slices were washed twice for 5 min each with water, once for 5 min in 0.25 M Tris-HCl *p*H 6.8, and once for 10 min at 37 °C in electrophoresis sample buffer. The slices were loaded onto SDS-gels and the cleavage products separated by SDS-PAGE using the Laemmli discontinuous buffer system (main gel: 15% acrylamide, 0.4% methylene bisacrylamide).

phosphorylation site is near the amino terminus of lipocortin. The positions of serine, threonine and tyrosine residues within fragment 1 place further boundaries on this site. Recombinant lipocortin also can be phosphorylated *in vitro* by the catalytic subunit of protein kinase A. The cleavage profile of protein kinase A-phosphorylated lipocortin (Fig. 3*d*) suggests a modification within fragment 3.

In addition to the *in vitro* experiments, we have evaluated the phosphorylation state of lipocortin in metabolically labelled A431 cells. Figure 2*i–p* shows the results of an analysis in which crude lysates from labelled cells were treated with either anti-lipocortin serum or preimmune serum, and the immune complexes analysed by SDS-PAGE. In lysates of ^{35}S-methionine-labelled cells, the anti-lipocortin serum recognized a single protein of 35K which was not detected with preimmune serum from the same rabbit. Metabolic labelling of the 35K protein was independent of EGF treatment. The 35K protein was also detected in immune precipitates from ^{32}P-phosphate-labelled cell lysates (Fig. 2*m–p*), but only for preparations derived from EGF-treated cells. Similar results for metabolic labelling of the endogenous 35K protein have been described previously[10]. Using conditions that enrich for tyrosine phosphate (that is, the gel is treated prior to autoradiography with 1 M KOH for 1 h at 55 °C; ref. 20) we observed that the phosphorylated 35K protein was enhanced relative to background radioactivity (not shown).

Here we have presented data demonstrating that the endogenous 35K substrate for the EGF receptor/kinase from A431 cells is lipocortin, and therefore presumably a potent phospholipase A_2 inhibitor. This result was deduced from both

structural and immunological analyses. The relevance of the phospholipase inhibitory activity to the cellular function of these proteins remains to be established. Peptide mapping and the use of the anti-lipocortin antiserum should allow us to clarify rapidly the relationships between the 35K substrate for the EGF-dependent kinase[15,21,22], the 34–40K substrate for *src*-like kinases[21,23,24] and the 35K G-protein β-subunit[22], which to date remain controversial. The role of the 35K protein as a phospholipase A_2 inhibitor probably represents an important biological activity in EGF transduction.

We thank Barbara P. Wallner for the JA221 strain of *E. coli* transformed with plasmid LipTrc155A, a strain producing recombinant human lipocortin; and John Smart, Vicky Sato, Richard Flavell and Jeff Browning for critical reading of the manuscript. This work was funded by Biogen Research Corporation and by Yamanouchi Pharmaceutical Company.

Ha-*ras* hypervariable alleles in myelodysplasia

S. L. Thein*, D. G. Oscier†, J. Flint* & J. S. Wainscoat‡

* MRC Molecular Haematology Unit, Nuffield Department of Clinical Medicine, and ‡ Department of Haematology, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK
† Department of Haematology, Royal Victorian Hospital, Boscombe, Bournemouth BH1 4JG, UK

The somatic mutation of one of the *ras* oncogenes is now considered to be a critical step in the pathogenesis of many tumours[1,2]. Circumstantial evidence also suggests that some individuals may be genetically predisposed to malignancy[3] and a general method used to analyse such disease susceptibility is the study of restriction fragment length polymorphisms (RFLPs) at particular loci[4,5]. The Harvey *ras* (Ha-*ras*) locus includes a hypervariable region (HVR) which consists of a series of 28-base-pair (bp) tandem repeats 3′ to the gene[6]. This arrangement gives rise to alleles of a wide range of sizes, making such genetic analysis possible. A previous study reported that white blood cell DNA from cancer patients frequently showed allelic restriction fragments at the Ha-*ras* locus which were found only rarely in normal unaffected individuals, and it was concluded that the inheritance of such unusual alleles may be linked to a susceptibility to cancer[7]. As this conclusion has major implications we sought to investigate whether this association could be confirmed in patients with myelodysplasia, a common haematological malignancy reported to have the highest frequency of rare alleles[7]. The Ha-*ras* alleles were characterized in normal healthy individuals and compared with those found in patients with myelodysplasia (MDS). Our results, reported here, show that the distribution of Ha-*ras* alleles in myelodysplastic patients is not significantly different from that in normal individuals.

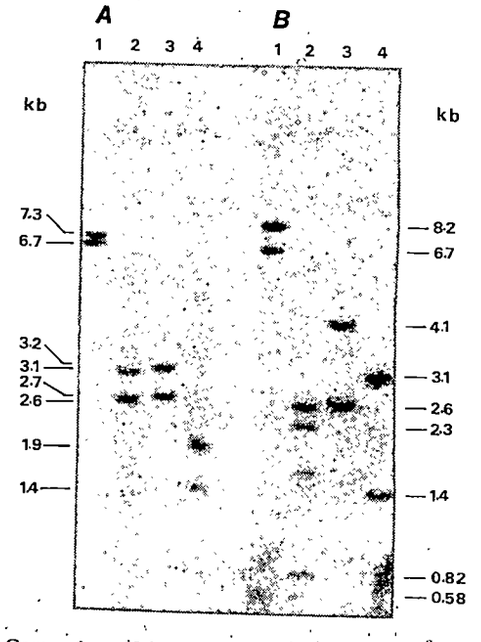

Fig. 1 Comparison of the Ha-*ras* alleles generated by four restriction endonucleases. DNAs from two individuals (*A* and *B*) were digested with *Bam*HI (lane 1), *Taq*I (lane 2), *Hin*fI (lane 3) and *Ava*II (lane 4). The digested DNA was hybridized to the 2.5-kb *Bam*HI–*Sst*I fragment containing the T24/EJ bladder oncogene[6]. *A*, An individual with the *a*/*b* Ha-*ras* alleles corresponding to the *Bam*HI 6.7/7.3-kb fragment and the *Taq*I 2.6/3.1-kb, *Hin*fI 2.7/3.2-kb and *Ava*II 1.4/1.9-kb fragments. *B*, An individual with two *Taq*I site polymorphisms. Corresponding sizes for the *a* allele were seen with *Bam*HI (6.7 kb); *Taq*I (2.6 kb), *Hin*fI (2.7 kb) and *Ava* II (1.4 kb) digests. *Bam*HI, *Hin*fI and *Ava*II digests gave appropriate corresponding sizes (8.2, 4.1 and 3.1 kb respectively) for the '*d*' allele but a pattern of three fragments (2.3 kb, 820 bp and 580 bp) was obtained for the *Taq*I digests. Further investigations suggested the presence of two *Taq*I site polymorphisms within the HVR. All alleles with the *Taq*I site polymorphisms were characterized by the *Ava*II '*d*' (3.1 kb) alleles, which suggests that these *Taq*I site polymorphisms are linked to a particular HVR allele.

Methods. DNA was prepared from peripheral blood buffy coat cells by digestion with proteinase-K and phenol–chloroform extraction as described previously[10] DNA (5 μg) was digested with 25 units of each restriction enzyme, separated by electrophoresis on a 0.8% agarose gel and transferred to nitrocellulose membrane by Southern blotting. The *Bam*HI–*Sst*I fragment of plasmid pEJ[6] containing the Ha-*ras* HVR was purified and nick-translated to a specific activity of $\sim 1.0 \times 10^8$ c.p.m. μg^{-1}. Pre-hybridization, hybridization and washing of the membranes were done as described previously[10]. Autoradiography was at −70 °C.

Fifty-two normal healthy individuals and 53 patients with MDS were studied. The diagnosis of MDS fulfilled the criteria of the FAB classification[8]. DNA was extracted from peripheral blood leukocytes, digested with appropriate restriction enzymes, Southern-blotted and hybridized to the *Bam*HI–*Sst*I fragment of plasmid EJ containing the HVR~1.5 kilobases (kb) from the 3′ terminus of the coding sequences of the Ha-*ras* gene. The first objective was to choose the most appropriate restriction enzyme to give maximal resolution of the different HVR alleles.

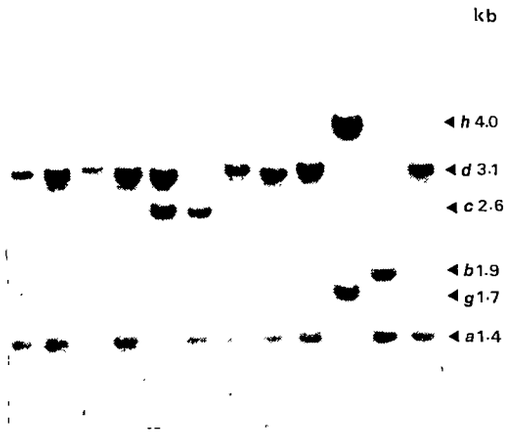

Fig. 2 Microheterogeneity of the common Ha-*ras* allele. DNA (5 μg) was digested with *Ava*II, electrophoresed on a 0.8% agarose gel, and transferred to nitrocellulose membrane by Southern blotting. Hybridization and autoradiography were as described in Fig. 1 legend. Microheterogeneity between the '*d*' alleles could only be visualized when the DNA samples were run in adjacent tracks. However, the differences between the various '*d*' alleles were too small to be measured reliably. There was no obvious microheterogeneity among the different '*a*' alleles.

Table 1 Distribution of the *Ava*II Ha-*ras* alleles

Allele	Size (kb)	Normal individuals	Myelodysplastic individuals	Total
Common				
a	1.4	71 (68%)	66 (62%)	137 (65%)
b	1.9	6 (6%)	15 (14%)	21 (10%)

DNA was prepared from peripheral blood buffy coat cells and the allele sizes determined as described in Fig. 1 legend. The numbers of particular *Ava*II Ha-*ras* alleles are given with the frequencies in parentheses.

DNAs from 10 unrelated individuals were digested with a panel of restriction enzymes and resolution of the different bands was found to be greatest with the enzyme *Ava*II, which cleaves just outside the HVR. In addition to *Ava*II, all DNAs were digested with *Bam*HI and *Taq*I to ensure that variation in allelic fragment sizes was directly related to the HVR length rather than to restriction enzyme site polymorphisms (see Fig. 1).

Although optimal resolution was obtained with *Ava*II digestion, it was difficult to compare similar-sized Ha-*ras* alleles between different gels. To overcome this problem, all DNAs with apparently similar-sized alleles were re-electrophoresed in adjacent tracks against control DNA samples (Fig. 2). Nine measurably different *Ava*II Ha-*ras* alleles were found, of which four were common and five rare. Microheterogeneity of fragment sizes was observed within the four common allele classes in both groups of indviduals. However, the degree of microheterogeneity was so small that it could be visualized only by examination of the autoradiographs when alleles of the same size class were in adjacent tracks; these small differences cannot be measured reliably. The degree of microheterogeneity was greater within the three classes of common, larger-sized alleles than within the smallest common allele class. This phenomenon probably relates to the greater likelihood of misalignment occurring during recombination between larger HVR alleles. This result is in accord with the observation in a study of the hypervariable minisatellite regions that those probes with the longer HVRs detected more allele sizes[9]. There was no observable difference in the degree of microheterogeneity in the allele sizes between the two groups of individuals.

Table 1 shows the numbers of the different Ha-*ras* alleles found in the two groups of individuals. The frequencies of the four common *Ava*II alleles are not significantly different between the two groups and are very similar to those previously reported using *Bam*HI. The rare alleles were found sporadically in both groups: 5/104 in normal chromosomes and 3/106 in MDS chromosomes. Therefore, there is no significant increase in the frequency of rare alleles in the MDS patients compared with normal individuals. The frequency of the rare alleles in our group of normal individuals (4.8%) was not significantly different from that in the group of normal individuals observed previously (3.9%)[7]. The patients reported previously as having the highest proportion of rare alleles had MDS, 6/7 patients having rare alleles[7]. Here we studied 53 patients with MDS of which only three had rare alleles. Therefore, our finding that the MDS patients do not have an increased frequency of rare alleles is in striking contrast to the previous study, although the reasons for this difference are not clear. Thus, we have found no evidence to suggest that the inheritance of rare HVR alleles at the Ha-*ras* locus prediposes to myelodysplasia.

We thank Liz Gunson for typing the manuscript; Drs D. R. Higgs and A. J. Jeffreys for critical comments on the manuscript; and Dr F. G. Bolton and Professor D. J. Weatherall for their support and encouragement.

Spectrin assembly in avian erythroid development is determined by competing reactions of subunit homo- and hetero-oligomerization

Catherine M. Woods & Elias Lazarides

Division of Biology, California Institute of Technology, Pasadena, California 91125, USA

Erythroid differentiation entails the biogenesis of a membrane skeleton, a network of proteins underlying and interacting with the plasma membrane[1–3], whose major constituent is the heterodimeric protein spectrin, composed of two structurally similar but distinct subunits[4], α (relative molecular mass (M_r) 240,000) and β (M_r 220,000), which interact side-on with each other to form a long rod-like molecule[1,3,5–10]. Interaction of this network with the membrane is mediated by the binding of the β subunit to ankyrin[1,6,11–14], which in turn binds to the cytoplasmic domain of the transmembrane anion transporter (also referred to as band 3)[1,15–19]. Purified α and β subunits of spectrin from the membrane of mature red blood cells will spontaneously

heterodimerize[13,14,20–23], suggesting that assembly of the spectrin-actin skeleton is a simple self-assembly process, but *in vivo* studies with developing chicken embryo erythroid cells have indicated that assembly *in vivo* is more complex[24–29]. We now present evidence that newly synthesized spectrin subunits *in vivo* or *in vitro* rapidly adopt one of two competing conformations, a heterodimer or a homo-oligomer. These competing reactions seem to determine the overall extent of spectrin assembled during erythroid development by determining which conformation will assemble onto the membrane-skeleton (the heterodimer) and which conformations are targeted for degradation (the homo-oligomers).

When chicken erythroid cells are pulse labelled with ^{35}S-methionine and lysed hypotonically, excess unassembled ankyrin, β-spectrin and α-spectrin remain soluble[29]. We characterized the unassembled polypeptides by chromatographing hypotonically soluble fractions through an Ultrogel Ac22 gel filtration column, and found that unassembled β- and α-spectrin eluted as distinct species (Fig. 1*A*), well ahead of the fractions where globular proteins of their size would be expected to appear. β-Spectrin was only just included in the column, eluting with the purified adult red blood cell $\alpha\beta$-spectrin heterotetramers used as a standard eluate. Most of the α-spectrin migrated behind β-spectrin, at the position of the heterodimeric red blood cell spectrin standard. Ankyrin eluted in a manner that would be predicted for a globular monomeric protein of its size, slightly ahead of haemoglobin and the bulk of the other polypeptides.

Immunoprecipitation of unassembled β-spectrin, α-spectrin and ankyrin across the column after a pulse-labelling period as short as 5 min showed clearly that the three polypeptides eluted as distinct peaks, with most β- and α-spectrin eluting respectively with the $\alpha\beta$-heterotetramer and $\alpha\beta$-heterodimer standards (Fig. 1*E*). The high mobility of the unassembled β-spectrin was not the result of association with organelles because these should have eluted in the void volume and this β-spectrin species was clearly included in the column. Also, pretreatment of the hypotonically soluble fraction with puromycin, to release nascent polypeptides from ribosomes, or inclusion of 0.5% Triton X-100 in the elution buffer, to disrupt membranous organelles, had no effect on the elution pattern of either α- or β-spectrin (data not shown). Furthermore, neither unassembled α- or β-spectrin sedimented after centrifugation at 150,000*g* for 30 min (see Table 1). Thus, β-spectrin seems to be associated in a species of relative molecular mass equivalent to that of a spectrin tetramer and α-spectrin to that of a spectrin dimer.

Further evidence that the unassembled β- and α-spectrin subunits were indeed separate homo-oligomeric species was obtained by analysing fractions off the column by two-dimensional non-denaturing followed by SDS-polyacrylamide gel electrophoresis (PAGE). The two spectrin species clearly did not co-migrate even in fractions where the β- and α-spectrin peaks overlapped; β-spectrin consistently migrated close to the position of adult red blood cell spectrin $\alpha\beta$-heterotetramers and α-spectrin with spectrin $\alpha\beta$-heterodimers (Fig. 2*A*,*B*). Furthermore, no other protein co-migrating with either spectrin homo-oligomeric species was observed (Fig. 2*A*) even after labelling

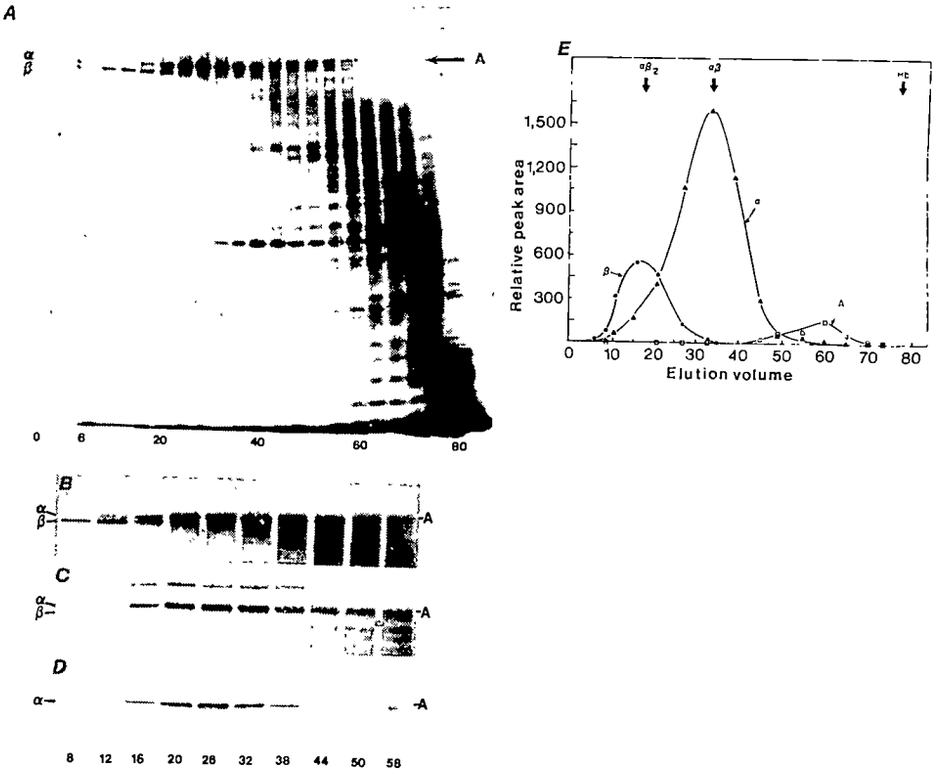

Fig. 1 Gel-filtration elution profiles of the hypotonically soluble fraction of pulse-labelled erythroid cells from 10-day chick embryos. Results shown are for lysates from erythroid cells lysed immediately after 10 min labelling with ^{35}S-methionine (*A*), after 10 min pulse-labelling followed by 30 min chase (*B*), after 1 h chase (*C*), or 4 h chase in the presence of cold methionine (*D*) and quantitation of β-spectrin, α-spectrin and ankyrin in fractions across the column by immunoprecipitation (*E*). *A*–*D* Show autoradiograms after exposure for 48 h. α = α-spectrin; β = β-spectrin; A = ankyrin. The numbers beneath the lanes represent V_e, that is, volumes eluting after the void volume. *E*, Quantitation by immunoprecipitation of β-spectrin (β), α-spectrin (α) and ankyrin (A) across the column shown in *A*. *B* The arrows indicate the peak fractions of the rabbit spectrin $(\alpha\beta)_2$-tetramer and $\alpha\beta$-dimer, respectively, and also the fraction where haemoglobin beings to appear (Hb).

Methods. Samples (0.75 ml) of packed, washed erythroid cells isolated from 10-day chick embryos as described previously[29] were preincubated in methionin e-free minimal essential medium (MEM) supplemented with 5% dialysed fetal calf serum (FCS) labelled for 10 min with 300 μCi ^{35}S-methionine (specific activity 11,000–13,000 Ci mmol^{-1}) and chased for various time intervals in fresh MEM-FCS media containing 2 mM unlabelled methionine all at 38 °C in a humidified atmosphere. Aliquots of cells were collected by centrifugation in ice-cold choline chloride (155 mM), HEPES (5 mM) buffer *p*H 7.2, then lysed in 4 vols ice-cold hypotonic lysis buffer (5 mM Tris-HCl *p*H 7.2, 5 mM $MgCl_2$, 0.1 mM dithiothreitol (DTT), 1 mM EGTA, 1 mM *p*-tosyl-L-arginine methyl ester (TAME) 1 mM phenylmethylsulphonyl fluoride). After centrifugation of the cell lysate at 13,000*g* for 10 min in an Eppendorf centrifuge, the supernatant was recentrifuged for 10 min before being layered on a 2.5 × 50 cm Ac22 Ultrogel gel filtration column (exclusion limit 3×10^6 daltons) and eluted with Tris-buffered saline (125 mM NaCl, 10 mM Tris-HCl *p*H 7.2, 1 mM $MgCl_2$, 1 mM EDTA, 1 mM NaN_3, 0.1 mM DTT; identical elution patterns of the spectrins and ankyrin were obtained whether or not Mg^{2+} or DTT was included) at a flow rate of 15 ml h^{-1}. Beginning at the void volume, the eluate was collected in 2-ml fractions and alternate fractions were assayed by SDS-PAGE using the modified Laemmli gel system described by Hubbard and Lazarides[36]. After processing in 20% diphenyloxazole (PPO) in dimethyl sulphoxide, dried gels were autoradiographed with Kodak XAR film at −80 °C. The levels of β-spectrin, α-spectrin and ankyrin were quantitated by immunoprecipitation using method B of Blikstad *et al.*[23], except that deoxycholate was omitted from the buffer for ankyrin immunoprecipitation, followed by SDS-PAGE. The gels were processed for autoradiography, dried and exposed to pre-flashed Kodak XAR film long enough to give bands of intensity within the linear range of intensity versus amount of ^{35}S. The bands were then scanned with a Quick Scan (Helena Laboratories) and the peaks integrated by computer. Values represent arbitrary relative units. Rabbit spectrin $\alpha\beta$-heterotetramers and heterodimers were isolated from rabbit erythrocyte ghosts by the method of Ungewickell and Gratzer[20]. Their elution profiles through the column were assayed by SDS-PAGE followed by densitometry of the Coomassie-stained gels.

periods of 3–4 h (data not shown). Crosslinking experiments with dithiobis(succinimidyl)propionate provided further evidence that unassembled α-spectrin existed as a homodimer, for it could be efficiently converted to a species of $M_r \simeq 0.5 \times 10^6$, while β-spectrin existed as a homotetramer since an additional product of $M_r \simeq 10^6$ was observed on one-dimensional SDS gels in non-reducing conditions (Fig. 2*C*).

These elution patterns of the unassembled pulse-labelled spectrins and ankyrin persisted until the polypeptides had been turned over (Fig. 1*B–D*), the rates of disappearance of the β-spectrin, α-spectrin and ankyrin peaks matching the individual rates of turnover previously described for these polypeptides ($t_{1/2}$ = 15–20 min, 2 h and 1 h, respectively[29]). Together, our observations indicate that, unlike the assembled polypeptides, unassembled β-spectrin, α-spectrin and ankyrin behave as independent kinetic species and exhibit no obvious association with each other.

Isolated α- and β-spectrin subunits purified from adult red blood cell heterodimeric spectrin after denaturation with urea or SDS reassociate spontaneously into heterodimers upon renaturation[13,14,20,30]. Any α- and β-homo-oligomeric species that might form as the separated subunits are renatured have been considered to be metastable species that will spontaneously convert into heterodimers. The unassembled β-homotetramer and the α-homodimer behaved quite differently in this respect, as there was no evidence of interconversion to an $\alpha\beta$-heterodimer or tetramer even after incubation of an approximately stoichiometric mixture of the β- and α-spectrin peak fractions for 1 h at 37 °C and analysis by sieving chromatography. However, if such a mixture was first denatured with 3 M urea or 0.5% SDS and allowed to renature before chromatography[20], α- and β-spectrin co-eluted. Analysis by two-dimensional-PAGE confirmed that hetero-oligomerization occurred only after the two spectrin homo-oligomers had been previously denatured (data not shown). These results suggest that the homo-oligomeric forms assumed by the newly synthesized α- and β-spectrin subunits represent alternative, but stable, conformations to the normal $(\alpha\beta\text{-heterodimer})_n$ form of assembled spectrin. Similar association experiments showed no evidence of association between the unassembled homotetrameric β-spectrin and unassembled ankyrin (data not shown).

We next tested whether the unassembled forms of spectrin could bind to the erythroid plasma membrane, and whether binding would alter their capacity to interact with each other, by using spectrin- or ankyrin-depleted erythrocyte inside-out membrane vesicles (IOVs), which have been shown to bind chicken spectrin in a similar manner to rabbit spectrin[31]. The β-spectrin homo-tetramer was found to bind selectively to spectrin-depleted IOVs and this binding was inhibited by prior removal of ankyrin or prior trypsinization of the vesicles (Table 1*a*). In contrast, the α-spectrin homodimer did not bind to IOVs, whether added alone or in the presence of stoichiometric amounts of the β-spectrin homotetramer (Table 1*a*). The possibility that filtration through the Ultrogel column had somehow affected the membrane-binding properties of these unassembled spectrin forms was discounted because similar results were obtained with membrane-binding studies on the hypotonically soluble fraction immediately after cell lysis (Table 1*b*). Some binding of the unassembled ankyrin was also detected but this was often accompanied by proteolysis. The inability of the α-spectrin homodimer to bind to spectrin-depleted IOVs, even in the presence of the β-spectrin homotetramer, eliminates the possibility that heterodimerization occurs by nucleation of homo-oligomers by the membrane.

Previous kinetic analysis has indicated that the unassembled pools of the two spectrin subunits represent ~50% of the β-spectrin and 85% of the α-spectrin synthesized after a 10-min pulse-labelling period[24,25]. The rest assembles rapidly with the stoichiometry (1:1) observed at steady state (refs 24, 25 and

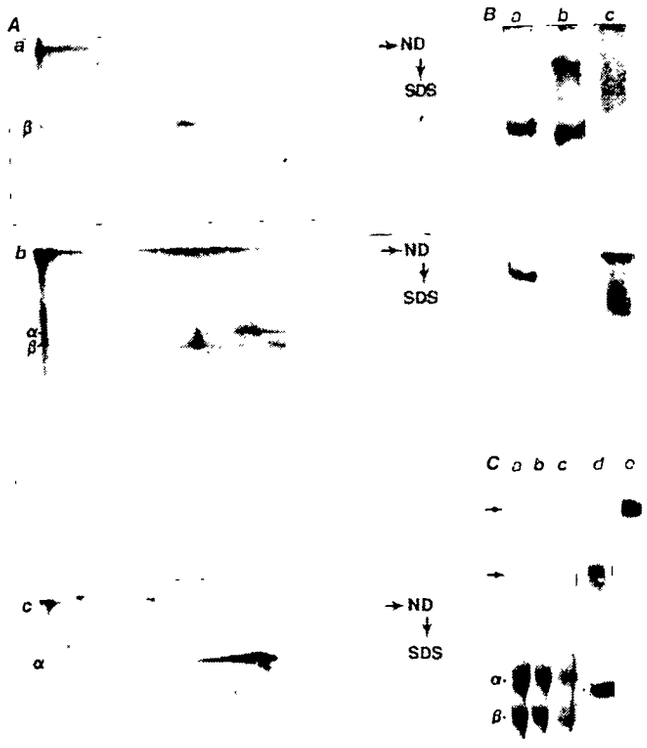

Fig. 2 *A*, *B*, Analysis of the β-spectrin and α-spectrin species from the β-peak fraction (*Aa*, *Bb*), the intermediate fraction (*Ab*) and the α-peak fraction (*Ac*, *Bc*) by non-denaturing PAGE in the first dimension (*B*) followed by SDS-PAGE in the second dimension (*A*), showing that the soluble unassembled α-spectrin and β-spectrin are distinct and separate species. Aliquots identical to those fractions eluting at 8 ml, 18 ml and 28 ml in Fig. 1*A* were analysed by PAGE on a 2.5–5% gradient, polyacrylamide gel under non-denaturing conditions (ND) as described by Morrow and Marchesi[22] in the first dimension, with duplicate lanes being excised and run in a second dimension on 10% SDS-PAGE (*Aa*, *b*, *c*, respectively). Gels were stained with Coomassie blue and then destained before being processed for autoradiography (PPO for the SDS gels, En^{3}HANCE for the non-denaturing gels), dried and exposed to Kodak XAR at −80 °C for 5 days (non-denaturing gels) or 18 days (second-dimension SDS gels). Lane *a* in panel *B* is the Coomassie-stained lane of rabbit spectrin heterotetramers and heterodimers run as standards on the nondenaturing gel. Lane *b* represents the β-spectrin peak fraction (V_e = 8 ml) and lane *c* the α-spectrin fraction (V_e = 28 ml). The smear running diagonally down to the right-hand side from the α-spectrin spot represents α-spectrin breakdwon products and/or nascent chains, since they react with α-spectrin-specific antibodies under stringent conditions but not with β-spectrin antibodies. Some aggregation occasionally occurs in both rabbit spectrin standards and the radioactive chicken spectrin species on electrophoresis in the first (native) dimension and is seen as material at the top of the gel. *C*, The unassembled α-spectrin and β-spectrin species can be crosslinked to a species of $M_r \simeq 0.5 \times 10^6$ and $\sim 1 \times 10^6$, respectively. Rabbit spectrin heterodimer standards (*a–c*) and aliquots from the peak fractions of hypotonically soluble β-spectrin (*d*) and α-spectrin (*e*), partially purified by gel filtration, were incubated in 10^{-3} M dithiobis(succinimidyl)propionate for 0 min (*a*), 10 min (*b*) or 30 min (*c–e*) at 25 °C. The samples were then denatured by addition of 1/5th volume 5% SDS sample buffer in the absence of any reducing agent and boiled for 5 min before loading onto a 3.5–10% polyacrylamide gradient SDS gel. After electrophoresis the gel was stained with Coomassie brilliant blue, destained and processed for autoradiography. Lanes *a–c* represent Coomassie-stained lanes, lanes *d* and *e*, autoradiograms after 48 h exposure. The arrows mark crosslinked products.

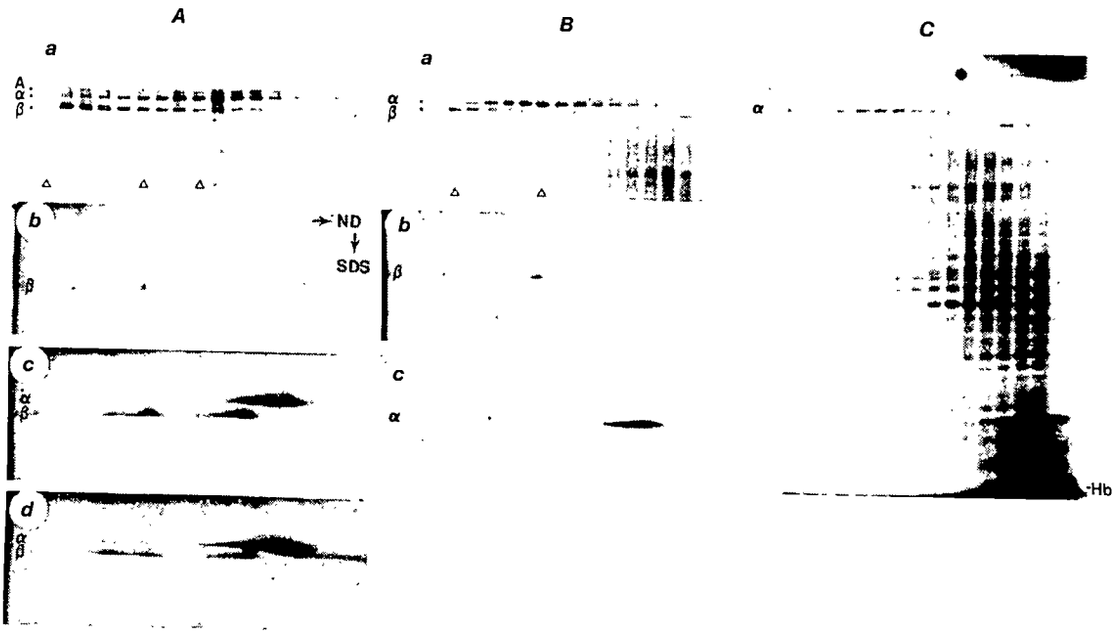

Fig. 3 Products of *in vitro* translation from pre-existing polyribosomes isolated from erythrocytes from 9-day chick embryos. Autoradiograms of the elution profiles of the soluble products of *in vitro* translation carried out in the absence (*Aa*) or presence of 40 μg ml^{-1} of rabbit erythrocyte spectrin-depleted, inside-out vesicle (IOVs; *Ba*) or 330 μg ml^{-1} of rabbit IOVs (*C*). Autoradiograms of the two-dimensional non-denaturing, SDS-PAGE analysis of the fractions, designated by Δ under the elution profiles, are depicted below their corresponding elution profiles in sequence. The smear running diagonally to the right-hand side from the main α-spectrin spot (most prominent in *Ad*) seems to represent nascent α-spectrin chains.

Methods. Erythrocytes from 9-day chick embryos were collected into sterile choline chloride (155 mM), HEPES (5 mM, *p*H 7.2) buffer on ice, concentrated by centrifugation and washed through sterile cotton wool to remove any contaminating white blood cells and platelets with 135 mM NaCl, 5 mM KCl, 10 mM HEPES (*p*H 7.2), 10 mM glucose and recentrifuged. Cells were then lysed in 1.8 vol of sterile distilled H_2O on ice and after 10 min, with periodic gentle mixing, were spun for 10 min at 13,000*g* in an Eppendorf centrifuge. The resultant supernatant was primed for *in vitro* translation as described for rabbit reticulocyte lysates[38] together with 300 μCi ^{35}S-methionine per 475 μl of primed lysate. After incubation at 30 °C for 45 min, rabbit spectrin-depleted IOVs were added at 0 (*A*), 40 (*B*) or 330 (*C*) μg ml^{-1}. After a further 30 min of incubation at 30 °C, the translation mixtures were centrifuged for 30 min at 150,000*g* in a Beckman airfuge with the vesicles pelleted through a 0.6 M sucrose pad. Aliquots (250 μl) of the supernatans were applied to a 1×17 cm Ac22 gel filtration column and fractions of 200 μl collected. Alternative fractions after the void volume were analysed by SDS-PAGE followed by autoradiography as described for Fig. 1.

The fractions designated by Δ were further analysed by two-dimensional non-denaturing followed by SDS-PAGE as described for Fig. 2.

Woods and Lazarides, personal observations). These observations, together with the above results, suggest that the fractions that assemble must exist in an alternative form to the homo-oligomeric conformations that accumulate in the unassembled pools. To approach this issue, we uncoupled synthesis from assembly onto the membrane and analysed any intermediates formed during assembly by a series of *in vitro* polysomal run-off experiments using hypotonic lysates made from erythroid cells isolated from 9–10-day chick embryos[31]. The Ac22 Ultrogel elution profile of the proteins synthesized *in vitro* was similar to that obtained with the *in vivo* labelled soluble proteins (Fig. 3*A*). In this case, however, there was a greater overlap of the β-spectrin with the α-spectrin peak, while a small subset of both proteins also eluted as monomers. Analysis of different fractions across the column by two-dimensional PAGE revealed that whereas there was no evidence for spectrin heterodimers in the soluble pool after *in vivo* labelling, close to 50% of the β-spectrin synthesized *in vitro* existed in the form of heterodimers with α-spectrin; the remainder of β-spectrin existed predominantly as homotetramers (Fig. 3*A*). Similarly, a fraction of the α-spectrin synthesized *in vitro* existed as heterodimers with β-spectrin, with the remainder existing mainly as homodimers (Fig. 3*A*). The proportion of β-spectrin in the form of heterodimers was remarkably close to that of newly synthesized β-spectrin which assembles on the membrane skeleton *in vivo*[25].

The heterodimeric spectrin produced *in vitro* bound to rabbit erythrocyte spectrin-depleted IOVs but not to right-side-out vesicles, ankyrin-depleted or acetic acid-stripped IOVs, similarly to the homotetrameric β-spectrin (Table 1*c*). Binding studies at different IOV concentrations revealed preferential binding of the heterodimeric over the β-homotetrameric species at sub-saturating concentrations of IOVs. At a concentration of IOVs equivalent to 330 μg membrane protein per ml, both β-spectrin-containing forms bound effectively to the IOVs (Fig. 3*C*, Table 1*c*). With 40 μg membrane protein per ml, all of the heterodimeric spectrin bound to the membrane whereas most of the β-homotetramer remained in the soluble fraction (Fig. 3*B*, Table 1*c*). Such experiments suggest that these heterodimers constitute the fraction that rapidly assembles on the membrane *in vivo*, and that their assembly occurs too rapidly for detection after *in vivo* labelling of erythroid cells from 10-day-old chick embryos.

In conclusion, the data presented here indicate that newly synthesized α- and β-spectrin monomers rapidly assume one of two configurations, an αβ-heterodimer or a homo-oligomer (β_4 or α_2). Interestingly, only newly synthesized spectrin polypeptides can assume a stable homo-oligomeric conformation, suggesting that the folding of the nascent polypeptide may begin from the NH_2- towards the COOH-terminus in parallel with synthesis. The diffusion–collision theory of protein-folding dynamics predicts that native secondary structure is achieved within each microdomain of a polypeptide by random events and is stabilized by subsequent interactions between micro-domains[32,33]. Human α- and β-spectrin polypeptides are known to consist of multiple homologous non-identical repeating triple helical segments, each 106 amino acids long[4,7]. as has also been observed in chicken α-spectrin[34,35]. If this model is correct, these

Table 1 Membrane-binding ability of unassembled β- and α-spectrin

a, Partially purified by gel filtration

Membranes added	% Pelleted β-Spectrin	α-Spectrin	Mixture of α+β-spectrin α	β

Aliquots of the peak fractions of pulse-labelled β-spectrin and α-spectrin, partially purified by gel-filtration chromatography as described in Fig. 1*A* legend. (*a*), total soluble hypotonic lysate, prepared immediately after a 10-min pulse of erythroid cells from 11-day chick embryos (*b*) or the products of *in vitro* translation as described for Fig. 4 (*c*) were incubated either alone or in the presence of rabbit erythrocyte ROVs, spectrin-depleted IOVs, acetic-acid-stripped, ankyrin-depleted IOVs or trypsinized IOVs prepared by the protocol described by Bennett and Branton[37]. Equal aliquots of ghost erythrocyte membranes were used for the preparation of each of these types of vesicles and the resultant vesicles suspended in identical volumes. The volumes added to the soluble spectrin fraction gave concentrations of IOV membrane protein equivalents of 330 μg ml^{-1}. After a 20-min incubation at 38 °C, the vesicles were pelleted through a 0.6 M sucrose cushion in Tris-HCl (5 mM, *p*H 7.2) for 20 min at 150,000*g* in a Beckman airfuge. The relative amounts of α- and β-spectrin in the supernatants and pellets were analysed by SDS–PAGE followed by autoradiography and densitometry of the resultant autoradiograms. The values represent the mean values from three separate experiments; variability was less than 7%.

helices will presumably begin to form as each 106-amino-acid segment is synthesized. The fact that the two spectrin molecules are so long (~4,000 amino acids each) probably increases the chances of coiled-coil interactions occurring between adjacent nascent chains before synthesis is complete. Therefore, the formation of stable spectrin homo-oligomeric species *in vivo* may result from the greater chance of coiled-coil interactions occurring between like rather than unlike spectrin subunits, even though the αβ form may be thermodynamically favoured.

It has been proposed (ref. 25) that spectrin and ankyrin assembly occurs through a cascade of limiting steps, where the extent of α-spectrin assembled is limited by the amount of β-spectrin assembled, which in turn is limited by the amount of ankyrin bound. The data presented here suggest instead that the limiting factor is the extent of heterodimerization. Furthermore, homo-oligomerization prevents the unassembled spectrins from reacting with each other or with ankyrin and in the case of α-spectrin also from binding to the plasma membrane. Although β-homotetramers can bind to spectrin-depleted plasma-membrane vesicles, presumably to ankyrin, they appear to bind with lower affinity than heterodimers. The difference in membrane affinity, coupled with the fact that unassembled β-spectrin (β_4-spectrin) is degraded extremely rapidly and selectively[29], makes it feasible that if any β-homotetramers do bind to the membrane *in vivo*, they are displaced by αβ-heterodimers and then degraded rapidly, thereby ensuring the correct stoichiometry of assembled spectrin.

Finally, it is interesting to note that the β-homotetramer appears to bind to preassembled ankyrin, yet no association can be detected with the unassembled ankyrin that accumulates transiently in the soluble pool. This paradox suggests that this unassembled ankyrin must also exist in some modified form unable to interact with β-spectrin.

Template-free RNA synthesis by Qβ replicase

Christof K. Biebricher, Manfred Eigen & Rüdiger Luce

Max-Planck-Institut für Biophysikalische Chemie, D-3400 Göttingen, FRG

In the absence of extraneously added template, standard preparations of Qβ replicase spontaneously synthesize RNA *in vitro*, possibly as a result of RNA contamination[1]. Using special enzyme purifications, Sumper and Luce[2] presented evidence that self-replicating RNA not present *ab initio* can grow out of 'template-free' incorporation mixtures. In contrast to DNA polymerase I and RNA polymerase, which also show *de novo* synthesis[3–5], the products synthesized 'de novo' by Qβ replicase are RNA species containing nonrepetitive sequences of defined lengths which differ between experiments, even when synthesized under identical condi-

tions, in fingerprints, chain lengths and kinetic parameters[6]. Kinetic analysis of the *de novo* processes[7] distinguished it from template-instructed synthesis and excluded an assumption of self-replicating RNA contamination. These conclusions were questioned recently by Hill and Blumenthal[8], who claimed to show that highly purified Qβ replicase preparations cannot produce RNA *de novo*. We now present evidence that, under the conditions required for *de novo* synthesis, Qβ replicase prepared according to their method is also capable of *de novo* synthesis. Furthermore, we show that Qβ replicase condenses nucleoside triphosphates to more or less random oligonucleotides.

Hill and Blumenthal[8] presented kinetic profiles of RNA synthesis for standard Qβ replicase preparations, for which RNA synthesis was detectable after about 30 min, and for specially purified R(−S1) Qβ replicase, for which no RNA synthesis was detected over a 4 h; addition of heat-treated standard enzyme preparations restored nucleotide incorporation in a way they claimed to be "kinetically indistinguishable from *de novo* synthesis". None of their data show the characteristics of what we called *de novo* synthesis. Instead, their Figs 1 and 3 identify the underlying process as template-instructed, with much shorter lag times than necessary for amplification of a single strand of self-replicating RNA to macroscopic appearance (see Table IV of ref. 7). Their finding that "the length of the lag period" was "inversely proportional to the concentration of nucleoside triphosphates" is also typical of template-instructed reactions, quite in contrast to the process we called *de novo* synthesis, which depends on the 2.8 th power of nucleotide and 2.5 th power of enzyme concentrations. (Both exponents represent lower bounds.) Hence, their incorporation products indeed did not result from *de novo* synthesis but rather from template-instructed amplification of RNA impurities present in their standard enzyme preparations.

Using enzyme purified by a different method, they detected no incorporation up to 4 h without added template. At R(−S1) enzyme concentrations as low as used in their experiments (68 nM), we also observed no *de novo* synthesis[7] over this time. Other groups have performed experiments with Qβ replicase[9–11] without reporting interference by *de novo* synthesis, and examination of the conditions used by these groups shows in each case that no *de novo* synthesis would be expected.

Unfortunately, Hill and Blumenthal were unable to cooperate in an effort to determine whether their purification procedure yields an enzyme unable to synthesize RNA *de novo* (T. Blumenthal, personal communication). We therefore repeated their experiments independently as well as was possible using the sparse data given in their report. Our results are:

(1) Enzyme prepared according to Blumenthal's standard procedure[12], despite being electrophoretically ~90% pure, contained RNA at optically detectable levels, part of which was self-replicating as macroscopic RNA synthesis started after short lag times. The products were defined RNA species reproducibly selected under identical conditions. However, even minor changes in conditions often resulted in different electrophoretic patterns of the products.

(2) Although phosphocellulose–urea purification step introduced by Hill and Blumenthal indeed removed the RNA, the acidic enzyme subunits S1, and later elongation factors (EFs) Tu and Ts, eluted slowly from the column under their conditions. Depending on the wash volume and time of the urea step, only 10–50% of the input viral β-subunit was recovered. Resulting preparations still contained 10% S1, but excess EF Tu and Ts.

(3) Excess EF Tu.Ts and residual holoenzyme could be removed in the next step if the described stepwise elution was replaced by gradient elution[2,13]. SDS-gel electrophoresis combined with silver staining revealed no impurities in the resulting preparation or in our standard preparations (see Fig. 3 in ref. 14). However, the low synthesis rate found by Hill and Blumenthal (1.6×10^{-3} s^{-1} compared with our $3.3–6.5\times10^{-3}$ s^{-1}) led us to suspect that the concentration of active enzyme in their preparation was overestimated.

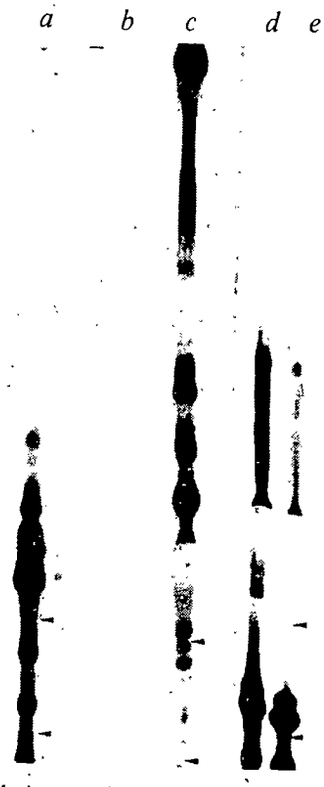

Fig. 1 Electropherograms showing condensation of triphosphates to oligonucleotides by Qβ replicase. The incorporation mixtures contained in Qβ buffer (0.05 M Tris-HCl buffer *p*H 7.5, 0.2 mM dithiothreitol, 10 mM $MgCl_2$, 20% glycerol) were: lane *a*, 500 μM[α-^{32}P]ATP, 200 μM GTP, 50 μM PP_i, 500 nM replicase; lanes *b*, *c*, 200 μM GTP, 50 μM ATP, 1.5 μM[α-^{32}P]CTP, 20 μM PP_i, 200 nM replicase; lane *d*, 800 μM ATP, 800 μM GTP, 20 μM PP_i, 600 nM replicase; lane *e*, 800 μM ITP, 800 μM GTP, 20 μM PP_i, 600 nM replicase.
Methods. Incubations were for 5 min (*b*), 68 h (*a*, *c*) or 16 h (*d*, *e*) at 30 °C. The oligonucleotides from incubations *d* and *e* were treated with phosphatase, isolated on QAE-Sephadex-A25 and labelled with polynucleotide kinase and [γ-^{32}P]ATP before loading onto the gel. The incubation mixtures were analysed on sequencing gels (12% acrylamide). The arrows give the positions of the dyes bromophenol blue (mobility of the undecamer) and dinitrophenol (mobility of the pentamer). Electrophoresis was from top to bottom. The material eluted from the gels was degradable by alkali or snake venom phosphodiesterase.

(4) Using conditions appropriate for observing *de novo* synthesis, we found that replicase purified by their method has about the same ability to synthesize RNA *de novo* as was observed with our preparations. The essential point is to choose sufficiently high enzyme (and nucleoside triphophate) concentrations to utilize the strong concentration dependence of lag times (see Fig. 4 of ref. 7). Concentration of the enzyme on QAE-Sephadex (step VIII of ref. 2) was therefore required for the *de novo* experiments. In accordance with earlier reports[6], the products were different even when synthesized under identical conditions.

(5) Enzyme preparations isolated by the standard purification method[2] from uninfected *Escherichia coli* containing a plasmid carrying the structural gene of the viral replicase showed the same enzyme concentration threshold for *de novo* synthesis and the same product characteristics as found with preparations from Qβ-infected bacteria.

We conclude that the experiments of Hill and Blumenthal do not support their interpretation. Our original kinetic analysis was, as reported[7], an adequate method to disprove a template-instructed process resulting from RNA impurities. Although the molecular mechanism behind this process is unknown, a

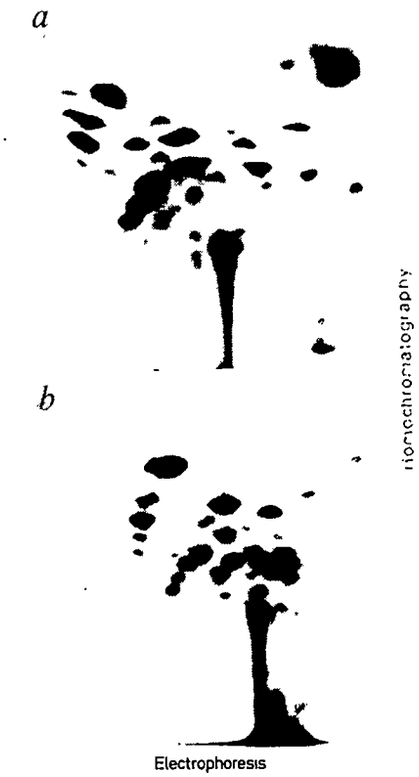

Fig. 2 Fingerprinting of the oligonucleotides. Incorporation mixture (100 μl): 200 μM GTP, 200 μM ATP, 200 μM UTP, 10 mM $MgCl_2$, 1 mM $MnCl_2$, 400 nM holoreplicase in Qβ-buffer. *a*, No addition; *b*, 400 nM yeast 5.8 S RNA.
Methods. The mixture was incubated for 21 h at 30 °C. The enzyme was denatured for 1 min at 100 °C and removed by centrifugation. The soluton was diluted with 500 μl 0.02 M Tris base and treated with 8 U alkaline phophatase (calf intestine, Boehringer, Mannheim) for 1 h at 37 °C. The products were isolated by loading the mixtures on 1-ml columns of QAE-Sephadex-A25 Cl^--form. The column was washed with 0.05 M Tris buffer (*p*H 7.5) and the oligonucleotides eluted with 0.5 M NaCl, desalted on BioGel P2, lyophylised twice and dissolved in 20 μl H_2O. The yields were 0.08 A_{260} (80 μM nucleotide incorporated) in the absence of RNA and 0.21 A_{260} (210 μM nucleotide, 35% incorporated) in the presence of yeast 5.8 S RNA. 500 pmol oligonucleotides were labelled at the 5′ ends with [γ-^{32}P]ATP and polynucleotide kinase (1 h, 37 °C), isolated on BioGel P2 and fingerprinted according to ref. 18. Analysis of the 5′ end of the oligonucleotides: The incorporations were with 5.8 S RNA as described above. Yield of 5′ ends, 43 μM: the 5′-labelled oligonucleotide material was degraded with 10% piperidine and the products separated on polyethyleneimine-impregnated thin layer plates. *pGp was found to be the only labelled product and its radioactivity was measured. Incorporation of [γ-^{32}P]GTP, 48 μM: incubation as in *a* except that [γ-^{32}P]GTP was used. The material was separated on Biogel, degraded with piperidine followed by treatment with snake venom phosphodiesterase to destroy GTP. The degradation products were separated by electrophoresis on DEAE paper in 7% formic acid. The *pppGp spot was cut out and the yield measured by counting the radioactivity. Yield of pppGpA-ends, 29 μM: analysis was as for [γ-^{32}P]GTP, except that [α-^{32}P]ATP was used and the pppGp* spot was counted. The degradation products also included Gp*, Ap*, *pA and Up*. The quantitation method was checked by measuring template-instructed incorporation of [γ-^{32}P]GTP into MNV-11, isolating the products and analysing them as for [γ-^{32}P]GTP.

hypothesis agreeing with the experimental data has been presented[4,6,7], and consists of two phases. In the first, polymerase slowly catalyses random synthesis of oligonucleotides, and in the second, once a suitable template is formed by chance, rapid evolution and autocatalytic amplification to macroscopic appearance occur. It is not surprising that the *de novo* products of DNA polymerase I and RNA polymerase are so different from those of Qβ replicase. The slipping homo- or co-polymer products of DNA polymerase I are indeed the only templates it can amplify autocatalytically, whereas they cannot be amplified autocatalytically by Qβ replicase, because RNA with high internal stabilization of its single-stranded structure is required to escape double-strand formation with replica[15]. It is doubtful whether the first phase can be realized at all with DNA polymerase I, which is unable to initiate a new chain, as the lag times suggest autocatalytic amplification of preexisting impurities[3,16]. The latter possibility, however, is excluded by the kinetic analysis for Qβ replicase[7], whose two nucleotide binding sites would provide, in principle, for slow condensation of nucleotide triphosphates to oligonucleotides.

Under normal conditions, template-instructed nucleotide incorporation proceeds much too rapidly for observable accumulation of the initial *de novo* synthesis products[6]. We blocked RNA amplification by omitting one triphosphate, and were successful when one or both of the pyrimidine nucleotides were omitted; however, ATP and GTP were both required for nucleotide condensation to oligonucleotides. Pyrimidines, if present, were also incorporated. The rate of phosphodiester formation under these conditions was four or five orders of magnitude below that of the template-instructed process. The chain lengths of the oligonucleotides that accumulated to larger concentrations ranged from 5 to 20 (Fig. 1); the fingerprints suggest that there is little sequence preference (Fig. 2), although the 5′ end was always pppGpR- (Fig. 2 legend). Elongation of preexisting oligonucleotides by Qβ replicase therefore did not occur under these conditions. The presence of 5.8S yeast RNA, but not transfer RNA, doubled the incorporation rate. The screening of oligonucleotides synthesized with 5.8 S RNA present showed no biases (Fig. 2), as would be expected if there was any instruction by the RNA.

For RNA synthesis in the absence of extraneously added template, we find: (1) The self-replicating RNA species produced in each template-free experiment differ from each other in sequence and chain length even in experiments performed under identical conditions. (2) Kinetic analysis of the *de novo* synthesis process[7] reveals fundamental differences from the well-understood kinetics of template-instructed replication[17]. (3) When replication is inhibited by omitting one triphosphate, many different oligonucleotides accumulate. (4) Highly purified preparations of Qβ replicase isolated from uninfected *E. coli* cells containing plasmids carrying the structural gene of the viral replicase show the same *de novo* synthesis characteristics as those isolated from infected bacteria.

No alternative has been presented to our original interpretation of these results, that Qβ replicase, in the absence of self-replicating RNA templates, is able to synthesize them in a non-instructed way by trial and selection.

We thank Dr M. A. Billeter for supplying us with the bacterial strain carrying a plasmid with the replicase gene of Qβ, and Dr W. C. Gardiner for critical reading of the manuscript.

Computer-assisted model building

from W.C. Ripka

Developments in computer graphics and distance geometry have provided important tools for comparative model building of protein structures.

THE explosion in the number of available protein sequences derived from gene sequence information has created a wealth of opportunities for molecular modellers. Ideally one would like to use only these amino acid sequences and some set of structure-based rules to arrive at accurate secondary and tertiary structures. Recent efforts using an artificial intelligence rule-based system have shown promise for one structural class, the α-β proteins. Accurate structures were found within families generated by this approach[1]. In the general case, however, even secondary structure predictions are often less than 60 per cent accurate. The problem of protein folding, that is, the determination of a protein's tertiary structure from its amino acid sequence, is one of the major unsolved problems of molecular biology.

The problem becomes more manageable, however, if a few assumptions are made. The few hundred protein structures that have been solved by X-ray crystallography show that proteins may be classified in a relatively small number of structural classes. From one of these classes an appropriate homologous member can sometimes be chosen for comparative model building. This assumes that the protein structure to be determined is not too different from the known example, and that changes in side chains and residue insertions and deletions can be considered relatively minor perturbations of the structure as a whole. Such a model can then be used to direct synthetic efforts in drug design and protein engineering.

Model building, particularly of structures as complicated as proteins, has been greatly aided by the increasing number of commercially available computer graphics programs that allow interactive, real-time three-dimensional manipulations of complex molecules[2] [Some of the available software packages: Mogli (Evans and Sutherland), Insight (Biosym), Biograph (Biodesign), Chemmovie (Chemical Design), Midas (Univ. of Cal., San Francisco), Frodo (Rice Univ.) MMS (Univ. of Cal., San Diego), Syble (Tripose)]. These programs can perform bond rotations, on-line calculations of contact distances, side-chain alterations and residue substitutions. Both solvent-accessible and van Der Waals surfaces can be generated to display the space-filling properties of the molecules. Since these surfaces can be selectively coloured to represent partial atomic charges of the atoms that contribute to each surface element, these models also give an indication of charge distributions.

In addition to the increase in available software, the rapid fall in computer hardware prices has made these facilities available to both industrial and academic laboratories.

Bases for structure

Comparative model building can offer insight into the relationship between amino acid sequences and three-dimensional structure, but its ultimate promise lies in its ability to elucidate the molecular basis of enzyme-substrate and protein ligand recognition and specificity. Such knowledge would provide the basis for rational and productive drug design. Although model building should be most effective when the protein of interest is closely related to the macromolecule for which detailed structural information is available, successful examples of molecular modelling have ranged from very qualitative models to very precise, comprehensive models.

At one extreme, Ondetti *et al.*[3] used primarily chemical and biochemical considerations to suggest a qualitative relationship between the active sites of carboxypeptidase A, whose structure was known, and angiotensin converting enzyme (ACE), for which no structural information was available. A number of potential enzyme inhibitors of ACE were designed, one of which, captopril, proved to be a potent inhibitor and an effective antihypertensive agent. At the other extreme, Beddell *et al.*[4] used the X-ray crystal structure of human haemoglobin to design compounds for that molecule. Their modelling suggested an allosteric site at which compounds designed for this site would modulate the protein's oxygen affinity. These compounds are now in clinical trials as anti-sickling agents.

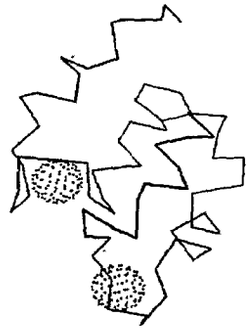

Fig. 1 A computer graphics representation of the ICB protein which provided the starting point for calmodulin modelling. The dot surfaces show calcium locations.

Comparative model building addresses the cases in between these extremes, by constructing useful models of structures from limited information. For example, using the three-dimensional structure of homologous aspartic proteinases and the primary structure of human renin, Blundell and co-workers[5,6] have employed interactive computer graphics to propose a tertiary model of human renin. This model may prove of value in the design of specific renin inhibitors.

Greer[7] has compared the structures of chymotrypsin, trypsin and elastase to allow the construction of 'new' serine proteases based on structually-conserved and variable regions of these proteins. Using computer graphics, coordinates for the main chain atoms of the model are taken from the conserved region, while side chains are substituted to fit the new protein. Modelling of variable regions is considerably more difficult since these areas involve insertions and deletions for which there is no exact correspondence. In these cases, main chain reconformations are required, rather than simple side-chain substitutions. Feldman *et al.* have suggested some simple techniques using interactive computer graphics to approach these problems.

Distance geometry

A potentially more powerful approach for modelling both side-chain and variable region conformations resides in the methodology of distance geometry[8], which allows the construction of random conformations that meet selected distance constraints. These constructs can then be evaluated according to energetic considerations and other geometric criteria.

O'Neil and De Grado have used distance geometry methods[9] along with interactive computer graphics to construct a model of calmodulin based on the structually related intestinal calcium binding (ICB) protein (Fig. 1). In this study, distance geometry was used to construct one of the calcium binding loops by holding the main-chain atoms of the model fixed to the coordinates of the known ICB protein and allowing the side chains to adopt numerous conformations; ligand oxygen atoms were constrained to those positions required in the approximate octahedral geometry of the coordination sphere of calcium. A number of conformers were generated, from which the lowest energy

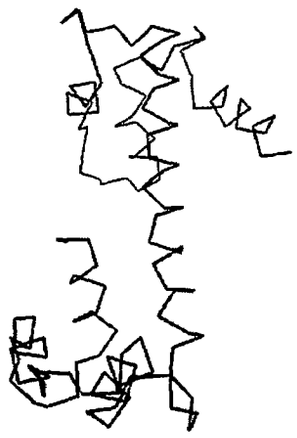

Fig.2 O'Neil and De Grado's calmodulin model.

examples (calculated by molecular mechanics) were selected. Of these, only one could be modelled into the proposed calmodulin structure while maintaining reasonable contacts with the rest of the protein (Fig. 2).

Limitations

Although protein models are useful, they may fall short in detailed structural interpretations. The success of comparative modelling depends on correct sequence alignment of the proposed structure with the known example. Even a single mistake can lead to an incorrect result. James and co-workers[11] have evaluated the types and sizes of errors in such model building based on a comparison of two proposed models for *Streptomyces griseus* trypsin with the experimentally-determined structure. A second sobering report comes from a study of the structures of bovine and porcine phospholipase A2, in which a single residue change from valine to phenylalanine in an otherwise extended homologous chain, leads to a major reconformation of the chain[12]. Whether those kinds of changes are predictable remains to be determined. □

W.C. Ripka is at the Biomedical Products Department, Medicinal Chemistry Division, E.I. DuPont DeNemours Co, Wilmington, Delaware 19898, USA.

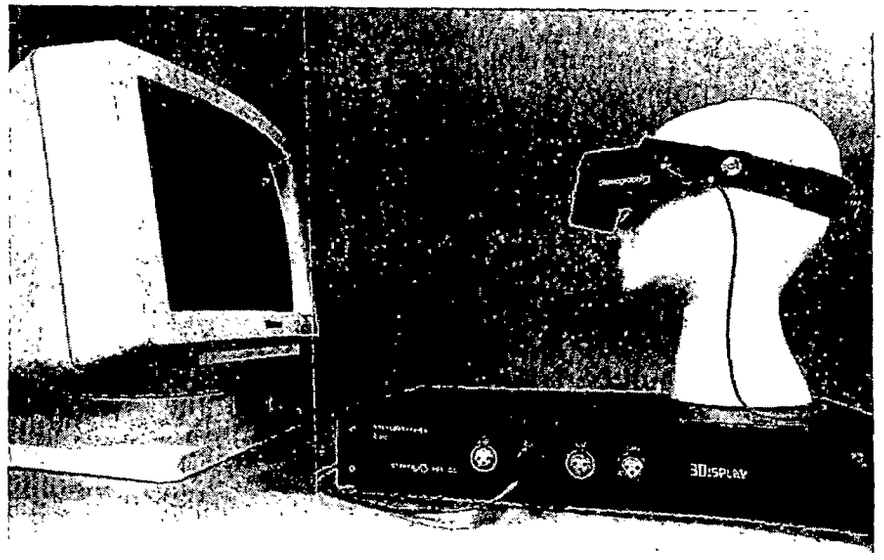
Chemical design takes to the terminals

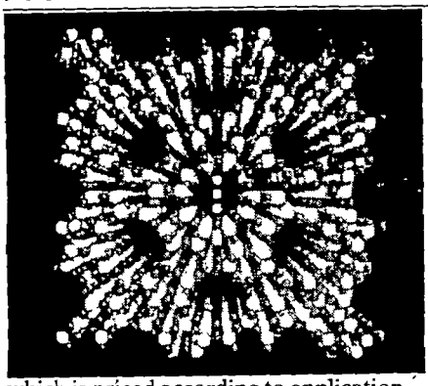
Software packages for chemists turn ordinary microcomputers into tools for molecular modelling, structural analysis and reaction planning.

DEMONSTRATION kits for Molecular Design Ltd's series of PC software provide a low-cost indoctrination into **chemical database programs**. Beginning last month, MDL now offers their ChemBase database manager, designed for IBM PC's in a $50 (US) demo version that allows the user to experiment with features such as custom table editing, chemical drawing templates, and multi-condition data searching (Reader Service No. 100). ChemText, a chemical wordprocessor package, and the mainframe hook-up ChemTalk/ChemHost, are also available as demo kits. These programs give graphical representations of molecules and reactions in the same format as MDL's mainframe database REACCS (a reaction access system) and MACCS (a molecular access system). CHEMLAB-II, a computational chemistry package, completes MDL's mainframe threesome. The microcomputer demo kits' cost will be deducted from the price of PC software purchased within 30 days of the demo package.



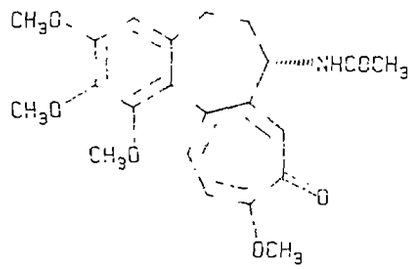
A California company has taken the lead in **three-dimensional molecular modelling** that is both useful and entertaining. Stereographics Corp. has a $20,000 (US) graphics display system that uses alternating viewpoints and visors with liquid crystal shutters to create a convincing 3-D image (Reader Service No. 101). Stereographics' 3Display accepts output from any computer and works with all 3-D graphics software packages. Its imagery provides insight into hidden surfaces with twice the number of fields per second that previous stereoscopic viewers have afforded, reducing irritating flicker effects. A 3-Display system includes a display controller, a 120 Hz RGB monitor and viewing visors.

Chemical Design has a **molecular modelling system** that will run on DEC VAX



Modelling by Chemical Design. See oppostie for other examples.

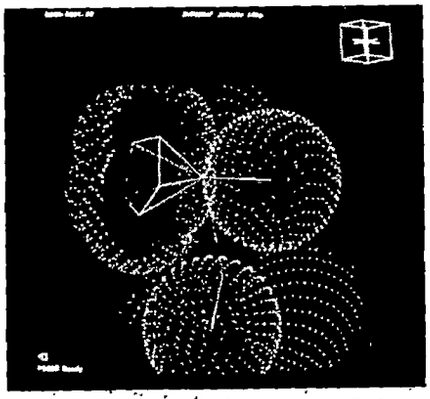
computers under the VAX/VMS operating system. Chem-X integrates five specialized modules for design, manipulation and analysis (Reader Service No. 102). The system has a user-friendly front end and interfaces to Quantum Chemistry Program Exchange (QCPE) software (see below) as well as MACCS and CHEMLAB-I. Standard supported graphics terminals or PCs with graphics options can run Chemical Design's 4-megabyte program. Chem-X can be incorporated in a combined hardware/software package called MicroGRAF-2,



Head-up display in 3-D from Stereographics.

which is priced according to application.

The most affordable **modelling system** for IBM desktops comes from Xiris Corp. in the form of the $1,000 (US) XICAMM software (Reader Service No. 103). XICAMM can perform many of the tasks of much more expensive systems (albeit more slowly) including molecule comparisons, bond angle determinations, structure rotation and generation of QCPE's MOPAC- or MM2-compatible input data files. An evaluation system with full documentation is also available for users who want to gauge XICAMM's merits for themselves. Xiris provides any or all of the hardware needed to run their system, which is based on the same algorithms used in certain mainframe and super-mini computers.

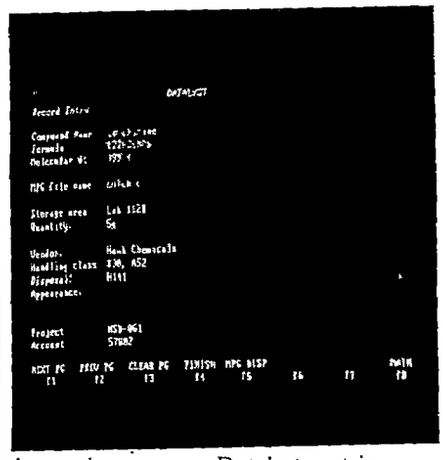


An unconditional 30-day money-back guarantee accompanies Molecular Pre-

A plot straight from the HP 7470 plotter.

sentation Graphics, the **chemical drawing package** from Hawk Scientific Systems (Reader Service No. 104). Hawk's $225 (US) package is compatible with the IBM PC and Hewlett-Packard-150, among others, and excels at the speedy generation of quality diagrams for research texts. MPG is not a modelling system, but can supplement one or stand on its own as a useful aid at the write-up stage of research projects. The menu-driven software gives clear drawing instructions, and diagrams can be printed on Epson or HP LaserJet and ThinkJet printers via MPGLASER, a Hawk option that merges text and diagrams.

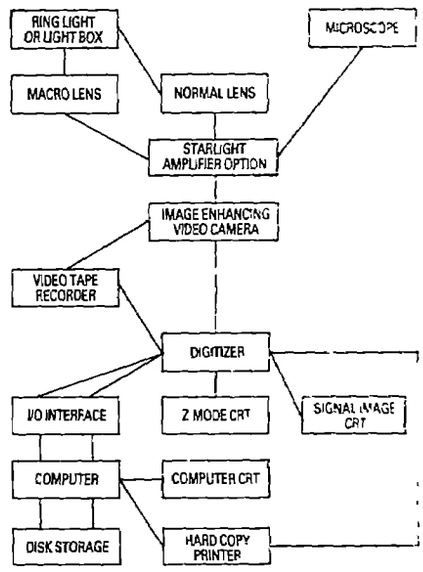
Chemdata Ltd makes **molecular graphics packages** for Apple II/IIe and BBC model B/Master 128 microcomputers. Their integrated hardware/software unit, including a graphics display processor unit and (for the Apple series) a hard-wired multiplier card, gives 512 by 512 pixels displays in eight colours (Reader Service No. 105). A structure file editor, model builder, graphics module and library of structure files comprise the software for these units. By merging Chemdata's structure files, two chemical structures can be manipulated together. Chemdata's hardware/software duo costs £890 (UK); in addition, software files with file editors, graphics modules and structure libraries are also available for BBC Master 128 and Apple machines. The Master 128 version, at £75, is priced slightly higher than the £45 Apple series package, but offers sevearl options, such as file merging and model building on a double-buffered four-colour graphics mode, that the less expensive Apple software lacks.



The chemistry department at Indiana University runs a **'library' of chemical analysis software** for IBM and compatible computers called the Quantam Chemistry Program Exchange (QCPE) (Reader Service No. 106). Most of QCPE's offerings are molecular mechanics packages adapted from mainframe programs, which the exchange distributes free of charge to non-profit institutions. Manager Richard Counts conceived the program only a few years ago, since when it has amassed 10 varieties of software for the chemist, including the well-known MOPAC, MM1, MM2 and Galsien 80. Counts plans to expand the program to include a broader range of chemical design packages.

Disks over index cards

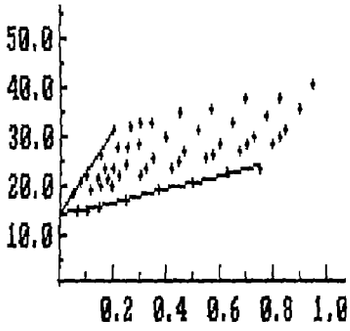
The final component of ISI's Sci-Mate version 2.0 software system has now joined the fleet. The editing function for **bibliographic formatting** rounds out Sci-Mate's search and management functions for researching journal literature, building text files and preparing manuscipts (Reader Service No. 107). ISI's package comes in MS-DOS or CP/M 80 formats and cost $399 (US), with volume discounts available.



Autoscribe Ltd. distributes a **chemical filing system** for IBM PCs or Hewlett-Packard-150s with a minimum of 256K of

internal memory. Datalyst entries can store compound names, molecular formulas, chemical formulas, vendor information, laboratory storage location, quantity in stock and details of handling requirements (Reader Service No. 108). The £295 (UK) program will also calculate molecular weights and access chemical structure files from Molecular Presentation Graphics systems (see above). Demonstration disks are available.

Software branches out



Five new **image analysis programs** from Darwin Instruments, Inc. link Colorado Video's 270A vido digitizer with Apple II+ and IIe PCs. The programs were designed for "researchers limited by budget constraints," says Colorado Video (Reader Service No. 109). A scanning densitometer program will perform sum-averaging and multi-scan, baseline addition or subtraction, noise elimination, area integrations and peak identification. A topography program allows Darwin's system to count the total number of objects in a scan field, determine the area and perimeter of each object, calculate the total area of all objects, and delete

Darwin's route to analysed images.

objects based on size class or object number. Darwin also offers an area program for individual object or total area calculation, a program for automating growth curves for plants and sessile animals and a tracking program which can monitor the rate and direction of an object's movement.

In less than 1 minute, software from Wyatt Technology can generate a Zimm plot and **calculate molecular weights** using data from DAWN laser light scattering

Wyatt's Zimm plot.

instruments. Wyatt's package has a menu which allows users to choose different order polynomials for extrapolating the Zimm plot curves (Readear Service No. 110). Instead of being limited to linear extrapolation, the program can handle quadratics, cubics and higher-order expressions. Wyatt's $1,000 (US) software was developed for IBM PCs, XTs and ATs. Several user inputs, such as the number of concentrations, solvent refractive index and scaling factors for the graphics, must be manually entered for the program to go to work.

Varian Associates put two programs together in a software package that facilitates **automatic data transfer** between atomic absorption spectrometers and a variety of computer systems. With Varian's $2,000 (US) data communications package, the user can specify how much information needs to be transferred, and send data on-line or as a summarized report (Reader Service No. 111). An external communications module accepts information and instructions from a remote keyboard or disk file, then transmits results through an IEEE or Centronix port or to remote computers via either or two RS-232C channels. The other half of Varian's package is the public domain program KERMIT, which can transfer files from the spectrometer to micro- or mainframe computers operating with appropriate versions of the program. IBM PC, DEC VAX and Rainbow, HP-110 and HP-150 and WANG PC are among the compatible computers for these data communications.

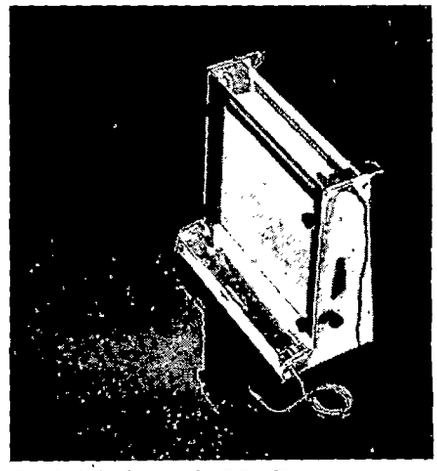
Microbore tubing up for grabs

Elkay Products' latest catalogue contains $100 (US) worth of coupons for new products including autoclavable pipette tip racks, 1.5 ml microcentrifuge tubes and 50 ml sterile centrifuge tubes (Reader Service No. 112). In 48 colour pages, *Elkay 86* presents a complete line of plas-

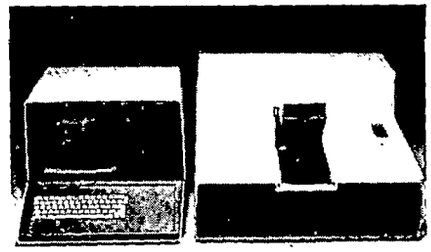


Elkay's latest.

tic disposables for laboratories. General reference material, such as an equipment/consumables compatibility chart, accompanies technical specifications and performance data for Elkay's products.

Elkay is also giving away samples of their extruded microbore tubing (Reader Service No. 113). Sample packages permit inspection of tubing material quality and standards for flow, physical dimensions, durometer and resilience, which Elkay says they carefully control. One package contains six different kinds of tubing for a variety of applications including pump, transmission and bellow forms.

Gel sequels



A **sequencing gel electrophoresis system** from Bethesda Research Laboratories promises precision with 48 lanes of read-

Barely $10 a lane in the BRL S2.

able date for less than $500 (US). The model S2 apparatus has an aluminium plate for even heat distribution and 0.4 mm side spacers that won't interfere with gel polymerization (Reader Service No. 114). A removable tray allows easy buffer disposal, and the entire unit is constructed of chemical-resistant, unbreakable plastic. BRL's system comes with an accessory package.

Ciba Corning's **scanning densitometer** can analyse up to 64 samples at a time without operator attendance. The model 780 fluorometer/densitometer is pre-programmed for Ciba Corning procedures, but the protocol can be altered for additional tests (Reader Service No. 115). The system's editing function allows the addition or deletion of minima, baseline adjustment, peak deletion or magnification and repositioning of minima. If used in conjunction with Ciba's 16-track agarose gels, the 780 can analyse all 64 samples in less than 12 minutes. An alphanumeric keyboard, 12-inch CRT and fluorescent pre-viewer have been built in to Ciba's unit. All types of electrophoretic media

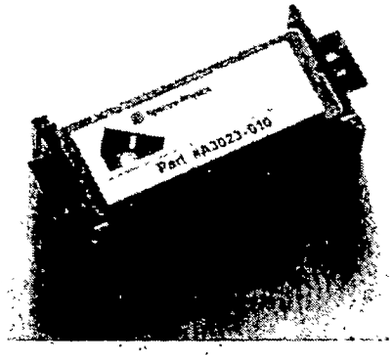
Sixty-four samples a time in the model 780.

can be accommodated, and the operator can select the units in which results should appear.

Narrowing the scope to **DNA sequenc-**

ing, Bio-Rad's Gene-Master has been designed for speed and convenience in one particular application (Reader Service No. 116). The system includes an IBM PC AT microcomputer that stores and analyses sequences entered via a digitizing pen. Bio-Rad's model also uses a voice synthesizer to call out bases as the pen records them, so that sequences can be verified without looking away from the autoradiogram. Lane and band curvature doesn't throw the Gene-Master off track, and the menu does not require pen activation which Bio-Rad has deemed distracting. As with most pen-operated readers, the reading process is accelerated when the user can keep an eye on the gel.

Patrons of Shandon's Electrafor products for electrophoresis can now **order supplies by phone** with the Cheshire company's free telephone order service (Reader Service No. 117). A rapid delivery service, combined with the direct-dial



ordering system, helps speed up restocking of the cellulose acetate membranes, buffers and stains in the Elecrafor range. First-time customers will get free samples from Shandon, and all customers get a free box of Electrafor membranes with every 10 purchased. Until the end of May, buffers and stains ordered with membranes will also be discounted 10 per cent.

A New York-based mail-order company has moved into the scientific arena. Transcat Inc. has published its first issue of **Laboratory & Scientific Instruments,** a 274-page catalogue that describes the products of over 200 manufacturers (Reader Service No. 118). Companies featured include Bausch & Lomb, Beckman, Corning, Ohaus, Orion Research, Techne, Thermolyne and Wallace & Tiernan, and products range from microscopes to hot plates. Transcat gives prices, ordering information and a toll-free number to facilitate inquiries.

Tomorrow's program

Spectra-Physics has put a program for **automated stop-flow UV-Vis scanning** on a chip that plugs into their SP4200 computing integrator (Reader Service No. 119). The integrator is attached to a Kratos Spectroflow 783 detector through a current loop serial connection. The program, on the $1,500 (US) 783 SCAN chip, will perform background subtraction, peak ratioing and time-programmed wavelength changes for selected liquid chromatography components; scanning parameters can be set via the integrator.

Three new **software utility programs** now complement IBM Instruments' CAP 2 software for their chromatography workstation (Reader Service No. 121). One of the programs, a utilities library, can aid in the analysis and display of chromatography data. Another, called Touch & View, manages screens, keyboards and key pad functions to allow up to seven programmes to run concurrently. GC/9630 Emulation, the third program, was designed to replace the standard VDU control terminal component of IBM's GC/9630 chromatograph: it provides comprehensive instrument control during data acquisition. IBM Instruments sells the programs for $250, $400 and $200 (US) respectively. □

These notes are compiled by Karen Wright from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal.

Data acquisition by word of mouth

In over 2,500 laboratories across the United States, microcomputers that once turned deaf ears to their surroundings may soon be called on to perk up and listen. Laboratory Technologies, makers of the data acquisition package LABTECH NOTEBOOK, recently agreed to develop a scientific vocabulary for their software commands that would enable the package to respond to voice commands. LT's arrangement with Kurzweil Applied Intelligence will link the Kurzweil Voicesystem (KVS), a 1,000-word speech recognition system, with the IBM PCs that run LABTECH NOTEBOOK (Reader Service No. 120).

LT is hoping that setting up and controlling LABTECH NOTEBOOK will be much easier using simple spoken words. The operator talks into a telephone handset or a lightweight headset microphone, and the NOTEBOOK software does the rest: the PC channels will automatically gather information from attached sensors, instruments or gauges, and pass it on for analysis, control and monitoring. A KVS with an IBM PC AT interface costs $6,500 (US); the $895 (US) LABTECH NOTEBOOK package can integrate with Lotus 1–2–3, Symphony and RS/1 for detailed statistial analysis and display. □

Bringing home the technology

from Richard Pearson

New technology is now enabling more people to work from home rather than in the traditional workplace.

EMPLOYMENT and working patterns are constantly changing in response to economic and social and technological developments. In the United Kingdom, the recession of the early 1980s has been seen as a watershed in terms of patterns of working, with employers restructuring their workforces and making greater use of temporary and part-time staff.

Since 1983, the main areas for new employment have been for part-time work, where there has been an increase of more than 300,000 jobs, and self-employment, where the number of people has also increased by over 300,000 to total over 2.5 million. Self-employment has been helped by employers, who are increasing their sub-contracting of work activities such as catering, transport and legal work to concentrate on what they are good at. New technology, in the form of cheaper telecommunications and computing, is also enabling more people to work from home, again showing more opportunities for flexible employment patterns.

In theory, the technology offers the opportunity for vast numbers of office-based

workers and others to carry out their work at home using computer links. Jobs in computer programming, word processing, accounting, statistical analysis and management information processing are all amenable to distance working. In the United States, AT&T estimates that up to half of its executive jobs could be carried out from home by 1990, while in San Francisco it has been estimated that one in five commuters could stay at home to work. But such distance working need know no boundaries. American Airlines moved its data entry operation from Oklahoma to Barbados in the West Indies, where 200 keyboard operators now process tickets, using a satellite link to receive the work from the US data-processing centre. Another US company with a similar operation claims "we can do the work in St Michaels, Barbados for less than it costs us to pay for the floor space in New York". Yet another company flies its paper work to Singapore, where it is keyed in, and then beams the finished work by satellite to its data-processing centre in Australia.

In the United Kingdom, homeworking is not new; cottage industries in light manufacturing and clothing have been around for generations, although such workers are now a minority of the "homeworkers". Much more common are white-collar workers doing clerical work, or working in occupations such as selling or writing where the home is used as the base. There are estimated to be more than 650,000 homeworkers in the United Kingdom.

There are now a number of initiatives in the United Kingdom aimed at allowing and encouraging traditional office-based professional workers to work from home, becoming the 1980's homeworker or "teleworker". The largest and longest running is the operation of 'F' International, a computer consultancy which employs some 900 people, predominantly women, to work from their homes. The staff, computer programmers, systems analysts and project managers, take on assignments for clients of 'F' International and operate as high-tech cottage workers, working in part from home and in part in the clients' premises. A small core of permanent staff organizes and manages the work, but the 800 or so self-employed workers are able to combine domestic flexibility with a career. They are of course aided in gaining regular work to fit in with their own availability by having skills in short supply.

Another scheme that has attracted a lot of publicity is that started by Rank Xerox, which has cut the number of staff employed in its expensive central London offices. Originally some 20 staff, mainly managers and professionals, were helped to hive themselves off from the company and to sell their services back to Rank Xerox instead of being employees. As well as being paid special bonuses and provided with training and low-cost equipment, the "networkers" as they were called, were guaranteed two days' work per week at consultancy rates for two years. The company saved significant sums on office rental and services, payment of support staff, canteen facilities, pension, company cars and the like. It also freed itself of a long-term commitment to employing those staff. The networkers gained a sheltered transition to self-employment and starting their own businesses, and flexibility to work in the way they wanted. Many have been able to achieve much higher levels of output, without for example the interruptions of working in a major office complex, and thus to boost their earnings. Other companies also have hybrid schemes of networkers, freelancers and teleworkers although the technology, other than the telephone, has assumed a less important role than many had first imagined.

There are of course problems. Many people look to the work place to provide social interaction and a structure for their lives, and not all homes and families' lives are conducive to working at home. There is also the uncertainty for the individual in working in a new and uncertain way. For the employer, there are new skills to be acquired in "managing" such people and setting payment systems where it is difficult to measure the output. With a traditional employee, this is easier because the relationship is one of buying the individual's time for, say, forty hours per week.

The productivity gains benefit both sides, and while the individual gains flexibility of working pattern the employer gains flexibility over controlling labour inputs and transferring many of the overheads and "risks" to the individual. The homeworkers gain most when skills are in short supply, and if the pattern is to develop in the future a key issue will be "who pays for the training and development of new skills as they are needed?".

Distance and homeworking will increase in the future as more workers and employers seek part-time and flexible employment relationships. The increasing numbers of women seeking work, and the shift away from manufacturing-based employment to services will also facilitate this trend. The rate of expansion will probably not, however, be as quick as some of the publicity suggests. While the lower costs of technology will aid the process, economic and social factors will be the prime determinants of its development, while the main beneficiaries will be those whose skills are in scarce supply. □

nature

The long shadow from Chernobyl

Last week's reactor accident in the Soviet Union is an historic event that will change the course of the remainder of the twentieth century. But the clouds may also have a silver lining.

EUROPEAN governments' attempts to deal with the consequence of the reactor accident at Chernobyl have been seriously impeded by the lack of data from the Soviet Union. Information bearing on two crucial issues has been withheld. At least for the first week after the accident, the Soviet side had nothing to say about the composition of the radioactive material from the damaged reactor. And there has been no serious attempt to estimate what quantities of radioactivity were released. Even allowing for the difficulty of making considered judgement while the graphite moderator of the reactor was still on fire, for the need to protect the local population from serious long-term consequences and for national pride, there is no excuse for having kept silent on these issues for so long.

That is why the Soviet Union may have only itself to blame for the indecently gleeful way in which Western observers of this tragic accident, especially some in the United States, have given currency to wild speculations about the scale of the damage near Chernobyl. In reality, there is no reason to disbelieve the Soviet statement that only two people were killed by the explosion that appears to have marked the onset of the release of radioactivity; the more important questions are whether local fallout has caused potentially fatal radiation sickness among the neighbouring population, and what will be the longer-term load of increased cancer in a wider population.

When the dust has almost literally settled, there will be other international issues on which a fuller degree of Soviet understanding of other people's problems will be required. Who will meet the cost of the trouble which the Scandinavian governments have had to take? What if events in the next few months suggest that some people outside the Soviet Union have been acutely damaged? And what happens twenty or thirty years from now if people die from cancers which may be caused by radioactive effluent from the Chernobyl reactor, but which are most probably due to natural causes? Will those affected have a suit against the government of the Soviet Union? Or merely grounds for a lasting grudge? On past form, the Soviet Union will be grudging with helpful information, perhaps because it is unwilling to admit to its own people that its domestic arrangements are not by definition unalloyed benefits. On this occasion, the pressure for openness from outside may happily coincide with what Mr Mikhail Gorbachev has been advocating domestically.

The consequences of the accident for Soviet plans for the further development of nuclear power will nevertheless be substantial. It is unthinkable that the Soviet government will push forward with the construction of reactors of the type that caught fire at Chernobyl until it fully understands the risks of a repetition of the accident. The essential weakness of the design is its assumption that two mutually energetically reactive materials (graphite and steam) can be rigorously separated from each other by means of welded steel tubes; the assumptions are obviously no better than the quality of the welds. The obvious difficulty now for the Soviet government is that its plans for the generation of electricity hang crucially on the construction of nuclear reactors. Luckily, most of the plants now being built are the more rigorously tested pressurized-water reactors. But it will serve nobody's interests if the Soviet economy, and its refreshing new leader, are set back a decade or so in their expectations for the years ahead.

The consequences of Chernobyl for the nuclear industry elsewhere will be devastating. Mr Saul Steinberg, the US financier, has made something of a splash in the past few weeks by buying a substantial proportion of the shares of the Long Island Lighting Company, the owner of the Shoreham nuclear power plant which has lacked an operating licence for the past several years. His envious competitors had been admiring his flair for making wagers that cannot fail; either Shoreham would be allowed to produce electricity, or the utility that owns it would be nationalized (by the state of New York). But now, Mr Steinberg will be seen to be betting on a single horse, one that hobbles a little. In the adversarial process by which the public good is balanced against the private interest in the United States, the dice will now be further weighted against those who may wish to build the odd nuclear reactor. Even in Britain, where the government is likely to be told in September by the Roskill Commission that it would be safe to allow the nationalized electricity utility to build a pair of pressurized water reactors, there will be a temptation to postpone the decision. In short, whatever the explanation of the Chernobyl accident, the event will reinforce the general prejudice against even the sensible use of civil nuclear power.

The trouble is the public understanding of the concept of probability. Nobody disputes that a substantial release of radioactivity into the atmosphere can damage people and that reactors are a potential source of large quantities of activity. Most designers of nuclear power stations have taken to calculating the chance that the plants they build will suffer a catastrophic accident; the usual outcome is that the chance of catastrophe is one in a million or more per year of operation. Put simply, reactors would not be built if the chance that they would go seriously wrong were much greater, for then utility systems operating several reactors would imply to their taxpayers that there is a chance that a catastrophe would arise within a human lifespan or thereabouts. But this average time does not exclude much shorter intervals, or excuse carelessness.

What side-benefits can there be in such a sombre litany of trouble? Much depends on how serious the local consequences of the accident have been. But even if, as must be hoped, there is no serious loss of life in the immediate neighbourhood of the reactor, there is bound to be a moral obligation on the Soviet Union to acknowledge the trouble and even damage it has caused elsewhere. For what it is worth, the Soviet Union is not a signatory of the 1963 Vienna Convention on the regulation of nuclear accidents, but the past few years have shown clearly that international conventions have a moral force that non-signatories cannot shrug off. Similarly, within the Soviet Union, there is bound now to be built-in pressure on the authorities to be more open about the risks of nuclear power, and of some of the other schemes on which the Soviet Union is engaged. And of course, if the accident has been as serious as it might have been, the internal pressures may be even greater — perhaps even greater than those needed to blow the lid off an isolated nuclear reactor. □

Chernobyl

Anxiety about reactor accident subsides

LAST week's panic in Western Europe and elsewhere about the explosion and subsequent graphite fire at the Soviet nuclear plant north of Kiev was in retreat earlier this week, as the scanty data available outside the Soviet Union were pieced together. While it is plain that the accident at Chernobyl on 26 April was the world's most serious nuclear accident so far, there is no reason to dispute the Soviet statement that only two people at the plant were killed, perhaps a consequence of the initial explosion. The longer-term consequences, including cases of radiation sickness which will become apparent in the next few weeks, and excess cancer deaths, which will be delayed by decades, cannot yet be estimated.

Part of the basis for this reassuring conclusion is the examination of members of the party of British students from Kiev and Minsk, who returned via Moscow last week. Although some of the party's clothing was contaminated with local fallout, ingestion of airborne radioactivity was apparently not sufficient to cause risk of thyroid cancer. An account of the fallout over Poland during the past week, given by a group of Polish experts in Vienna, has led the Polish authorities to the conclusion that there is "no significant risk to the health of any person".

Other estimates of the total quantity of radioactivity released from the Chernobyl reactor have been derived from computer models normally used in the assessment of the risks of nuclear accidents. These suggest that the release from the plant may have been upwards of two orders of magnitude greater than from the British accident at Windscale in 1957, previously the worst nuclear accident on record.

The Swedish measurements, the first clue (on 28 April) to the accident at Chernobyl, suggest that airborne activity over Scandinavia peaked on Tuesday last week at about 10 to 20 times the normal level, mostly because of iodine-131 and caesium-137.

Fallout in the neighbourhood of the plant has been much more serious. Close on 50,000 people have been evacuated from a 30 km radius. Soviet spokesmen visiting the West have spoken of radiation doses at the plant which were initially 200 roentgens an hour, falling to 100 roentgens an hour after a week. In this light, the Soviet statement that 200 people were hospitalized (of whom a quarter were discharged) probably refers to those showing symptoms of radiation sickness.

The cause of the accident remains a matter for speculation. The most common suggestion is that a leak in the steam-raising water circuit which contains the fuel elements and interpenetrates the 1,000-tonne graphite moderator would have produced water gas (carbon monoxide and hydrogen), which might then have caused the explosion that destroyed the roof of the reactor building. It is not known whether Soviet statements that "human error" was responsible for the accident refers to the execution of an improper operation or to an inadequate response to warning signals.

Another possibility is that the accident arose during an operation to anneal the graphite moderator in the reactor to remove structural defects accumulated during prolonged neutron irradiation, and which entails heating the graphite above the normal operating temperature for more than a day.

Although the Chernobyl accident may have been less serious than first reports in Western Europe suggested, most Western governments have been indignant that so little information has been available from Soviet sources to suggest how governments elsewhere might best deal with the fallout from the plant. More detailed information about conditions at Chernobyl began appearing only earlier this week. On Tuesday *Pravda* carried a long article describing conditions around the reactor site.

Perhaps more significantly, an apparently painful interview last Wednesday between the director-general of the International Atomic Energy Agency, Hans Blix, and the Soviet envoy in Vienna had led, by Sunday, to an invitation for Blix to visit Moscow. He left the same day, accompanied by Maurice Rosen, the agency director of nuclear safety.

According to a spokesman of the agency on Tuesday this week, the intention is that the visitors will have full access to what information there is available in Moscow, although it is not known whether the party will be able to visit the reactor site. Blix's companions may stay in the Soviet Union for several days.

Within the Soviet Union, a commission of enquiry under a deputy prime minister is said to be hard at work on an investigation of the causes of the accident and into its aftermath. On the assumption that the reactor building can itself eventually be made safe, the most haunting problem will be that of managing the health of the population in the neighbourhood of the accident over the next three decades. □

Soviet nuclear reactors

Ambitious plans with red tape

UNTIL 26 April, the Soviet Union had a nuclear generating capacity of 28 GW, 11 per cent of total electricity output, but the new five-year plan (1986–90) includes the commissioning of a further 41 GW of nuclear capacity.

Guarded comments by Soviet officials last week suggest that there will be no change in these plans, even though it has for the first time been admitted that the use of nuclear power, even for peaceful purposes, cannot be totally safe. Previously, the Soviet line has been that incidents such as Three Mile Island were the result of corner-cutting by capitalists bent on profit.

Soviet plans specifically suppose the construction of nuclear stations close to major cities. Although, a few years ago, a leading party monthly carried an article suggesting that nuclear stations should be confined to the remoter areas of Siberia, they are now considered so safe that they can serve as thermal generators for city district heating systems, but with a green belt of 1–3 km radius around each station, which would be used for recreational purposes and allotments.

Current plans call for several such "atomic-thermal-power" stations to be commissioned during the next five years, including Gor'kii, Voronezh, Odessa and Minsk, while the construction of several more is to be started. If the Chernobyl accident has any effect on Soviet nuclear policy, it is in this sphere that it is most likely to be felt.

The resiting of at most 10 or 12 power stations (and the quiet dropping of the district heating part of the programme) would be far less difficult, both logistically and politically, than a total reversal of Soviet commitment to nuclear energy. There is likely, too, to be an increased impetus to the fusion energy research programme, which for years has been formally hailed as the ultimate solution to Soviet energy problems.

The Chernobyl station had four RBMK reactors with a fifth under construction. This is a light-water-cooled uranium-graphite channel system, with zirconium alloy fuel cans. As a number of commentators have noted, this type of design has been rejected in Western countries as unsafe, and the presence of the earliest example of this type near Leningrad has, during the past few days, evoked considerable concern in Finland.

The Soviet designers seem to have relied on the regular ultrasonic and acoustic monitoring of the metal coolant loops, which, it was claimed in the technical journal *Atomnaya Energiya* (**50**,

253; 1981) "guaranteed that sudden rupture of the pipes could not occur" and, as a measure of last resort, the incorporation of an automatic emergency water cooling system. This was designed to cope with the worst possible case foreseen, the transverse fracture of a 900-mm turbine pressure collector. On 26 April, however, this system clearly failed to work.

If the Soviet atomic energy commission preserves the reticence it has shown so far, it may be difficult to discover not only what caused the initial fault but also why the emergency system failed to operate. (Earlier this year, the daily *Sovetskaya Rossiya* called for greater openness in the reporting of natural disasters, but the atomic energy commission could well reply that the Chernobyl accident was not "natural".) One possible explanation, however, may lie in Soviet construction procedures which are prone to produce shoddy and hazardous results, in spite of the fact that there is no "capitalist" profit motive.

The Soviet practice of laying down quarterly, annual and five-year production targets (with pay and bonuses dependent on their fulfilment), coupled with a highly bureaucratic supply system and a transport network too overloaded to ensure prompt deliveries, has led to the practice of "storming" — last-minute speed-ups and overtime to catch the target date.

Hasty construction is further exacerbated by the emphasis placed on fulfilling targets ahead of plan, and, in particular, the making of "voluntary" pledges by the workers to reduce their target time in honour of major patriotic events. Although, in 1976, a glowing description of the construction work at the Chernobyl site merited front-page treatment in *Pravda*, an article that appeared in the weekly *Literaturna Ukrayina* just a month before the accident gave a very different picture.

According to the author, Lyubov Kovalevs'ka from the town of Prypyat', building standards have from the very beginning been neglected. The construction of a project such as a nuclear power station, she says, must be "a continuous flow on the basis of the strictest adherence to building technology. But this did not happen here."

The various problems that arose with the first unit (Kovalevs'ka does not specify what they were) were never properly solved, but simply "transferred" to the second, and then to the third and fourth units.

What this meant in practice is seen from her description of current construction work on the fifth unit. The project, she says, is beset by constant shortages; materials are delivered in inadequate quantities and are frequently substandard, yet the planned construction time has been cut from three years to two. The workforce therefore has no option but to try to fulfil its targets by neglecting the specifications and "stretching" such materials as there are as far as possible, and accepting defective supplies even when so vital an item is concerned as the case she cites, the roof-plate for the spent fuel bunker. Quality and inspection of the finished construction moreover, seems to connive at the situation which, Kovalevs'ka warned a month ago, will have to be "paid for over the course of decades". Has this bill yet been paid? **Vera Rich**

Nuclear prognostications

Estimating gravity of problem

ALTHOUGH several agencies in the West have been hard at work during the past week trying to estimate the seriousness of the accident at the Soviet nuclear reactor north of Kiev, nobody is confident of the outcome of their calculations. As part of the now-standard process of calculating the consequences of hypothetical nuclear accidents, several computer models have been developed for estimating what happens to radioactivity released from a damaged reactor. But, as one modeller explained last week, "usually we start with something that we know".

Part of the problem is meteorological. One of the team at the British Radiological Protection Board, an independent government agency based at Harwell, Oxfordshire, explained last week that there is relatively little experience of even models of the spread of radioactive materials from sources remaining active for several days, and that the calculation of the consequences of Chernobyl have been complicated by the rapidly changing wind patterns.

Data from Sweden and elsewhere in Europe have thrown some light on the composition of the fallout from the Soviet reactor. It seems to be agreed that the concentrations of volatile materials such as radioactive iodine and caesium are in the proportions to be expected from fresh fission products. The modellers are, however, unable to estimate with any certainty what proportion of the total emission from the damaged plant will have been deposited in its immediate locality.

This uncertainty bears most directly on the difficulty of estimating the damage that may have been done to the population in the immediate vicinity of the plant, which will become apparent there only in the next few days and even weeks. One of those concerned says the uncertainties are such that the data from outside the Soviet Union are consistent both with the assumption that many people will have been exposed to damaging doses of radiation and that there will be no casualties from radiation sickness even in the neighbourhood of the plant.

There is, however, general scepticism about some of the estimates of Soviet casualties such as that given to a congressional committee by Dr Kenneth Adelman, director of the US Arms Control and Disarmament Agency. It is pointed out that calculations of the consequences of releases of radioactivity from pressurized water reactors, such as the estimates prepared for the public inquiry into the British plan to build such a plant at Sizewell in Suffolk, suggest that acute deaths (within a few weeks) would be counted in hundreds, not thousands. The longer-term consequences — excess cancer deaths — would usually be greater in number.

The generalized effects of the radioactivity observed in Sweden will be much smaller. If atmospheric radioactivity was last week six times greater than the natural background for two or three days, the result will be increased exposure to radiation by a few per cent of the annual dose arising naturally. But this reassuring yardstick does not exclude the possibility that some people may ingest exceptional amounts of artificial radioactivity by the accumulation and concentration of particular radionuclides in foodstuffs.

Attempts to estimate the total amount of radioactivity released at Chernobyl are similarly uncertain. The source of the estimate that a total of 10^{18} bequerel were released at Chernobyl was most of all anxious that the uncertainties, which must be several orders of magnitude, should be clearly appreciated. By this yardstick, the Chernobyl accident may be 100 times potentially more damaging than that at Windscale in 1957, when an air-cooled graphite reactor caught fire. That accident was in turn much more serious, as measured by the total quantity of radioactivity released, than the accident at Three Mile Island eight years ago.

Among those with military and arms control interests, some importance is attached to the likelihood that reactors of the "Leningrad" type such as those at Chernobyl would have been a useful source of military plutonium.

According to the International Atomic Energy Agency's survey of the world's reactors published at the end of last year, there were 26 light-water-cooled graphite-moderated reactors in operation in the Soviet Union at the end of 1984, producing between them a total of 13.7 GW of electricity. A further nine reactors of this type were being built at that stage, although the bulk of the reactors now under construction in the Soviet Union are pressurized-water reactors.

France in Tokyo

Two heads better than one?

FRANCE has had two heads at the economic summit in Tokyo, one of them gung-ho for technological cooperation, and the other apparently lukewarm. The future of French policy in this increasingly important area of politics, which covers matters from the Strategic Defense Initiative (SDI) to joint industrial development and the mobility of scientists, is thus becoming somewhat murky.

At previous summits, President François Mitterrand, head of state and a socialist, has blown the trumpet for technology. His ministers, until the March election which threw them out, energetically pursued at least European cooperation in high technology and research. He launched Eureka, a kind of European civil answer to SDI. From the new Prime Minister, the right-wing Jacques Chirac, who is accompanying Mitterrand in Tokyo, little has been heard on these matters, apart from his proposing a candidate for foreign minister who was highly favourable to French government participation in SDI. Mitterrand vetoed the appointment: he believes out-and-out French participation will lead to a brain-drain, and a loss of French control of important new industrial technologies.

If this was a negative step (in the sense of international cooperation in technology), Chirac has also taken negative steps in his major reduction of the French research budget (see *Nature* **321**, 8; 1986) — which will reduce the capacity of French bodies to join international collaborations — and in a sweeping reduction in the powers of the research ministry, which has lost control of technology policy as well as a number of technological programmes (such as space and energy) to the traditionally inward-looking ministry of industry.

Meanwhile other major divisions seem likely to plague the house of French international cooperation. A highly competent official, Robert Chabbal, ex-director of science for the North Atlantic Treaty Organisation (NATO), has been appointed coordinator for international research affairs, but he will reside in the weakened ministry of research. The ministry's links with the Elysée, President Mitterrand's palace and office across the Seine, were originally strong and well-used in the development of Eureka, but they must now seem somewhat redundant as both parties have lost influence.

The demise of the ministry of research was clear in the new government's attributions of power and budget: the decline of the Elysée is less easy to identify.

When before the election Mitterrand was discussing the possible "cohabitation", as the French like to call it, between himself and a potential right-wing prime minister, he made it clear that he would hold on to one thing: foreign policy. This area of action for the President would of course include his dreams of a "technological Europe", driven by France.

Since the election, however, Chirac, apart from losing his first choice of foreign minister, who might anyway have been a symbolic sacrifice, has made it clear that he, not the President, will determine French foreign policy. Chirac had made four foreign tours before the visit to Tokyo to establish his links with French Africa, and the British, German and Italian Prime Ministers, while President Mitterrand has remained at home. Moreover, Chirac has established a private foreign policy advisory unit in his offices in the Hôtel Matignon, and it seems clear now that French foreign policy is being run by Chirac and the foreign ministry at the Quai d'Orsay. Links between the Elysée, where the Eureka programme originated, and the ministry of research are therefore unlikely to have the importance they once did; in Tokyo, Mitterrand is little more than a constitutional monarch, and his past presidential pronouncements on a new world of technology merely echoes.

What everyone is waiting for, however, is to see where the new power, Chirac, moves in this area. His new foreign policy advisers have a strong industrial slant. Their chief is François Bujon de l'Estang (not to be confused with ex-President Giscard d'Estaing), a past international relations director of the French atomic energy agency (CEA), head of the US subsidiary of the nuclear fuel company COGEMA and chief cabinet adviser to Giscard d'Estaing's minister of industry, André Giraud. Moreover, Chirac's ministry of industry is as strong as the ministry of research is now weak. However, with the appointment as his science adviser of Yves Durant, an advocate of the freedom of research from state interference, who will be counselling Chirac to reduce the power of the ministry of research and its organizations still further, the chance of a renewed campaign by France for a research-led, high-technology future seems small.

Robert Walgate

Good week for Pasteur institute

THE Institut Pasteur, the biological and medical research institute in Paris founded by Louis Pasteur in the nineteenth century, has learned from a US court that it may, after all, be granted priority in its patent dispute with the US National Institutes of Health over who first invented blood tests for AIDS (acquired immune deficiency syndrome).

Millions of dollars could be involved in the argument, which dates back to September 1983, when the Pasteur filed a patent based on the discovery by its researcher Luc Montagnier of the virus that causes AIDS ("HIV", according to the recommended new nomenclature). Robert Gallo of NIH filed a similar patent based on his own work many months later, and was awarded his while the French application is still pending.

Now, the US Patents and Trademakers Office has announced "an interference" between the applications, in terms which, according to the Pasteur, mean that the institute will be awarded the patent rights unless Dr Gallo can prove prior discovery of HIV. Here Pasteur scientists feel on firm ground, but recent statements by Gallo (see p. 119) may give cause for doubt.

Moreover, all is not yet jubilation in Paris, as a final judgement in the US courts will take two years, and any redistribution of royalties on tests will take place only from the date of the judgement and will not be retroactive. Meanwhile, attempts to achieve a negotiated end to the dispute continue, and at the Pasteur (already heartened by a bequest from the Duchess of Windsor) they now feel they have a trump card.

ESF joins Ocean Drilling Program

Washington

THE European Science Foundation (ESF) has signed on as the seventh member of the Ocean Drilling Program (ODP), an international project for ocean basin exploration. ESF has been interested in joining for some time, but the $2.5 million membership price tag was a stumbling block that has only recently been overcome.

As an ODP member, ESF can send two scientific representatives on each ODP cruise, and one co-chief scientist each year. ESF will also participate in mission planning and site selection.

Representatives of ESF and the National Science Foundation signed the memorandum of understanding sealing the deal at a meeting in Annapolis, Maryland, last week of the ODP executive committee. ESF joins France, West Germany, the United Kingdom, Japan, Canada and the United States as members of ODP. A representative of the Soviet Union attending the Annapolis meeting indicated that his country is seriously considering rejoining ODP, but has not yet made a decision on that score.

US technology

Parallel computer unveiled

Cambridge, Massachusetts

JUST two and a half years after setting out to build the world's first "fifth generation" computer, Thinking Machines Corporation (TMC) of Cambridge, Massachusetts, last week unveiled the Connection Machine (CM), a massively parallel computer with 65,536 individual processors. TMC has already developed some remarkable applications for the new machine but the company consultant, Richard Feynman of California Institute of Technology, says the problems have yet to be dreamed up that will make full use of CM's unique abilities.

While a graduate student at Massachusetts Institute of Technology (MIT) in Cambridge, CM's spiritual father Danny Hillis came up with the blueprint for a data-level parallel processing computer. Using data-level processing leads to a more natural way of thinking about certain problems, says Hillis. For example, organizing a visual image by examining one small section at a time makes less sense than processing all the information in the image simultaneously. Data-level processing works best on problems with large amounts of data, whereas control-level parallel processing machines are most effective when the ratio of program to data is high. But control-level parallelism involves the difficult task of developing algorithms for asynchronous control of operations.

Communication among processors is the key to CM. Locally, this is done by interconnections among neighbouring processors. For general communications and dynamic reconfiguration, CM uses routers to send messages to the 64K processors arranged in a 16-dimensional hypercube at speeds of up to 3,000 megabits per second.

CM consists of a front-end computer, either a VAX or a Symbolics 3600, that sends instructions to the parallel processors. Each processor contains 4K of memory, so a fully configured CM has 32 megabytes of memory. Even with a $3 million price tag, or $1 million for a CM with 16K processors, prospective buyers are lining up to get hold of the new machine. TMC has so far delivered only one CM, to the Defense Advanced Research Projects Agency (DARPA), but in two months machines will be heading to MIT (2), Yale, Perkin Elmer Corporation and a second machine to DARPA.

In 1983, Hillis teamed up with Sheryl Handler to form TMC. Handler wanted to find a product that would provide a "fundamentally new way of computing". The new company quickly brought on board top scientists as consultants: Hillis's adviser Marvin Minsky and Thomas Poggio of MIT, Stephen Wolfram of the Center for Advanced Study at Princeton and Caltech's Feynman. With $16 million in equity capital and a $4.7 million DARPA contract early on, TMC was able to take the risks Handler felt necessary to leapfrog the competition.

A major advantage of CM for new users is its ability to run in familiar operating environments. Extensions to C and LISP computer languages designed by TMC allow immediate access to CM's parallel capabilities. TMC has already come up with applications packages that show off CM's power. A search for key words in a 16,000-document database takes only 30 milliseconds, much faster than conventional searches. Image processing, very large scale integrated (VLSI) circuit design, and fluid flow problems all take advantage of CM by assigning one processor to each element of the problem's dataset. CM can achieve operating speeds up to 7,000 MIPS (million instructions per second) on certain applications, faster than the fastest computer utilizing more conventional architecture.

Although CM's initial capabilities are impressive, Wolfram believes that a new computer language is needed to take full advantage of it. CM is well suited to cellular automata, and Wolfram predicts that almost all problems now being solved using differential equations will be done in future by constructs like cellular automata.

Another plus for CM is its expandability. While traditional computers using principles developed 40 years ago by von Neumann are inherently limited by a single central processing unit, an arbitrarily large number of processors can in theory be linked together using CM's design. TMC scientists have already written simulations of a machine with one million processors that can run on current CM computers.

Hillis says TMC's next goal is to develop a true learning system. In a small way, the interconnecting processors of the CM resemble the interconnections of individual neurones of the brain. Hillis hopes that this type of architecture will encourage the development of learning algorithms that more closely resemble biological processes.

Other groups around the world are working on new computers using parallel architecture, but Poggio points out that CM has one obvious advantage over other projects: "It works". **Joseph Palca**

AIDS in India

Pool of infected women?

New Delhi

THE Indian Council of Medical Research (ICMR) is expanding its network for surveillance on acquired immune deficiency syndrome (AIDS) following the detection of six cases in Madras, capital of the southern state of Tamilnadu.

All those concerned are female prostitutes aged between 20 and 30. Two of them have disappeared and are being sought by the state government and the other four are under observation. Professor V. Ramalingaswami, director-general of ICMR and chairman of the AIDS task force that has been set up, says that none of the women showed clinical manifestations of AIDS except one who lost weight. The women were among 102 prostitutes whose sera were subjected to enzyme-linked immunosorbent assay (ELISA) at the ICMR centre at the Christian Medical College in Vellore.

The findings were confirmed by scientists at the Centers for Disease Control in Atlanta, Georgia, where the sera were analysed by Western blot technique.

ICMR fears that more AIDS cases may be detected once the male contacts of the prostitutes are traced, but this is an almost impossible task. The women have told social workers that they usually had ten partners a day, mostly truck drivers; they all denied having foreigners among their customers.

It is not yet known if the virus is HTLV-III or a related virus recently found in Senegal, West Africa. As there is no experience in India of isolating or characterizing the virus, ICMR has sent three scientists to the United States and West Germany for training.

Meanwhile, ICMR is launching a programme to train physicians and technicians in the diagnosis of AIDS. Twenty-five thousand test kits have so far been imported. It is proposed to set up surveillance centres in each district, and to test donations from professional blood donors. Imported blood and blood products now have to be accompanied by certificates testifying that they are free from AIDS, and a requirement for health certificates from visiting foreigners is being seriously considered.

A separate section is being created in the health ministry to implement the AIDS detection and control programme. Ramalingaswami says this will put an extra strain on the health budget, half of which at present goes towards control of malaria. "We have our priorities and there is not much money for AIDS observation", says Ramalingaswami, but he admits that the detection of AIDS must be a priority if it is not to become widespread. **K.S. Jayaraman**

Archaeology congress

US to attend or stay away?

New Orleans

ATTENDANCE at the 1986 World Archaeology Congress at Southampton, England, has become a "moral litmus test" for US archaeologists. But there was no consensus among potential participants at the meeting here last month of the Society for American Archeology (SAA).

The congress, planned over several years with special attention to the participation of scientists from developing countries, has been controversial ever since the British organizing committee sent letters of "disinvitation" to South African and Namibian scientists. In the aftermath, the international parent body, the International Union of Prehistoric and Protohistoric Sciences (IUPPS), withdrew its recognition of the Southampton meeting; a conference to be held in Mainz, West Germany, in September 1987 is now recognized as the official 11th World Archaeology Congress (see *Nature* **320**, 3; 1986).

Opinion at New Orleans seems to have been that it is for scientists individually to decide how to balance the principle of a stand against apartheid and that of free international exchange between scientists.

Thus one would-be participant said that he wanted nothing to do with a meeting that would exclude such noted scientists and opponents of apartheid as Professor Phillip Tobias (University of the Witwatersrand), but that "I don't go along with some colleagues' wish to ostracize those who may attend".

On the other hand, Thomas Patterson (Temple University), a co-founder of Archaeologists Against Apartheid, urged colleagues to attend the Southampton congress to avoid giving the impression that US archaeologists, "consciously or unconsciously", are in favour of apartheid. According to Ian Hodder (University of Cambridge), some 22 per cent of registrants from the United States have already cancelled.

The large number of participants from developing countries expected at Southampton adds another side to the question. Hodder says that many of them would either be prevented by their governments from attending, or would abstain on their own if South Africans were to be present.

Some at the SAA meeting raised the further question of whether an international congress is possible at all. "What guarantee is there that the same problems will not recur in Mainz?", one archaeologist asked. Hodder says that anti-apartheid groups in West Germany are mobilizing to protest at that meeting.

Meanwhile, in Berkeley, California, a symposium held in mid-April to honour anthropologist J. Desmond Clark upon his retirement, with the participation of several scholars from South Africa, passed without incident, because the existence of the symposium was not made known to anti-apartheid groups there (see *Nature* **320**, 562; 1986).

One project scheduled for discussion at Southampton is the establishment of a truly international body, to correct what is generally conceded to be a European bias in the present make-up of the international union. A more broadly based coalition, it is hoped, could better ensure the free assembly of its members.

James Sacket (University of California, Los Angeles) urged that the United States should bring more weight to bear in future actions of IUPPS, where its role is small although it contributes a large proportion of the world's practising archaeologists. He suggested that one step towards the greater internationalization desired by all would be to hold the 12th World Archaeology Congress, scheduled for 1991, in the United States.

A member of the IUPPS executive committee, Sacket had made several attempts to reconcile the position of the British national committee with the requirements of IUPPS, proposing for example that participants should have the option of registering simply as individuals and not in the name of their country, but was unable to effect a compromise. "I was told that 'We do not want interference from the great powers'", he said. Thus, at this point, the future role of the United States in the international union seems problematic. **Sandra Ackerman**

Biotechnology

DNA fingerprints go commercial

BY early next year, and for something like £250, it will be possible to obtain a DNA fingerprint from a blood or tissue sample sent to a testing centre in Britain. The initial demand is expected to be for paternity testing, but the test has already proved invaluable in proving relationships that are doubted by immigration authorities and has considerable potential in forensic testing too.

The centre is to be operated by the diagnostics group of Imperial Chemical Industries (ICI), the British chemical and pharmaceutical giant, which is in an advanced stage of negotiation with the Lister Institute for the exclusive rights to a test devised by Dr Alec Jeffries of the University of Leicester. Royalties from the tests, which are likely to be substantial, will be shared by the University of Leicester, Dr Jeffries and the Lister Institute, of which he is a research fellow.

It requires considerable expertise to carry out the test, which types individuals in terms of a set of highly variable DNA sequences on human chromosomes. At the heart of the test is a process of hybridization between the individual's DNA and radioactive DNA probes. Before the hybridization can be carried out, however, the DNA has to be extracted and cut by enzymes into fragments which are separated according to size. Even after hybridization, it is not a simple matter to interpret the "result", a series of radioisotopic bands on a gel.

Although such techniques are routine in molecular genetics laboratories, they are much too demanding for any routine diagnostic laboratory. That is why the DNA fingerprinting test will not be marketed as a kit but offered as a service. (There is one commercial kit based on DNA hybridization which is used for the detection of salmonella, and its manufacturers, Integrated Genetics, plan others. But none of these tests will require other than crude sample preparations and they only detect the presence or absence of a DNA sequence that identifies the organism.)

Demand for the test seems certain to be considerable, with estimates that many thousands of immigration disputes worldwide could be settled each year. Dr Jeffries has been able to cope with only a few per cent of the requests that he has received in the wake of the initial publications that illustrated the potential of DNA fingerprinting (*Nature* **314**, 67; **316**, 76; **317**, 818 and **318**, 577 (1985)).

Forensic testing is likely to be more problematic because of the need for prosecution and defence to have recourse to independent tests. There is therefore considerable uneasiness about there being only one centre to which samples can be sent. One solution in Britain would be for the Home Office Forensic Science Service, which has been evaluating the test, to carry out its own DNA fingerprinting, presumably for the police, while the defence made use of the ICI centre. Another solution would be to allow separate scientists, acting for the two sides, to have independent access to a single facility, as they sometimes do now in forensic science laboratories.

Further demand for testing may come from the armed forces. In the United States, at least, there have already been discreet enquiries about the possibility of having all military personnel DNA fingerprinted to make it possible to identify from tissue fragments the victims of air disasters or bombings. **Peter Newmark**

Research planning

UK needs a forum for decision

THERE should be a mechanism in Britain for directing public investment in research towards areas likely to yield economic benefit, according to a report of the Advisory Committee on Applied Research and Development (ACARD), published this week (HMSO, £4.90). But the report does not live up to its title, *Exploitable Areas of Science*, in that it fails to pick winners in which the government might invest, concentrating instead on the considerations it believes should determine investment in research.

The report is the work of a committee under Dr C.H. Reece, the director of research at Imperial Chemical Industries, which includes both academic and industrial scientists. The starting point for the study is the British view (which the committee denies) "that research cannot be organised to deliver economic returns". One of the chief conclusions is that, in the allocation of research funds, the public research councils should be more sensitive to estimates of the kinds of research that might yield economic benefit.

Like other such committees, the ACARD group wrings its hands over Britain's economic performance in recent years. Recognizing that the flow of oil from the North Sea has been one of the influences leading to the decline of British manufacturing industry and that oil will be a declining resource in the future, the committee says that research planning now should be aimed at the development of technology that will allow the maintenance of living standards when the North Sea is less prolific.

The committee says its chief task has been to decide whether deliberate research planning is feasible; it concludes that it is. But, according to the report, there is at present no forum in which these questions can be discussed and decided. ACARD asks for a process of continuing consultation with "researchers (new and established), research allocation organisations . . . and the industrial research community".

To these ends, the committee says, there should be a more systematic approach to the collection of data on the patterns of research in Britain. This echoes a growing concern that the data available on the conduct of research in Britain, even as now gathered in the annual review published by the Cabinet Office, are incomplete, unreliable and out of date.

The committee also asks that its new mechanism for research planning should include a means by which "relevant opinions and information" can be "evaluated". The committee would rely on informed discussion to reach conclusions, but it skirts around the question of who would be involved in such a process. Thereafter, the committee says, there should be a process for allocating funds to priority areas (at least at one point, the report uses the verb "to prioritise") and a "commitment to exploit the results of science to UK benefit".

If the government follows the committee's recommendations, there will be no change in the present arrangements for channelling funds towards research, but more resources will be spent on the gathering and evaluation of data. The report says that "there should be a small management group" to steer the process.

The committee acknowledges that its proposals would entail "changes in emphasis" of the present work of the research councils, but says that the result should be "a more rational allocation of resources to those science areas of prime national interest". On industrial research, the committee pleads for more foresight by industrial companies with the objective of defining "potentially useful fields in which to work." □

AIDS in California

State aid offered for vaccine

Washington

LEGISLATION that would "shut the door" on strict product liability for vaccines against AIDS (acquired immune deficiency syndrome) is working its way through the California State Assembly, with the blessing of the two biotechnology companies closest to vaccine development. In addition to its shield from liability, the bill provides $6 million in aid for clinical testing and $20 million for state purchase of the vaccine to guarantee a million-dose market. Genentech and Chiron, eager to see the bill made law, say it would remove economic obstacles to vaccine development; California hopes it would induce these companies to triple their development efforts.

California ranks second in the United States for diagnosed cases of AIDS, with over 4,600 reported, and a study released last month by the state's Department of Health Services (DHS) predicts the disease will have struck 30,000 Californians by 1990. Feeling both the pressure of a public health threat and the promise of engineered immunization from companies virtually in the legislative backyard, assemblyman John Vasconcellos last year met with Genentech and Chiron to discuss ways to accelerate vaccine development.

The companies outlined the reasons that hormones and growth factors grab most of the attention in their laboratories, while investment in AIDS vaccine research remains modest. They said they were deterred by the uncertainty of the market size, the costs of clinical trials, and the threat of litigation once the vaccine reaches the public.

Vasconcellos and other California assemblymen drew up a bill to answer these concerns. The measure would permit the state to grant each of three companies up to $2 million to defray the costs of clinical testing, the most expensive phase of drug development. If companies sold less than one million doses, California would buy the difference. And the state would also accept responsibility for injuries proved to have resulted from vaccine use, with recovery limited to $250,000 per case. The bill applies to California companies only, and they would still be held liable for cases involving negligence.

Most of California's legislators appear to favour the bill, which was introduced in January and heard in the Assembly judiciary committee last week. However, opposition may emerge next week, when the legislation goes before the Assembly's ways and means committee. But supporters can point to the DHS report, which expects medical costs for AIDS of $3,500 million by 1990, and a California Manufacturers Association estimate that each employee who contracts AIDS costs his employer $250,000. Faced with these figures, state-subsidized vaccines may seem like a bargain to Californians. **Karen Wright**

Degrees by consent

HIGHER degrees in Poland will in future be subject to party approval, according to a Polish scientist who emigrated last month. The PhD *Doctor Habilitatus* degrees can be conferred both by the universities and by the Academy of Sciences, but since 1982, there have been almost no formal doctoral studies in the universities (see *Nature* 320, 693; 1986), and graduates wishing to proceed to a higher degree can best do so by obtaining a research post in one of the institutes of the Academy of Sciences.

Until now, decisions on higher degrees awarded by the academy have been taken by the research council of the relevant institute. Some six weeks ago, however, Dr Zdzislaw Kaczmarek, the Learned Secretary of the academy, announced that from now on, he will decide, on the basis of a confidential report on the candidate from the party organization in the institute; this report will not be accessible to the members of the research council of the institute.

Vera Rich

Future of UK observatory

SIR—Your views on the future of the Royal Greenwich Observatory (RGO) (*Nature* **320**, 384; 1986) cannot be allowed to go unchallenged.

It is quite untrue that British astronomers are unperturbed by the announcement by the Science and Engineering Research Council (SERC) that RGO is to move; stunned would be a better word to describe our reaction to the extraordinary suggestion of a merger with the Royal Observatory, Edinburgh (ROE). But there is a growing ground swell of protest which will begin to surface as more people realize that they cannot this time leave action to somebody else.

I must also take issue with your use of the phrase "surplus observatory" in the heading. To put it at its lowest, if one observatory is surplus, why should it automatically be assumed that it is RGO? The telescopes at ROE are no more used for research than those at RGO. Moreover, I do not believe that either observatory is surplus to the needs of British astronomy. The two royal observatories are the major centres of research in optical astronomy in this country and it is healthy to have rivalry between them, just as it is good to have two major radio observatories and two major X-ray groups.

Each observatory runs large overseas facilities, which are complementary, and so no great benefit would accrue from administering them from the same site. A research council with vision would realize that developing the instruments for these facilities is only the first step in exploiting the overseas sites and that, far from their usefulness diminishing, both observatories can continue to play vital roles by collaborating with university astronomers to obtain the best results from the new instruments. It should not be assumed that the observatories' natural role is just to support university research; they will do that job far more effectively if they also collaborate actively in the research, as they do now.

RGO differs from ROE in not being actually on a university campus. (Actually, ROE is not quite on the campus either, but it is closer.) But that does not mean that it does not collaborate with university groups. Indeed, there has been very active collaboration with the University of Sussex for some twenty years, and we do not understand why the chairman of SERC feels that this connection is "not the kind of interaction we are looking for" (*Nature* **320**, 297; 1986). There are many places where related institutions on the same campus have far less interaction. Propinquity is no guarantee of interaction nor does separation preclude it.

In addition to the connection with its nearest university, RGO also collaborates with 12 British and European university groups on astronomical instrumentation and with more than 50 groups internationally on research projects. It is hard to see how a move to a particular university would increase this collaboration. As you say in your Opinion column, the benefits of an academic partnership are indeed huge, but they are already being realized. The danger of moving RGO from its present site is that the accompanying reduction of resources will be larger than the reductions already threatened at Herstmonceux and that universities as a whole will end up losing some of the valuable resources that they currently enjoy.

In short, the diffidence that you mention in deciding what to do about RGO arises simply from the fact that there is no obvious reason to do anything. RGO is doing a good job where it is and no serious scientific case has been made for moving it. The only conceivable reason for a move would be to save money, and there is no sign that that is possible without a massive reduction in resources which would defeat the claimed object of the move.

Sexist ads

SIR—In the issue of *Nature* for 3 April 1986, organic life forms were represented in your advertisements in the following proportions: four men, all wearing lab coats and engaged in "serious" scientific pursuits; one unisex doctor treating a female patient; one unisex mouse in a laboratory; one woman, dressed in tight-fitting jeans and denim jacket, exposing a portion of her lower back, smiling inanely and apparently advertising a product involved in DNA detection.

Unfortunately, the predilection of your advertisers to portray men (and in some cases animals) as serious-minded scientists, and women as dumb decorative objects, is not confined to this one issue. A notable feature of the back cover of past issues of *Nature* has been a dripping, apparently unclad blonde emerging from a lake and trying to sell air.

Please instruct your advertisers to take into account the fact that many of your readers are professional women, and are not responsive to the type of advertisement normally associated with the darker recesses of the tyre and car parts trades.

KATHLEEN WESTON, ALISON COZENS, HILLARY C.M. NELSON, LOUISE FAIRALL, LINDA AMOS, LAUREL MENGLE-GAW, FLEUR-ANGE LEFEBVRE, MELANIE J. CLARK, CYNTHIA KENYON, MARIANN BIENZ, LINDA BREEDEN, HEINKE SCHNABEL, MARGARET ROBINSON, DONNA ALBERTSON, IVA GREENWALD, MARIA LEPTIN, DANIELA RHODES, MARTINE VERHOEYEN, LYNETTE TIGHE, CLAUDIA BEREK, SANDRA SATCHWELL, C. JANE MITCHELL, CARLOS V. CABRERA, ROB WHITE, HUGH PELHAM, SEAN MUNRO, COLIN WATTS, R.J. BAER, ANDREW J.H. SMITH, ANDREW J. NEWMAN, KIYOSHI NAGAI, ALAN FORSTER, GREG WINTER, DAN BROWN, JEFFERSON FOOTE, LUIS MARTIN, PETER SORGER, GARETH WILLIAMS, GRAHAM COOK, ANDREW FIRE, VICTOR TYBULEWICZ, STEPHAN BECK, RICHARD TURNER, HORACE DREW, TOBY J. GIBSON, TONY KOUZARIDES
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

SIR—A recent series of advertisements in *Nature* shows us women in jeans or half-naked. Is it not a bit silly for a scientific journal to feature such silent propaganda for feminist and so-called liberal attitudes? Why not give women their dignity back by presenting them in skirts?

A. BRADBURY
F. VAN STRAATEN
MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

MRC unit closure

SIR—We are writing in response to the report (*Nature* **320**, 478; 1986) on the proposed closure of the Medical Research Council (MRC)'s Mammalian Genome Unit in Edinburgh. We find it disturbing that the MRC secretary, Sir James Gowans, should be unable to explain the failure to find a "suitable" director for a molecular biology unit of international reputation.

The reduction in funding of MRC, imposed by the government, is no doubt the root cause of the closure. Financial uncertainty from year to year, together with the greater rewards to be attained elsewhere, produces a decline in morale that increases the rate at which scientists leave the country.

We would have expected that the closure of a molecular biology unit of high calibre would have merited rather more than a "small decision" by MRC. If it cannot find a director deemed "suitable" by its present criteria, we suggest that those criteria may need re-examining. The loss of the Mammalian Genome Unit will be yet another nail in the coffin of British science in a field which is receiving encouragement and increased financial support from more farsighted nations.

Hanover highlights all the latest developments and industrial applications in the field of biotechnology

From its very inception BIOTECHNICA Hanover has established itself as Europe's leading forum for research, development and practical applications in the field of biotechnology. The basis for the unprecedented success of BIOTECHNICA is two-fold. Firstly, the excellent program of symposia, workshops and lectures held by internationally renowned experts. And secondly, the user-oriented exhibition presented by leading manufacturers and research institutes.

The international congress – a meeting-place for experts

On three successive days, 16 internationally renowned experts will deliver papers on the application of biotechnology in the following fields:

Medicine/pharmacology
e. g. diagnostics and various approaches to therapy following cardiac infarction

Food production/ agriculture
including the optimization of agricultural produce and quality control in foodstuffs

Environmental protection
from biological methods of combating air pollution to the treatment of sewage

Seminars and workshops – a spotlight on research and its practical application

Research institutes, universities and leading manufacturers will utilize the comprehensive parallel program of talks, symposia and workshops in order to present their latest research findings, products and processes. Hanover illustrates how research findings can be transformed into marketable industrial processes and products.

In a series of special seminars organized by the European Community, BIOTECHNICA '86 will also present the most important results of the biotechnological research projects funded by the EC.

The 3rd US Seminar for Biotechnology, organized by the US Foreign Commercial Service, will also be held on all three days of BIOTECHNICA '86.

The exhibition – geared to industrial applications

Over 200 research institutes and commercial firms will exhibit at BIOTECHNICA '86. The exhibition will highlight biotechnological processes and products, the latest developments in laboratory equipment and techniques, as well as new production technology. It's no surprise, therefore, that in 1985 some 3,500 professional visitors from 27 countries attended this comprehensive display.

At BIOTECHNICA Hanover '86 you can find out all you want to know about every major aspect of biotechnology.

If you require more information please contact:

Reader Service No.10

STILL FIRST WITH THE BEST IN SCIENCE

STILL AVAILABLE AT HALF PRICE!

A PERSONAL SUBSCRIPTION is now something *you* can afford... each week crucial research results and the most important scientific news at your door... keeping you fully informed and right up-to-date – all for just £1 a week, that's £52 a year and **half** the current institutional price.

There's *never* been a better time for you to subscribe. All 51 weekly issues will be delivered to the address of your choice. You can start your annual subscription with any issue you choose. And you will receive six bi-monthly author indexes, together with the annual index of subject and author.

COMPLETE THIS ORDER FORM TODAY 7B64

SPECIAL HALF PRICE RATE OF £52.00

☐ Please send me a personal subscription to Nature for one year (51 issues) at the SPECIAL HALF-PRICE RATE of £52.00

☐ I enclose my personal cheque for £52.00 made payable to Nature. (Note: Institutional cheques cannot be accepted at this special rate).

☐ Please charge to my credit card account: Access/American Express/Visa/Diners Club.

Please allow approximately 4 weeks for delivery of first issue

Mechanizing cellular automata

Whether or not it is possible to represent hydrodynamical systems by autonomous entities on the vertices of a lattice threatens to become an unreal issue.

THE news this week (see p. 103) of the new parallel architecture computer developed by Thinking Machines of Cambridge, Massachusetts, should be read in conjunction with two unusually contradictory papers in *Physical Review Letters* for 15 April. Both are stimulated by an as yet unpublished paper by J. Salem and Stephen Wolfram.

Wolfram is the Princeton-based physicist who carries a torch for von Neumann's model of the cellular automaton, the microscopic entity in an array whose state at any time is determined by its own state at some previous time and by those of its immediate neighbours.

Steven A. Orszag and Victor Yakhot first set out to show that cellular automata cannot be adapted in the real world to solve the problems of fluid dynamics (*ibid.*, **56**, 1691; 1986). The next paper (Margolus, N., Toffoli, T. and Vichniac, G., *ibid.*, **56**, 1694; 1986), based on the same unpublished paper, purports to reach the opposite conclusion. What is the innocent reader to conclude?

There is nothing startlingly novel about the model of the cellular automaton. Fill accessible space with microscopic cells, most simply of the same size. Then let each be occupied (or empty of) a physical entity which can be in only one of several states (most simply, finite in number), and then allow that future generations of this system will evolve, with the passage of time, according to rules applying equally to all of them (see Wolfram, S., *Nature* **311**, 419; 1984).

Such a system can obviously be a model for various aspects of the real world. If the entities occupying separate cells are members of a population, the evolution of the arrangement as time goes on may be a model of how a living population evolves. But if the cells are occupied by tiny magnets allowed to point in one direction or the opposite (for example), the system is a model for a ferromagnet.

Such systems are also capable of modelling the behaviour of ordinary dynamic systems such as those forever cropping up in physics. Anybody who doubts that has merely to recall that systems of differential equations can be approximated to by finite difference equations which may be more conveniently soluble, but which are in any case a convenient way of writing a computer program to simulate the original set of equations.

So why not think of using networks of cellular automata as means of solving real problems in applied physics? A few simple systems are easily imagined. Suppose, for example, that the objective is to follow the time course of a plucked violin string or of a bent beam; one might approximate the system by a one-dimensional array of cellular automata whose individual states might represent the displacement of the string from a reference datum. If the evolution of the system is then described simply in terms of the instantaneous state of each element and its nearest neighbours, the approximation is certainly no worse than that familiar in the simple textbooks of applied mathematics, where only first and second derivatives seem to matter.

The argument that has now arisen stems from what must be the most ambitious goal of all, how to use networks of cellular automata to stimulate the motion of fluids with real thermodynamic properties, heat capacity, vorticity and friction, for example. This, it seems, is what Salem and Wolfram have been up to, in a paper with the title "Thermodynamics and Hydrodynamics with Cellular Automata", which it is said is "to be published".

Orszag and Yakhot are against the conclusions of that unpublished paper, Margolus and his colleagues show that the arguments are valid. A curious almost-ethical point arises at this stage. It is rare that journals publish disputatious accounts of a paper that has not yet been made accessible to readers. The issue is only nearly ethical; readers who do not care for having to read between the lines can always read some other journal.

Reading between the lines, what Salem and Wolfram have done is to argue that it should be possible to represent a real thermodynamic fluid by a system of cellular automata in the sense that the space and time averages of the properties of cellular automata will follow the behaviour of incompressible fluids which are described by the Navier–Stokes equations. Friction enters, producing heat (and robbing the system of kinetic energy).

A crucial part of the Salem and Wolfram argument (again between the lines) is that the coming of computers with parallel architecture should make these simulations more accurate and also more real.

Orszag and Yakhot do not dispute the virtues of computers made from, say, 64,000 microprocessors strung together (who could?). Their quarrel is with the underlying physics and the computational economy of the cellular automata models Reading between the lines, one can conclude that Salem and Wolfram represent continuous variables such as the velocity (of the fluid) in a velocity field by means of averages over groups of neighbouring cells carrying separate cellular automata. Questions then arise about the efficacy of the representation; either there are so few cells in the group over which average values represent dynamical variables in the real world that the calculation is inaccurate, or the group is large enough to be realistic but the computational work is enormously increased. The essence of the argument is that tractable networks of cellular automata will usually be unrealistic, but that realistic networks will be less easily soluble than the equations to which they are an approximation.

Margolus *et al.* write in a quite different vein. "Surprisingly enough, cellular automata can faithfully model continuum systems such a fluids . . . [but] are poorly supported by conventional scientific computers . . . more appropriate architecture can easily gain a performance factor of at least 10,000 . . ." Part of the trick (to be revealed in the unpublished paper by Salem and Wolfram) is to devise the generation rules for the automata so that microscopic reversibility is assured. Margolus and his colleagues show, among other things, some pretty diagrams in which a central blob of fluid on a two-dimensional plane spreads outwards in a growing concentric ring. The authors surprisingly boast that one simple system (a two-dimensional lattice gas) is macroscopically as well as microscopically reversible.

Quite what the dispute is about can be read only between the lines, but there is an obvious and simple resolution of it: simply build computer systems with as many microprocessors as there are atoms whose behaviour must be simulated, and make sure that they respond at least as quickly. Then the objections of the Orszags and Yakhots of this world will melt away. As it happens, Margolus and his colleagues say that it should be possible to deal with 10^{7} elements (the square of the cube root of Avogadro's number) within a decade, and to "span the gap between the microscopic and the macroscopic world" soon afterwards. That may be possible, but the question will remain of whether it is science.

John Maddox

Protein translocation

A common mechanism for different membrane systems?

from Gottfried Schatz

ALL cells transport specific subsets of their own proteins across membranes in order to segregate metabolic pathways, to communicate with other cells or to build new membranes. Because each of the different membrane types poses the same problem — how to transport a large hydrophilic protein across a hydrophobic phospholipid bilayer — it has been tempting to suppose that cells have evolved a universal solution. Until recently, however, most of the experimental evidence seemed to argue otherwise[1]. Although the endoplasmic reticulum of eukaryotes seemed to translocate proteins only while they were still being synthesized (that is, by co-translational translocation), all other membrane types studied — bacterial, mitochondrial, glyoxysomal and chloroplast — can translocate completed protein chains post-translationally. Reports from several laboratories[2-8] now suggest that these differences are more apparent than real, and that the mechanism of translocation may indeed be fundamentally similar, or even the same for all membrane systems.

The co-translational model of protein translocation, derived from pioneering studies on the mammalian endoplasmic reticulum[9], is as follows. Proteins destined to be translocated into or across the endoplasmic reticulum membrane contain a specific signal sequence, usually located at the extreme amino terminus. As this sequence emerges from the large ribosomal subunit, it binds to a cytoplasmic ribonucleoprotein complex (the signal recognition particle) which stops further elongation of the polypeptide chain. Binding of the blocked ribosomal unit to a proteinaceous receptor on the cytosolic face of the endoplasmic reticulum releases the elongation arrest and causes the growing polypeptide to move across the membrane. Soon after the amino-terminal signal peptide has traversed the membrane, it is removed by a signal peptidase located in the lumen of the endoplasmic reticulum.

This model rests on several key findings[1,9]. First, attempts to translocate completed polypeptides into microsomes (isolated vesicular fragments of endoplasmic reticulum) have always failed: translocation occurred only while the polypeptide was still being synthesized. Second, the signal sequence was removed by the luminal peptidase before the carboxy-terminal domain of the protein had been synthesized; uncleaved, full-length precursors were thus undetectable in pulse-labelled intact cells. Finally, the signal-recognition particle arrested the elongation of secreted, but not of cytosolic proteins; the arrest of elongation could be abolished by adding mammalian microsomes, whereupon the growing secreted proteins were translocated into the microsomes. This tight coupling between synthesis and translocation seemed to be an elegant mechanism for ensuring that proteins destined to be inserted into or across the membrane were not released into the cytosol.

The co-translational model is purely operational and does not invoke an obligate mechanistic coupling between polypeptide elongation and translocation. It has, however, often been interpreted to imply that translocation is driven by chain elongation which is in turn powered by the hydrolysis of high-energy phosphate bonds. This interpretation is difficult to prove or refute: by its very nature, a co-translational mechanism makes it impossible to probe the energy requirement of translocation independently from that of protein synthesis. Moreover, it is clear that in other membrane systems there can be no such mechanistic coupling: all other membrane systems can translocate polypeptide chains post-translationally. For example, mitochondria efficiently import pre-synthesized precursor polypeptides, both *in vitro* and *in vivo*. Import across the inner membrane requires an electrochemical potential across that membrane[10]. Post-translational uptake of proteins is also observed with chloroplasts[11] and glyoxysomes[12]. With chloroplasts, uptake is dependent on ATP rather than a transmembrane potential[13]. Finally, bacteria can translocate proteins across their plasma membrane post-translationally in a process requiring an electrochemical potential across that membrane[14,15]. Although post-translational movement of proteins across bacterial membranes has long been controversial[1], it is now accepted by most workers in the field[16]. For a while it seemed, therefore, that nature had devised two distinct mechanisms for moving proteins across membranes, one coupled to protein synthesis and the other not.

Last year, however, obligate coupling between protein synthesis and translocation across the endoplasmic reticulum began to look less certain. For example, elongation arrest by the signal recognition particle was not detectable with all secretory proteins[17], or when protein-synthesizing systems from mammalian sources rather than from wheat germ were used[18]; this raised the possibility that elongation arrest was an artefact limited only to some secretory proteins, and only if these were synthesized in the heterologous wheat-germ system. Similarly, signal-recognition particles from which a segment of the RNA chain and/or two protein subunits had been removed no longer stopped elongation of secretory proteins, yet still mediated their translocation across the endoplasmic reticulum[8,19]. Finally, a signal sequence engineered into an internal location could effect translocation of both flanking domains into microsomes[20]. In this case, at least the amino-terminal domain had to be translocated after it had been synthesized. Still, there was no direct proof that a completed protein could be translocated into microsomes.

Such proof is now available. Hansen, Garcia and Walter[2]; Rothblatt and Meyer[3-5]; and Waters and Blobel[6] find that the precursor to α-factor (a secreted yeast mating hormone) can first be synthesized in a messenger RNA-dependent protein synthesizing system from yeast and then be translocated into yeast microsomes. Taken together, these experiments show that post-translational uptake into yeast microsomes can be as efficient as co-translational uptake, is insensitive to uncouplers and ionophores, and requires ATP. It will be interesting to see whether post-translational uptake into yeast microsomes can occur with proteins other than the α-factor precursor.

Energy-dependent post-translational uptake into microsomes is not unique to yeast: Mueckler and Lodish report[4] that dog pancreas microsomes can post-translationally incorporate the human glucose transporter, a glycoprotein of relative molecular mass 54,000 containing as many as 12 membrane-spanning segments. Even though post-translational uptake in this system is at least one order of magnitude less efficient than co-translational uptake, it is increased threefold

when an amino-terminal fragment of the glucose transporter is synthesized off a truncated messenger RNA that encodes the first 340 amino acids of the protein and lacks the stop codon. Uptake of this amino-terminal fragment is insensitive to various ionophores, but requires cleavage of high-energy phosphate bonds[7].

These new findings do not contradict the previous view that movement of proteins into the endoplasmic reticulum is, in fact, co-translational. But they do show that co-translational translocation is not obligatory. As this excludes a strict mechanistic coupling between elongation of a polypeptide chain and its movement across the endoplasmic reticulum, it is now a distinct possibility that proteins move through different membranes by fundamentally the same mechanism. This mechanism is still a mystery, but efforts to unravel it will benefit from the newly developed cell-free endoplasmic reticulum translocation systems from yeast[2,3,6]. As these systems should allow the molecular analysis of yeast mutants defective in early steps of secretion (see, for example, ref. 21), biochemists have been handed a sharp new scalpel for dissecting the machinery which moves proteins across the endoplasmic reticulum. □

Archaeology

Late Saxon ceramic utensils

from Richard Hodges

POTSHERDS — the tableware, cooking pots and storage containers of ancient times — appear at first sight to be the least attractive component of archaeological excavations. But the study of ancient ceramics turns out to be surprisingly useful, providing detailed information about past societies (see ref. 1). The significance of this approach is well illustrated by the recent work of Alan Vince[2] on the mediaeval pottery of London.

The sheer bulk of potsherds unearthed in modern open-area excavations (for example, several tons from the tenth century Viking dig at York in the United Kingdom[3]) has resulted in a shift of emphasis in ceramic studies away from distinguishing pottery in terms of its shape and decoration and towards a system based on pottery fabrics — the clay matrix used by the potters. This fabric series can distinguish between the workshops responsible for the pottery production. The approach necessitates identifying the macroscopic features of the clay; if these features are unclear or can be assigned more precisely to a specific source, a microscopic analysis is performed. The commonest technique in this second stage of analysis is ceramic petrology, in which thin sections of the fabric are examined under a petrological microscope. In some cases the exact provenance of the clay is apparent from its mineralogical character; more often the clay has been taken from some indistinctive riverine source and only the potter's 'recipe' can be identified.

There are tons of pottery in the excavations of the Department of Urban Archaeology at the Museum of London, making a typological listing impractical. Therefore, the fabric series was classified using macroscopic and microscopic principles[2]. Each fabric embraces forms which vary according to its date of manufacture. Potsherds discarded in the Middle Ages offer fascinating patterns of the history of the potter's craft and how and where these low-grade utensils were sold.

The Late Saxon ceramics from London illustrate this point vividly. It is highly debatable whether London was a significant community before King Alfred's time, but with the explosion of urban development in the tenth century London grew rapidly, so by the end of the century it was engaged in international trading. The ceramic history puts some interesting flesh on this skeleton. First, there was no Middle Saxon (pre-Alfredian) potter serving the community; the pots were made only primitively on a hand-rotated wheel. But, with what I have recently described in *News and Views* as the first English industrial revolution[4], the role of the potter changed. Vince shows that the well-dated tenth century groups are dominated by so-called shelly wares (see figure). Petrological analysis of this fabric shows that it contains abundant calcareous inclusions typical of clays in the Oxford region. Pit-groups dated dendrochronologically (tree-ring analysis of their timber content) to the first half of the eleventh century demonstrate a marked change in the type of pottery being discarded. The amount of shelly ware was halved and replaced by other 'imported' pots from areas such as East Anglia, and lead-glazed pitchers made in the town of Stamford also appear in eleventh century contexts in London. A distinctive local fabric, Early Mediaeval Ware, shows abundant sand-grains in thin sections and is one of various recipes used by potters operating near the city. By the end of the tenth century the products of as many as a dozen workshops had broken a virtual monopoly. Thereafter, the rise and fall of industries follows an inexorable pattern, punctuated by a succession of imported wares that reveals London's overseas connections.

Museum of London

A group of Late Saxon shelly ware vessels from various sites in London. Vessels of this type were made from a clay containing abundant fragments of the fossil *gryphaea*, characteristic of the Jurassic clays of midland England but not of the Thames Basin.

The definition of fabrics has made it possible to chart the history of England's earliest craftsmen. Vince's study of London ceramics, like his earlier studies of mediaeval pottery in the Midlands, reveals the rapid development of workshops and their adaptive attitudes to widening their range of products. The scale of the industry and its fast expansion also sheds light on the customers of these potters. The large quantities of tenth century pottery from lower-ranking urban dwellings in sites like London and York, as well as from many villages, reflects a voracious demand for mass-produced commodities.

It has previously been suggested that the peasantry of Late Saxon and Mediaeval England, in common with many traditional nineteenth and twentieth century peasant societies, had minimal access to commodities[5]. In the opinion of some historians, feudal arrangements meant that rural populations had little opportunity to take advantage of urban industrial output. It is still too early to generalize definitively from these studies of mainly urban pottery assemblages, but a picture of a highly integrated, prosperous community is emerging. Potsherds provide details of industrial and commercial connections beyond the scope of the written sources. In many ways these fragments constitute a new form of historical epigraphy and to judge from Vince's results in particular, the collection and processing of archaeology's seemingly least interesting objects is well justified. □

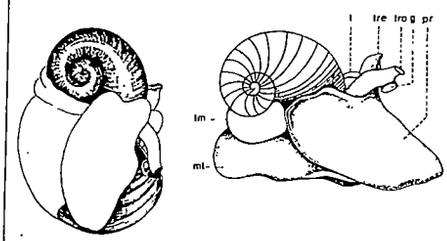
Macroevolution

Predation by drilling gastropods

from Michael J. Benton

PREDATION is an important agent of natural selection, and it is regarded by many as an important driving force of evolution[1]. There is growing evidence that the fossil record can offer unique information on the history of particular predator–prey systems, and thus complement the work of ecologists on living forms. Gastropod molluscs (limpets, winkles and other molluscs with 'coiled' shells) are major marine predators on other shelled animals, and they use various mechanical and chemical means to drill or bore through the shell (see figure). Evidence of this activity has been found in the fossil record, although until recently, the oldest precisely identified gastropod borings dated from the early Cretaceous Blackdown Sands of Southern England — about 100 million years (Myr) ago. But new evidence shows that drilling by gastropods occured much earlier and suggests that these early gastropods had a different form from their present-day counterparts[2].



Gastropod drill holes are readily identifiable in fossils or recent specimens of shells. They are round, perpendicular to the shell surface, cylindrical or conical in cross-section, generally pass right through the shell at its thinnest point[3] and are produced by the mechanical action of tooth-like structures on the gastropod radula and by the chemical action of acids.

Certain families of gastropods produce quite distinctive holes. For example, naticid gastropod drill holes are tapered inwards, forming a broad parabolic section on the outside (countersunk) and are 0.2–3.1 mm in diameter; there is a central boss in incomplete holes where the animal has stopped before reaching the flesh inside.

The fauna from the early Cretaceous Blackdown Sands of Southern England[3,4] contains naticid gastropods and other boring forms, as well as various bivalve species. Of the 83 species of bivalves, 43 show gastropod borings, 11 of which account for 73 per cent of the attacks. One species, *Corbula elegans*, accounts for 28 per cent of the attacks. The naticids also bored into the shells of other gastropods. In general, for the Blackdown fauna, prey preference tends to vary with the relative abundance of the prey species, although some particularly thick-shelled oysters (which were quite common) were not drilled very much and some quite rare gastropod prey species were heavily attacked. The naticids selectively attacked medium-sized shells, avoiding very small ones (not enough meat inside) and very large ones (too thick to make the effort worthwhile)[5].

The siting of drill holes is also fairly constant — there seem to be preferred locations that depend on the way the predator grasps the prey shell in its fleshy foot, and on the size, shape, ornamentation and behaviour of the prey species[4,5].

The Blackdown Sands fauna, with its evidence of extensive naticid gastropod predation, forms part of the Mesozoic marine revolution[6], a phase marked by the simultaneous evolution, from the early Cretaceous onwards, of powerful, relatively small, shell-destroying predators such as teleost fishes, stomatopods, decapod crustaceans and drilling gastropods. In response, prey animals took to burrowing and evolved stronger, thicker shells that often had heavy sculpture, spines and narrow apertures[1,4–6]. After the Cretaceous, the shell-drilling gastropods became more efficient — in the Blackdown fauna, about 4 per cent of all bivalve specimens contain drill holes, and this rose to 5–26 per cent afterwards. The numbers of drilled gastropod prey rose from 5 per cent in the Cretaceous to 11–26 per cent afterwards[4].

Right, *Natica josephina*. Feeding apparatus: g, 'foraging gland' secreting acid; t, tentacle) tre, respiratory tube; tro, proboscis containing radula system. pr, lm, mt comprise the hinged foot. (From Ankel, W.E. *Veh. dt. zool. Ges.* **40**, 223; 1938.) Left, *N. josephina* eating a bivalve.

There are several examples of predation by naticid gastropods before the Cretaceous. Newton[7] reported examples from the late Triassic of North America (about 220 Myr ago) and Fürsich and Jablonski[8] described some slightly older late Triassic cases from Italy (about 225 Myr ago). The latter bore holes show all the typical naticid characteristics, and coincide in age with the oldest known naticid gastropods. It had been assumed previously that these gastropods were initially non-drillers, and that they acquired this skill only 125 Myr later in the early Cretaceous.

Fürsich and Jablonski[8] argue that naticid drilling ability evolved twice but became successfully established only the second time. The evidence for this assumption is the absence of naticid bore holes in the intervening Jurassic period. In evolutionary terms, Fürsich and Jablonski view the late Triassic drillers as well enough adapted, but afflicted by bad luck — they may have had low speciation rates, or may have been wiped out in a chance extinction event. When the drilling habit was reinvented by their close relatives in the Cretaceous, it was associated with high rates of diversification, and the habit persisted to the present day in a wide range of naticid species.

But Smith and colleagues now report an even older occurrence of drilling[2] from the middle Devonian of North America (about 380 Myr ago). The holes are indistinguishable from those made by naticid gastropods, but they pre-date the oldest known naticid shells by 155 Myr. The bore holes were made in articulate brachiopods, and the predators show all the features of modern naticid behaviour: the drill holes are highly prey-specific in all localities sampled; they are concentrated over the 'meaty' part of the shell; and the brachiopods were attacked while still alive. As many as 44 per cent of preferred prey species were drilled, but the predators were relatively inefficient — in one locality nearly half of the drill holes were incomplete. This case forms part of the mid-Palaeozoic revolution[9] during which several groups of predators became adapted to shell-crushing and boring (placoderm and chondrichthyan fishes, shrimp-like arthropods and possibly naticid gastropods) and the prey species evolved stronger shells with ribbing and spines in tandem.

In evolutionary terms Smith and colleagues propose that their sample documents a third origin of the naticid-like drilling habit in the Devonian, but they argue that is was not chance that terminated the first attempt at drilling. In the Devonian, there are no known naticids, nor are there any relatives that are fossilized. Smith *et al.* argue that the Devonian driller was a shell-less form (thus not fossilizable) that had evolved the physical and chemical means of drilling. Drilling is a slow process, and the predator was vulnerable itself while going about its business (hence the high number of abandoned drill holes which indicate that the predator may have been disturbed, or

indeed eaten, before it could withdraw its drilling equipment). In either case, Smith *et al.* argue that the two 'failures' of the naticid-like shell-drilling habit in the Devonian and the Triassic were the result of poor adaptation. Only in the Cretaceous did the naticids evolve the necessary drilling techniques and the means of self-protection.

Many older examples of predatory bore holes in shells are known — for example from the late Cambrian of the United States (about 510 Myr ago)[10], from the Silurian of Sweden (about 420 Myr ago)[11,12] and from the early Devonian of Canada (about 400 Myr ago)[13]. The predators could have been gastropods in some of these cases[12,13] but the holes are either much smaller than those produced by living naticids[10,11] or they lack the central boss and the inwards taper[12,13]. The holes could have been produced by cephalopods[3,11,12], or by unknown forms[3,11]. Whatever the answer, these studies offer much scope for further work on the history of marine predation, on the modelling of predator–prey interactions[5] and on establishing the role of predation in macroevolution. □

Astrophysics

Unravelling fates of black holes

from Don N. Page

EVER since S.W. Hawking's remarkable theoretical discovery of thermal radiation emitted from black holes[1,2], it has been clear that these objects cannot be the stable final states of gravitational collapse they were once believed to be. But what happens during the last stages of black-hole evaporation has remained uncertain, leaving unanswered several important conceptual issues such as the fundamental predictability of the ensuing state[3-5]. Now M.J. Bowick, L. Smolin and L.C.R. Wijewardhana argue[6] that superstring theories[7,8] can help unravel the answer.

Black holes allow nothing to escape, according to classical (that is, non-quantum) physics in which each particle has a definite position and a definite velocity, which must not exceed c, the speed of light. However, in quantum physics the uncertainty principle prevents a particle from definitely being confined to the space inside the hole and simultaneously definitely having a velocity $\leq c$. In this way quantum mechanics allows a particle to tunnel out from a black hole. Hawking[1,2] calculated this black-hole emission process in a semiclassical approximation in which quantum mechanics was applied to the particles being emitted, but not to the black hole itself, which was instead assumed to have a definite classical gravitational field.

Conservation of energy requires the black hole to lose mass, and hence shrink, as particles carry away its energy. Eventually it evaporates to such a small size that the semiclassical approximation becomes invalid, and quantum mechanics must be applied to the gravitational field of the black hole itself. It is not known how to do this in a completely consistent manner, hence the uncertainty of what happens in the last stages of black-hole evaporation. It has been variously suggested that a black hole stops radiating and shrinking when it reaches a positive-mass stable remnant; that it continues radiating until its mass becomes negative; or that it completely disappears.

There is also the question of whether the quantum evolution of the state is deterministic, or whether there is a new breakdown of predictability beyond the ordinary limitations of the uncertainty principle[3-5]. If the black-hole emission is precisely thermal, with no correlations between different modes (as is predicted by the semiclassical approximation), then its evaporation results in a loss of information or an increase in entropy even without any coarse graining of the final state. Furthermore, in a classical description of the gravitational field, the disappearance of a black hole would be accompanied by a so-called naked singularity (a visible edge to space-time), at which unpredictable information might enter the Universe.

Bowick, Smolin and Wijewardhana[6] now offer a preliminary analysis of these questions in the context of superstring theories[7,8], exciting new candidates for a consistent quantum 'theory of everything' (unification of the fundamental forces, including gravity; see ref. 9 for review). If one of these theories is indeed correct, it should in principle be able to explain what happens when a black hole evaporates. Unfortunately for our curiosity (but perhaps fortunately for the continuation of our careers), our understanding of superstring theories is still far too meagre to say definitely what they imply about black-hole evaporation. Bowick *et al.* readily admit this limitation, but investigate what can be said from our present knowledge of superstring theories.

By a thermodynamic analysis of perturbative (linearized) string modes, Bowick *et al.* conclude that it is statistically probable for a black hole to turn into a massive string when it gets sufficiently small. The string itself then decays into ordinary radiation (massless particles). The authors suggest that this allows the black hole to disappear completely (yet without the accompaniment of a naked singularity) because the gravitational field is only part of the superstring field.

This conclusion is eminently reasonable, although it must be admitted that the paper of Bowick *et al.*[6] is hardly a rigorous derivation of the result. Even before superstring theories, one could have postulated that a sufficiently small black hole turns into a suitable spectrum of massive particles without having a classical gravitational field that would lead to a naked singularity. Superstring theories give hints as to how this could conceivably happen, but so far they are just hints.

On the question of whether there is a breakdown of predictability in black-hole evaporation, Bowick *et al.* admit that they do not see how superstring theory will resolve the problem. Indeed, one would need a method for correctly calculating the enormous number of multi-particle correlations between the different black-hole emission modes. Each one of these correlations is likely to be very small and hence individually close to the semiclassical approximation that it is zero, but cumulatively it is conceivable that the correlations could gradually restore to the exterior all the information that enters the hole during its formation and evaporation process. It is still too early to say whether or not superstring theory will show this possibility to be the case. □

Lipocortin residues	287 303	Lys–Gly–Val–Gly–Thr–Arg–His–Lys–Ala–Leu–Ilu–Arg–Ilu–Met–Val–Ser–Arg

In the article by Robert H. Kretsinger and Carl E. Creutz "Consensus in exocytosis" (*Nature News and Views* 17 April, page 573), two of the amino-acid residues that should have been included in the figure were omitted. The correct figure is shown above.

Steroid receptors

Oncogenes as hormone receptors

from J. Michael Bishop

THE district of Hades most feared by scientists is that ignominious corner called neglect[1]. This is the fate that until recently threatened v-*erb*-A, an oncogene with modest biological effect and no known function. Now however, with the discovery of structural kinship between the v*erb*-A gene and the genes encoding the receptors for steroid hormones[2-4], the oncogene assumes its rightful place among a family of genes whose actions help to orchestrate the specialization of cellular function that typifies metazoan organisms.

Like other retroviral oncogenes, v-*erb*-A arose by transduction of a cellular proto-oncogene (c-*erb*-A)[5]. But v-*erb*-A is unusual in that it shares the genome of the avian erythroblastosis virus (AEV) with another oncogene, the more prominent v-*erb*-B, transduced from the gene that encodes the cell surface receptor for epidermal growth factor[6]. AEV causes erythroleukaemia in chickens and transforms haemopoietic cells of the erythroid lineage in cell culture[7]. The principal responsibility for neoplastic transformation by AEV rests with v-*erb*-B[8,9], whose action impedes the maturation of erythroid precursor cells[7,10]. But when v-*erb*-B acts alone, the transformed cells tend to escape the blockade and mature spontaneously[8]. The leukaemia is consequently sluggish. The cooperative action of v-*erb*-A tightens the leukaemogenic grip on the cell: spontaneous maturation becomes rare, and the leukaemia becomes correspondingly more aggresive.

What is the mechanism of this effect? Our only clues come from the structure of v-*erb*-A. The deduced amino-acid sequence of the v-*erb*-A product reveals a frail resemblance to the enzyme carbonic anhydrase[11]. We still do not know what — if anything — that resemblance signifies; but in the face of what else has now emerged, neglect may be its fate. Our story leads instead, and unexpectedly, to steroid hormones.

The structures of steroid hormones are too simple to embody much information. The cellular receptors for the hormones must therefore serve as molecular adaptors to mount a signal of considerable complexity[12]. Steroids apparently enter cells by diffusion through the plasma membrane and then combine with specific receptor proteins inside the cell. The binding of ligand 'arms' the receptor so that it in turn binds with increased affinity to select sites in cellular DNA — sites that are thought to be enhancers of transcription whose activity requires the hormone–receptor complex. By these means a steroid hormone can induce the expression of a substantial battery of genes.

Each step in this remarkable sequence is clouded by controversy. But matters should soon become clearer because we now have molecular clones and amino-acid sequences for the glucocorticoid receptors of humans[13], mice (G. Ringold, personal communication) and rats (K. Yamamoto, personal communication) and for the oestrogen receptors of humans[3,4] and of chickens[14]. What these results make clear, first and foremost, is that all of the receptors named — and the product of v-*erb*-A for good measure — share an ancient progenitor. The structural similarities that this kinship engenders permit some powerful arguments by analogy.

There are in the receptors several domains whose conservation or other features bespeak important contributions to function. The first of these comprises approximately the amino-terminal half of the receptor molecules. Two functions have been attributed to this domain[12]: it may mediate the effect of the receptor on gene expression by interacting with the enzymatic apparatus for transcription; and it is reputed to exert allosteric influence over the remainder of the receptor. This region of the glucocorticoid receptor also commands attention because it carries prominent antigenic determinants[12,15], and because it contains two short stretches of very limited homology with proteins encoded by the homoeotic genes of the fruitfly *Drosophila melanogaster*[2]. These homologies are not found in the oestrogen receptors and involve no more than six identities among amino-acid residues, so it is a tribute to the communal esteem for homoeotic genes that the homologies are given any mention at all — either here or in the original publication.

The second recognizable domain of the receptors resides near the middle of the proteins, is the most intensely conserved and harbours the site that binds DNA (refs 2–4; K. Yamamoto, personal communication). The third domain includes the carboxy ends of the receptors and extends a still-uncertain distance upstream. That this portion of the receptor binds hormone has been suspected for some time and has now been substantiated in two ways. First, two versions of the glucocorticoid receptor have been found that may arise from alternative splicing (or experimental artefact)[13]. They differ only by short substitutions of amino-acid sequence at their carboxy termini. One version binds glucocorticoids, the other does not. The drastic effect of this small difference in structure, and the means by which similar domains of protein are nevertheless able to distinguish between glucocorticoids and oestrogens pose marvellous puzzles for the crystallographer. Second, mutations have been fashioned in the putative hormone-binding region of both the oestrogen and the glucocorticoid receptors: the fabricated mutants do not bind hormone (ref.14; K. Yamamoto, personal communication).

All of the domains within a receptor molecule may therefore have discrete functions, but they constitute a cascade, and each component may contribute to specificity in the action of steroid hormones: the ligand-binding domain is a trigger that can be thrown only by the correct hormone; the DNA-binding domain recognizes specific nucleotide sequences, whose elements of consensus are beginning to emerge[12]; and the amino-terminal half of the receptor may selectively interact with the transcriptional machinery. Cooperative division of labour of this sort within protein molecules has been elucidated in great detail with examples from bacteria and yeast.

The topographies of steroid receptors again evoke the popular scheme in which complex genes are said to have been cobbled together by genetic recombination, recruiting constituent domains from diverse parts of the evolving genome. The most adventuresome proposal is that the hormone-binding domains arose from primitive enzymes once devoted to the metabolism of steroids[12].

Whatever the origins of steroid receptors, they are apparently similar to those of the protein encoded by v-*erb*-A, which is now seen to contain domains analogous to those that in the receptors bind DNA and hormone[2-4,14]. There is, however, no analogue in the v-*erb*-A protein for the amino-terminal half of the receptors. Instead, v-*erb*-A is fused to a portion of the viral gene *gag* that encodes virion proteins[7]. The topography of c-*erb*-A, from which the viral gene is transduced, has yet to be described. Presumably a

region that encodes an amino-terminal component has been shorn from c-*erb*-A in the course of transduction from the gene that gave rise to v-*erb*-A. So far, there is no hint as to what the ligand for the truncated v-*erb*-A protein may be — if one indeed exists.

But the analogies we do have bring the product of v-*erb*-A into a new light: until now there was nothing to suggest that this protein might interact with nucleic acid; or that it might be activated by natural ligand; or that it might spend part of its functional life-span in the nucleus. This last point raises a question still vigorously debated by students of steroid receptors. It was once thought that the receptors in their inactive form loiter in the cytoplasm, entering the nucleus only after activation by the binding of ligand; more recent evidence places the receptors in the nucleus even in the absence of hormone[16,17]. In either case, the subcellular location of the v-*erb*-A protein — until now thought to be the cytoplasm — deserves careful reappraisal.

What do these new findings suggest about the mechanism by which v-*erb*-A contributes to neoplastic transformation? Perhaps the simplest hypthesis is that v-*erb*-A is a transcriptional regulator run amok — a dangerously constitutive version of c-*erb*-A[2,18]. This hypothesis ignores the possibility that the v-*erb*-A protein may lack a structural domain required for enhancement of transcription. Moreover, there are two forms of mutant glucocorticoid receptors whose properties suggest other mechanisms[12]. The first of these mutant receptors binds ligand and DNA, yet fails to muster any physiological response. These 'increased nuclear transfer' or nt^i mutants (the designation reflects increased affinity of the mutant receptors for the nucleus) bear a striking resemblance to the protein encoded by v-*erb*-A: both contain only the carboxy-terminal half of the archetypal receptor molecule, including the regions that are thought to bind hormone and DNA. For the moment, we can only speculate that v-*erb*-A has structural and functional defects similar to those of the nt^i mutants. But were that speculation correct, the v-*erb*-A protein might occupy sites on DNA in a sterile manner, competing with the product of c-*erb*-A and preventing the activation of genes that would otherwise come into play during erythroid differentiation. The hypothesis demands that c-*erb*-A play a part in erythroid differentiation and that v-*erb*-A be expressed in substantial excess of c-*erb*-A; both are reasonable possibilities, but neither has yet been tested experimentally.

The second pertinent form of mutant receptor (nt^-) binds glucocorticoid, but not DNA. An nt^- mutant has now been sequenced, to reveal (among other abnormalities) substitution of glycine for glutamic acid at a position that might account for the defect in DNA binding (G. Ringold, personal communication). The v-*erb*-A protein has glycine at the analogous position. If the protein were similarly unable to bind DNA, it might represent an inactive 'sump' that could compete with the product of c-*erb*-A for ligand. The physiological effect would be the same as that envisioned for the nt^i mutants: a sufficient excess of the v-*erb*-A protein would nullify the action of c-*erb*-A.

I have previously argued[19] that it may be fallacious to deduce the physiological functions of proto-oncogenes from the properties of their progeny oncogenes. The present instance may be an exception. If the product of v-*erb*-A does indeed act by nullifying the action of c-*erb*-A, then the genes and cells that v-*erb*-A affects are salient clues to the function of c-*erb*-A — clues that moreover deserve the attention of anyone who is interested in normal erythropoiesis.

So once again the study of tumour viruses has conjoined with other disciplines to enrich our knowledge of cell biology, and the obscure v-*erb*-A (or more accurately, its cellular counterpart c-*erb*-A) has acquired new lustre by its accession to a gene family whose members contribute mightily to homeostasis. As one oncogene after another is equated to a previously known determinant of normal cellular phenotype, a brash question comes to mind. Might all the major devices that control the growth of vertebrate cells already be in view? Prudence forbids an answer. □

Animal locomotion

Three kinds of flying in animals

from R. McNeill Alexander

JEREMY Rayner and his colleagues report in this issue (*Nature* **321**, 162; 1986) their work on bats that are trained to fly through clouds of helium-filled soap bubbles. These bubbles have the same density as air, so their images in multiple-flash photographs show how the air is set in motion as the bat passes through. As wings generate forces by giving momentum to the air the new results give information about the forces on the wings and allow comparison with the flight of birds.

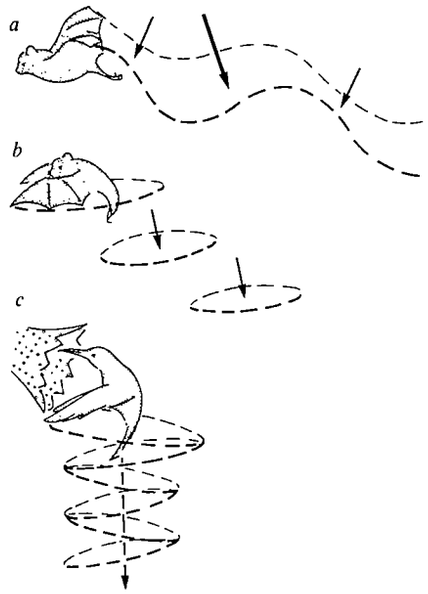

Fig. 1 Diagrams of air movements produced by *a*, kestrels and bats flying fast; *b*, pigeons and bats flying slowly and *c*, hummingbirds hovering. The broken lines represent vortices and the arrows show directions of air movements.

The experiment had been done previously with birds and gave two kinds of result (Spedding, G.R. thesis, Univ. Bristol; 1982). Pigeons produced a downward puff of air in each downstroke, and little air movement in the upstroke. Thus the downstroke produced the force that supported the animal's weight, and the upstroke was passive. Kestrels, which flew faster in the conditions of the experiment, produced downward airflow during the upstroke as well as the down-stroke. Now it has been shown that Noctule bats use both techniques. In slow flight, only the downstroke is active, but at higher speeds both strokes are active. It seems likely that the two techniques are characteristic of slow and fast flight of birds and bats generally. They can be thought of as gaits, the aerial equivalents of walking and running.

Puffs or jets moving through stationary air set up vortices. Smoke rings consist of smoke trapped in the vortex around a puff of air. Vapour trails behind the wing tips of aircraft also mark vortices: the air between the two trails is moving downwards. The two flying gaits of birds and bats produce distinctive patterns of vortices, which were made visible in the experiments of Rayner *et al.* by the helium bubbles. The fast gait produces a pattern like the vapour trails of aircraft, with an important difference. The wing tips are brought closer to the body in the upstroke than in the downstroke, so the vortices undulate in and out instead of remaining parallel (Fig. 1*a*). The slow gait produces a series of vortex rings, one for each downstroke (Fig. 1*b*).

Both aircraft and flying animals need

forces to support their weight and to drive them forward through the air. Aircraft get support from their wings and thrust from their engines, but birds and bats get both from their wings, by flapping them. These mechanisms can help us to understand the difference between the gaits.

Air is driven roughly at right angles to the path of the wing through it. The downstroke drives air downwards and backwards, providing weight support and thrust. The upstroke of fast flight (Fig. 1*a*) drives downwards and forwards, tending to cancel out the thrust of the downstroke. To prevent this, the forces produced by the upstroke must be reduced, either by reducing the wingspan so that less air is moved by the wings, or by weakening the vortices so that the air is driven less fast. (This can be done by adjusting the angle of incidence of the wings.) Rayner has argued (*Biona Rep.* **5**, 27; 1986) that it is most economical to reduce wing span and keep vortex strength (circulation) constant as kestrels and bats seem to do.

Figure 1*c* shows a possibility for hovering and very slow flight, when the wings can be flapped so as to move backwards (relative to the air) in the upstroke. Circulation may be reversed at the end of each stroke so that the wake is a series of linked vortex rings, a ring for each downstroke and one for each upstroke. Hummingbirds seem to do this, but the vortices have not been demonstrated. Many insects apparently are able to do the same (Ellington, C.P. *Phil. Trans. R. Soc.* **B305**, 1; 1984).

The slow gait (Fig. 1*b*) is intermediate between the other two. Circulation is eliminated but not reversed in the upstroke, so vortices (and useful forces) are produced only in the downstroke. There is scope for an optimization theory that would predict the speed at which the change should be made between the slow and the fast gaits. □

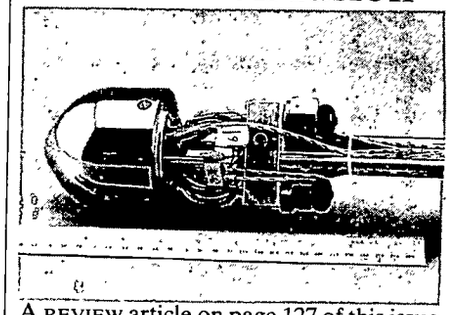
Circadian rhythms

Benzodiazepines set the clock

from A. T. Winfree

THE time will come when a traveller leaving for the airport, having frantically searched for and found his ticket, will still not be ready: it will be necessary to dash to the medicine cabinet to rummage for the inevitably misplaced bottle of jet-lag pills. Elsewhere in this issue (*Nature* **321**, 167; 1986) Fred Turek and Susan Losee-Olsen, in a simple, straightforward experiment with triazolam and hamsters, provide the strongest hint yet that the elusive jet-lag pill is within reach.

Like any other mammal, humans have a persistent strong tendency to regularity in the ups and downs of diverse physiological functions, such as core temperature and the alternation of sleep and waking. The latter regularity has a native circadian periodicity close to 25 hours, and is usually synchronized by the 24-hour alternation of day and night, so it is called the biological clock. The mechanism of this clock seems rooted in the central nervous system, particularly in the suprachiasmatic nucleus of the hypothalamus. A gene whose alleles determine the periodicity of the circadian clock of the fruitfly has recently been sequenced: it appears to be a proteoglycan (Jackson, F.R. *et al. Nature* **320**, 185; 1986).



Little more is known of the mechanism of circadian clocks, but their pharmacological sensitivity has recently provided us with some powerful hints about phase shifts such as those one encounters during east–west travel. Ionophores, brain hormones and neurotransmitter analogues are conspicuous among agents capable of permanently shifting the phase of the clock, much as visible light has long been known to do. Alternating light and darkness is the leisurely agent of synchronization that normally guides plants, invertebrates and mammals (including humans) to a standard phase relationship with the environment after a shift of phase. But gradual entrainment to local time requires exposure to cycle after cycle of the synchronizer; would it not be better if we could abruptly set our internal clocks in advance, much as we set our watches? My own favoured procedure involves exposure to bright sunlight at a carefully planned hour (Daan, S. & Lewy, A.J. *Psychopharm. Bull.* **20**(3), 566; 1984), but this is not necessarily convenient if, for example, it is snowing or it is night-time. Pharmaceutical assistance towards synchronization has long been sought; one need only stand in the aisle of any intercontinental jetliner to hear many superstitions about, for example, coffee, diet, alcohol and sleeping pills.

Turek and Losee-Olsen seem to have found a real effect — that of benzodiazepines — although the results of clinical trials have not yet been reported. Benzodiazepines, used for several years in the management of insomnia and related mental disorders, may act by potentiating the action of the inhibitory neurotransmitter γ-aminobutyric acid, which is known to be present in the suprachiasmatic nucleus. But its impact on circadian rhythms has never before been tested in the standard experimental protocol used by Turek and Losee-Olsen. These authors recorded the activity rhythm of a hamster for two weeks (so that the rhythm could be reliably extrapolated to the following days), then injected the animal intraperitoneally with a dimethyl sulphoxide vehicle at any one of eight equally spaced 'times of day' in its circadian cycle. The rhythm continued as anticipated. But if the vehicle carried a benzodiazepine (2.5 mg of triazolam, equivalent to about 5 times a heavy dose for an adult human) then the timing of subsequent activity was disrupted, causing an immediate phase advance or phase delay of about one hour. The exact amount of the delay depends dramatically and quite reproducibly on the timing of the dose, a dependency unlike that caused by stimulation of the retinohypothalamic pathway for phase-shifting by light. Hence Turek and Losee-Olsen have found a new avenue of entry into the clock mechanism.

The potential practical interest of their results lies in the hope that the same or a related fast-acting, quickly eliminated chemical without conspicuous side-effects may also abruptly reset the circadian clock in humans. If so then we may soon find ourselves carrying pills and a schedule whenever we cross time zones at a pace much in excess of one per day. The schedule will prescribe when and what dose of pills to take to achieve an immediate advance or delay appropriate to the foreseen change of longitude.

The result of Turek and Losee-Olsen raises another intriguing question — in three or four of the eight recordings shown not only is there an abrupt phase shift, but also the periodicity of the clock is substantially altered for at least a week. Yet the

Forward on fusion

A REVIEW article on page 127 of this issue describes experiments that provide new optimism for the possibility of generating power from nuclear fusion. The picture above shows the target capsule used to hold the deuterium-tritium mixtures for muon-catalysed fusion experiments at the Los Alamos Meson Physics Facility in 1984. The target was electrically heated to 800 K and then cooled to 14 K with liquid helium. Up to 150 fusions per muon (average) were observed with this apparatus.

drug, if metabolized as it is in humans, should have been eliminated within several hours. Does this mean that hamsters retain much of the large dose of triazolam, or that the clock mechanism has resettable periodicity as well as resettable phase?

The experiment also raises questions about the unforseen circadian side-effects of medications containing psychotropic compounds. David Earnest and Turek recently demonstrated (*Proc. natn. Acad. Sci. U.S.A.* **82**, 4277; 1985) that cholinergic neurotransmission centrally mediates the effect of light on the circadian clock of the hamster. This might lead one to wonder about over-the-counter 'sleeping pills' that contain belladonna and scopolamine: do they also have an impact on circadian coordination? □

Geophysics

Is there coherence between Earth tides and earthquakes?

from Paul W. Burton

Do tides in the Earth cause earthquakes? Are some types of earthquakes or regions of the Earth more susceptible to earthquakes triggered by tides than others? And is this relevant to the prediction of earthquakes? There has not yet been much success in answering these questions, although the thorough studies of T.H. Heaton[1,2] did demonstrate that some types of shallow earthquakes that have magnitudes greater than 3 are more easily triggered than are smaller events. But his later, more rigorous approach did not confirm his earlier hypothesis — much seems to be ambiguous or inextricably tangled in this subject. A. Palumbo is now trying to provide answers to some of the questions[3]. He finds that earthquakes most likely to be triggered by tides are those with magnitudes higher than 5 and that shallow earthquakes and their foreshocks in the Appennine Mountains are significantly more frequent when stretching in the crust caused by tides in the Earth is at a maximum.

Under consideration are stresses or tides in the solid Earth caused by the action of the Sun or the Moon on the deformable Earth. (Tides in the ocean and in the atmosphere are caused by the same actions but in more mobile and fluid media.) Stress and strain changes in the Earth caused by the varying proximity of the Sun and the Moon are accompanied by variations in the acceleration caused by gravity, g, at the surface of the Earth. Thus, g is not constant at 9.81 m s^{-2} but fluctuates both daily and over longer periods. This may be visualized simply (see figure) as deformation of the Earth's surface, and can amount to a semi-diurnal movement of the ground of as much as 0.1 m up or down. These motions are damped by friction in the Earth and so maximum strain lags behind the response expected in a totally elastic Earth; some parts of the Earth being stretched while others are compressed. Compression is maximum with the Moon or Sun on the horizon (morning earthquakes?), and some earthquake fault systems may be susceptible to compressional perturbations. Tensional regimes across fault zones may be susceptible when the Moon or Sun are overhead (midday earthquakes?).

Earth tides caused by lunar action. *a*, Without friction, Earth strain would cause an upward motion of the ground along a line joining the centres of the Earth and the Moon. With the Moon on the horizon the strain would cause a downward and inward motion of the ground. *b*, With friction, the tidal bulge in the Earth is carried forward by rotation of the Earth causing a phase delay with respect to the action of the Moon on the Earth. These small periodic strains may perturb strain energy stored in the Earth and trigger release of that energy as an earthquake. (Adapted from ref. 6.)

When the Earth acts gravitationally on the Moon (a larger body acting on a smaller body), it is an acceptable interpretation that tidal effects trigger moonquakes. The reverse situation, when the Moon acts gravitationally on the Earth, is riddled with complexity and ambiguity: for example, the perturbations to strain are not so large; the Earth has mobile oceans and an atmosphere which varies the surface loading; and earthquake catalogues are rarely homogeneous and complete. When many globally distributed earthquakes are considered no significant effect is discernible — presumably any effect is blurred by a multiplicity of unidentified fault orientations and stress regimes. Palumbo has deliberately isolated a relatively small region of the Earth, in Italy, and, largely rejecting Fourier spectral analysis, used the Chapman–Miller method to detect lunar daily variations (for an up-to-date account of the method with minimum mathematics, see ref. 4). Palumbo's results are clearer than his discussion and analysis: no tidal term is discernible in the Alpine or southern Calabrian areas but there is a lunar tidal term for major earthquakes and related foreshocks in the Appennines. He suggests that the tidal terms in the frequency of earthquakes are linked with extensional tidal stresses in the east–west direction.

Although hardly being on the level of prognostication associated with a 'Jupiter' effect, this suggestion is fascinating in relation to Appennine earthquakes. It will be interesting to see if the resolution of coherency achieved by Palumbo will improve when seismic moment tensor solutions (giving a full description of seismic fault orientations and slip vectors) for earthquakes in the Appennines can be combined with local tidal strain tensors.

Palumbo certainly seems to have identified one geographical region where tidal variations in the frequency of earthquakes are discernible despite the inevitable problems obscuring potential coherency between Earth tides and earthquakes. The relevance to earthquake prediction is another matter. Although much is known about Earth tides[5] and global and local seismicity, coherency between the two is usually within the noise of any analysis; certainly earthquake disasters do not show the sort of semi-diurnal or diurnal variation which would prompt an actuary to take cover at dawn or dusk.

The problem remains largely unresolved and confused from a statistical viewpoint. But instruments used to measure Earth tides and strain changes will also be sensitive to the volume increases that are thought to accompany changes in rocks before brittle failure. Here there may be a practical link between the two sciences; otherwise coherency between tides and earthquakes appears highly localized, where it merits further study, but elsewhere, given the present state of knowledge and the resolution of this coherency, these studies appear to be rather an esoteric pursuit. □

Immunology

Development and modification of the lymphocyte repertoire

from Malcolm Gefter and Philippa Marrack

ALTHOUGH recent advances in the understanding of the genes encoding the antigen receptors of T and B lymphocytes have allowed new approaches to some of the traditional problems of immunology, they have not, as quickly became apparent at a recent meeting*, yet provided much in the way of answers. The question addressed at the meeting was that of what determines which particular T- and B-cell receptors from the extraordinarily large potential repertoire will actually be represented in the repertoire of a given animal. Some of the most lively discussion, however, (which the meeting was organized to maximize) concerned genes that are not yet known to contribute to the receptor repertoire at all.

Holes in the idiotype net

One of the most elegant attempts to explain the mechanisms underlying the control of antibody and effector T-cell production was devised some fifteen years ago by Niels Jerne. He argued that what limits and modifies the receptor repertoire is the existence of interactions — which can be either stimulatory or inhibitory — between cells recognizing antigenic determinants called idiotypes on the antigen receptors of other cells of the immune system. Thus, for example, anti-idiotype antibodies may be able to recognize antibodies produced by B cells and the antigen receptors of T cells, and may stimulate or suppress the proliferation of the cells that bear them. This results in an interacting network of cells and products (the idiotypic network) that influences the available repertoire before the organism is ever exposed to environmental antigen.

Although evidence in support of the theory has since accumulated, proof has been difficult to obtain, partly because the theory, although elegant and provocative, is not specific enough to allow definitive experiments to be done. With the introduction of molecular biology into immunology, it has become possible to define both the potential repertoire and the available repertoire. Moreover, much has been learned about the mechanisms whereby the receptor repertoire is expressed.

Above all, it is now known that both antibodies and T-cell receptors for antigen are encoded by genes that are assembled by somatic recombination from separate gene segments drawn from gene pools which for some of the segments (the 'variable', or V, segments in particular) is very large and diverse. Directly or indirectly, an understanding of the molecular mechanisms by which the repertoire is generated may provide alternative explanations for some of the phenomena attributed to the operations of the network.

This applies, for example, to the recent discoveries made by Robert Kleinfeld from Martin Weigert's laboratory (University of Pennsylvania) and Michael Reth (University of Cologne). These two groups demonstrated that the genes encoding the variable region of the heavy chain of antibodies (the V_H gene segments) can undergo secondary intrachromosomal recombinations resulting in the expression of a new variable region, and thus a new recognition specificity, in an apparently already committed B cell. The mechanism of the recombination event is believed to be related to that of the normal mechanism of immunoglobulin-gene rearrangement, which depends on a conserved heptamer sequence; the site of the inter-V_H recombination appears to be a conserved heptamer within the coding region of the V_H genes. But to date, somatic inter-V_H recombination has only been seen in two B-cell lines, and it remains to be determined how general this observation will be.

Secondary recombination between V_H segments may help to explain an apparent paradox in B-cell repertoire expression: namely, that during fetal life it seems that the joining (J_H)-proximal V_H genes are preferentially rearranged (G. Yancopoulos, Columbia University), but by adulthood, all V_H segments appear to be relatively equally expressed. Perhaps the genes that undergo rearrangement early are substrates for further recombination events, the results of which shape the adult immunoglobulin repertoire.

This in turn might provide an explanation for the phenomenon of idiotype dominance — in which in certain mouse strains most of the antibodies produced in response to a particular determinant carry a specific idiotype. This phenomenon has been explained by network theorists as the consequence of amplification by anti-idiotypic interactions. For example, in the case of the T15 idiotype associated with the response of some mouse strains to phosphoryl choline, John Kearney (University of Alabama, Birmingham) provided convincing evidence for the operation of regulatory events involving cascades of anti-idiotypic antibodies. (Unexpectedly, this could only be demonstrated when antibodies were administered *in utero*: in the classical network experiments, anti-idiotypic antibodies administered in adults will affect the repertoire.) Norman Klinman (Scripps Clinic Research Foundation) however suggested that the dominant idiotype phenomenon might be explained just as well by preferential gene rearrangement to the V_H gene responsible for the T15 idiotype.

It is possible that similar phenomena can also account for the provocative observations reported by Tereza Imanishi-Kari (Massachusetts Institute of Technology) on transgenic mice harbouring an immunoglobulin heavy-chain gene bearing the idiotype associated with the response to nitrophenol (NP). B cells in such mice spontaneously express antibodies bearing the idiotype carried by the product of the introduced gene — but these antibodies are not encoded by the introduced gene. Moreover, this pattern of idiotype expression can be transferred to other mice by inoculation with T cells from the transgenic animals. On the face of it, this is strong support for an idiotype network in which the major perturbation consequent on the introduction of the transgene is reflected in a skewing of the repertoire by regulatory T cells that are part of the net and have themselves been elicited by the (presumed) overabundance of the idiotype encoded by the transgene early in ontogeny.

In the lively discussion that followed this presentation, participants at the meeting suggested that preferential V_H rearrangement might explain these results as well; clearly direct evidence on this, and further data from other transgenic mice, are needed.

In the meantime, other recent experiments suggest that antigen alone could account for the selection of a skewed repertoire. In most immune responses, the antibodies produced are very heterogeneous and diverse, and no two animals will be the same. But the response to some antigens seems to draw selectively on a very limited set of V regions which may be identified as the basis of the dominant idiotype. This initial selection is followed by somatic mutation of the V regions. Experiments designed to analyse the responses to the ars idiotype (Malcolm Gefter, MIT), the NP idiotype (Klaus Rajewsky, Cologne) and the Ox-1 idiotype (K. Berek, University of Cambridge) suggest that selection by antigen may be sufficient explanation for their dominance, as in all cases so far the somatic mutations increase the affinity of the antibodies for antigen. The acceptance of non-Jernian explanations for idiotypic phenomena however will undoubtedly require more time.

The most elegant postulate of the net-

* The winter workshop on T- and B-repertoire development, organized by Eli Sercarz and Alex Miller, was held at Lake Tahoe on 22-25 January 1986.

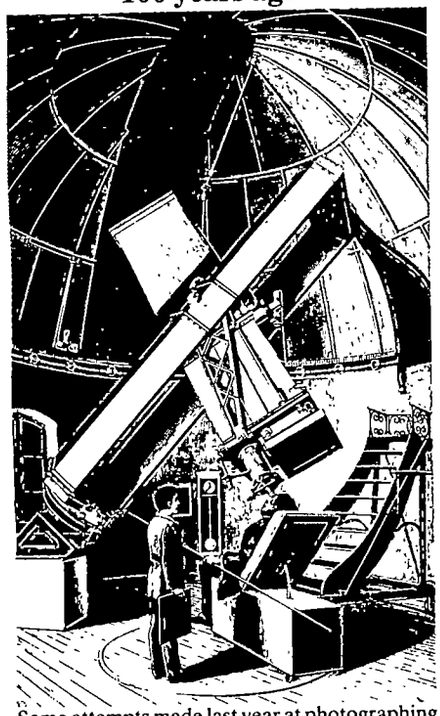
work theory — that idiotypes shared between T and B cells result from a shared genetic pool of *V* segments for B- and T-cell receptors for antigen — has already been excluded by molecular biology. How the cloning of the receptor genes has advanced the understanding of the T-cell receptor repertoire was the other main topic of the meeting.

T-cell receptor

Unlike B cells, T cells are able to respond to antigen only when it is presented to them in association with a cell-surface protein, a product of the major histocompatibility complex (MHC) of the animal in question, a phenomenon called MHC restriction. There has been much debate concerning whether such a feat requires one receptor or two, the bulk of the evidence strongly suggesting that a single T-cell receptor, made up of an α/β heterodimer, is sufficient (see Robertson, M. *Nature News and Views* **317**, 768; 1985). M. Steinmetz (Basel) presented further evidence from transfection experiments to support this point of view (Dembic, Z. *et al. Nature* **320**, 232; 1986). He and his collaborators have used α- and β-chain genes from a cytotoxic T cell specific for the hapten, fluorescein (FL) in association with the MHC product D^d, to transfect a T cell specific for a different hapten and MHC product and with this transferred the specificity for FL/D^d of the donor. This supports the earlier evidence that no clone-specific, variable molecule besides α and β contributes to the specificity of these cells.

The precise contribution of the α- and β-chains to the recognition of MHC and antigen, however, remains unclear. Several investigators reported the results of sequencing α- and β-chain genes from collections of T cells with related specificities for antigen and MHC, in the hope of discovering some correlation between the sequences and the specificities. S. Hedrick (University of California at San Diego) and A. Winoto (California Institute of Technology), for example, had used T-cell clones specific for a pigeon cytochrome C peptide, and with well-defined MHC reactivities (Fink, P.J., Matis, L.A., McElligott, D.C., Bookman, M. & Hedrick, S.M. *Nature* in the press). But although there were suggestions of some correlation between antigen specificity and a region of the β chain around the diversity (D) region (Fink, P.J. *et al.* and Winoto, A.), or the J region (A. Iwamoto, Toronto), J_β regions may also contact MHC (Iwamoto; K. Eichmann, Freiburg), so no general rules are yet apparent.

Gamma revisited



Such experiments still leave unresolved one of the major current T-cell mysteries; the problem of the role of γ chains. About eighteen months ago, Susumu Tonegawa and his colleagues at MIT reported the existence of a T-cell receptor-like complementary (c) DNA clone, the genes for which rearrange and are expressed only in T cells. Because the sequence and glycosylation patterns of the polypeptide predicted from the cDNA sequence did not match known α- or β-chain properties, the predicted protein has been named γ; it has yet to be identified as an entity. Much is known from cDNA and genomic sequences, however. Gamma products, which were at first though to be relatively invariant, are becoming more variable: T. Mak (University of Toronto) and D. Raulet (MIT) respectively, described a new constant (*C*) region and three new *V*-region genes in this complex, bringing the total number of known γ-chain genes in most mouse strains to four *C* regions (three of which cross-hybridize), each with a *J*, and six *V* regions (three of which cross-hybridize with each other). As in the mouse immunoglobulin λ locus, each *V* seems to rearrange to a particular *J–C* pair. Some *V* and *J* segments seem to be intrinsically non-functional.

The additional variability in the gene family implies that the product may play some part in specific recognition, and it has been suggested that it is essential for the function of mature cytotoxic T cells, the cells with which it was originally associated by Tonegawa, because of higher messenger (m) RNA expression in these cells than in helper-T cells. This possibility seems to be excluded, however, not only by the experiment of Steinmetz's group, but also because most rearranged γ-chain genes in peripheral T cells are non-functional, often because they contain termination codons consequent on out-of-frame joining of *V* to *J* regions. E. Reilly, from H. Eisen's group at MIT (Reilly, E.B. *et al. Nature* in the press), for example, has sequenced 11 different cDNA clones from three cytotoxic T-cell clones and found all to be non-functional, and similar examples are available from other laboratories.

The more recently discovered non-cross-hybridizing C_γ genes and the three new non-cross-hybridizing V_γ genes leave open the possibility that the functional γ-chain cDNA in these peripheral T cells has yet to be sequenced. Alternatively, functionally rearranged γ-chain genes may be present at an early stage in the history of the T cell and be lost before maturity. In support of this notion, Raulet (MIT) showed that rearrangement and mRNA involving two particular γ-chain *V* regions gradually disappear from thymocytes and peripheral T cells as the animal ages. He suggested that these *V* regions lie downstream (3′) of a third *V* region. A functional rearrangement to one of the 3′ regions could be deleted during maturation by the subsequent rearrangement of an upstream *V* by a mechanism similar to that described above for V_H genes.

If γ chains do play a part at a particular stage in the life of T cells, when is this likely to be? The γ mRNA is expressed at high levels in early fetal thymocytes illustrated at this meeting by the work of R. Snodgrass (Basel) and D. Pardoll (National Institutes of Health, NIH). It is not clear that these high levels of mRNA imply that there will be high levels of protein, however, because γ-chain rearrangements are rare in hybridomas prepared from early fetal thymocytes (W. Born, Denver) and not universal in adult 'early' thymocytes (M. Davis, Stanford University). Moreover, much of the fetal thymocyte mRNA, as in mature T cells, turns out on sequencing to contain frameshifts making it non-functional (Snodgrass). The cDNA may be overrepresented in non-functional transcripts, as Raulet reported that five out of six rearranged genomic DNA γ clones prepared from day 17 mouse fetal thymuses turned out to have open reading frames. The implications of all this, that γ proteins may be used only in small numbers for a short time during thymocyte development, and that the protein may down-regulate gene expression, are very intriguing in the light

100 years ago

Some attempts made last year at photographing the heavens by means of an instrument quite rudimentary having yielded good results, the director of the Paris Observatory gave orders for the construction of a special apparatus, the design of which is shown in the figure. This new instrument is composed of two telescopes in juxtaposition inclosed in a single metallic tube in the form of a parallelopiped, and separated from each other along their whole length by a narrow partition.

From *Nature* **34**, 34; 13 May 1886.

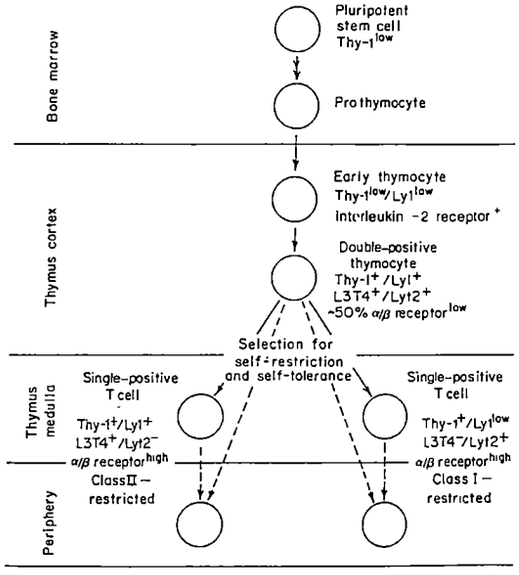
of a role for the putative γ chain suggested by Tonegawa and Raulet.

These authors hypothesized that the γ protein is important in one of the two critical events in the control of T-cell repertoire which occur in the thymus: the selection of cells bearing receptors that recognize antigen preferentially in association with MHC products expressed in that thymus (the phenomenon of self-restriction); and in the imposition on thymocytes of tolerance to self-MHC proteins themselves. Raulet and Tonegawa propose that immature thymocytes express receptors composed of β-and γ-chains, and that those recognizing self-MHC on thymus cells are selected. Later the γ chain is replaced by the α chain of mature T cells and the affinity of the receptor for self MHC thereby eliminated except in the presence of antigen.

The feeling at the meeting was that this theory is rather unlikely to be correct, at least in its baldest form. For example, there is no evidence in the structure/function experiments described by Hedrick, Winoto, Iwamoto, Eichmann and others (see above) that a particular β chain would predictably impose specificity for a particular MHC product on receptors in which it was first combined with one chain, γ, and then with a completely unrelated polypeptide, α. But although the theory is probably not completely correct, the data dealing with expression are becoming increasingly intriguing, and they do indicate the direction which future investigations will probably take.

Events in the thymus

Further elucidation of the events of thymic maturation will depend on the definition of the pathways of thymocyte differentiation, and these were therefore the focus of considerable interest at the meeting. The thymus contains several cell populations that have been well defined phenotypically but whose exact lineage relationships are only now becoming clear. A minimal outline of these populations and their relationships is shown in the figure.



There was general agreement that thymocytes become tolerant to MHC antigens expressed by bone marrow-derived cells (probably dendritic cells) and perhaps also epithelial cells in the thymus (R. Jordan, Newcastle University; E. Jenkinson, Birmingham University; J. Sprent, Scripps Clinic) and that they learn to recognize antigen in association with MHC molecules expressed by thymic epithelial cells (Sprent), although the experiments of D. Longo (NIH) stand in direct contradiction to this. If self-restriction is controlled by cortical epithelial cells, then receptors on cortical thymocytes must be involved in the process. One should therefore be able to learn something about this process, or perhaps tolerance induction (although the site where this occurs is less well understood), by examining receptors on cortical cells.

Complexes of cortical thymocytes and other thymus cells have been isolated by several investigators. For example, a recent paper by A. Farr (University of Washington) (Farr, A. *et al. Cell* **43**, 543; 1985) demonstrated by electron microscopy that cortical thymocytes bind epithelial cells, and that the α/β receptor is 'capped' on that part of the thymocyte surface which is in contact with the epithelial cells. This suggests that the receptor is binding some ligand, perhaps an MHC molecule, on the epithelial cell and that the process of self-restriction or tolerance induction can be seen in the micrographs.

At the meeting, A. Kruisbeek (NIH) reminded us of her past experiments showing that anti-Ia antibodies blocked the appearance of mature, L3T4$^+$, class II-restricted thymocytes, but had no effect on immature 'double-positive' cells, or on Lyt2$^+$ mature thymocytes (see figure). In analogous experiments, Born showed that anti-receptor antibodies also have no effect on double-positive thymocytes (although a portion of them bears receptors) but block completely the appearance of mature cells bearing receptors with which the antibody could react. Taken together, these experiments suggest that an important event involving thymocyte receptors and MHC occurs when immature double-positive cells turn into mature thymocytes and T cells. These are the first indications of the stage of thymocyte development at which self-restriction or tolerance is induced.

Jonathan Sprent summarized what is perhaps the consensus view on thymocyte maturation. Precursor cells enter the thymus, proliferate and rearrange and express their T-cell receptor and receptor-like genes α, β and γ. These cells also become double-positive L3T4$^+$ and Lyt2$^+$. From these cells a few are selected, by interaction of their receptors or γ-chain products with MHC products on epithelial cells, to become mature, single-positive cells. At some stage, cells that react with self-MHC, perhaps on dendritic cells at the cortico–medullary junction, are eliminated and fully mature selected cells are allowed to enter the periphery.

The participants left the meeting as they had come, with the feeling that many useful reagents and methods had become available for the study of lymphocyte repertoire, and with the hope and expectation that these new tools would clarify rather than confuse the situation. □

Thymocyte development. Like all haematopoietic cells in adult animals, thymocytes arise from bone marrow precursors. At the meeting C. Muller-Seiburg and G. Spangrude (Stanford University) showed that the so-called primordial stem cell in bone marrow bears low levels of Thy 1. After colonization, the earliest cells found in the thymus bear little Ly1 and are positive for neither of the surface molecules that characterize mature helper or cytotoxic T cells, L3T4 or Lyt2 (T4 or T8 in man). These cells, which can repopulate an irradiated thymus, are not self-renewing, but give rise to all thymocytes sequentially, being replaced themselves eventually by new precursors from the bone marrow (B.J. Fowlkes, NIH; B. Mathieson, Frederick Cancer Research Facility; F. Jotereau, Nantes). In elegant reconstitutions of thymus organ cultures, E. Jenkinson (Birmingham) showed that a single precursor cell could give rise to all types of thymocytes. Receptors for interleukin-2 on these cells may be important in the generation of later stage thymocytes, particularly the mature L3T4$^+$ or Lyt2$^+$ cells (A. Kruisbeek, NIH).

Later stage cells include L3T4$^+$; Lyt2$^+$ blasts and non-dividing cells; and cells bearing only L3T4 or Lyt2 (like peripheral T cells). There has been considerable argument about the pathways that lead to each of these cell types. Some have suggested that the L3T4$^+$, Lyt2$^+$ double-positive population which comprises the bulk of thymocytes is a compulsory intermediate between the double-negative precursor and single-positive mature cell. Others believe that double-positive cells are all destined to die in the thymus. Mathieson presented at the meeting the first direct evidence for the existence of the former pathway. She selected Lyt2-bearing blast cells composed mostly of double-positive cells, and showed that after intrathymic injection, they could give rise only to cells bearing L3T4.

First isolation of HTLV-III

SIR—We wish to address several points raised in a recent commentary in *Nature*[1] regarding HTLV-III/LAV (human T-lymphotropic virus type III/lymphadenopathy-associated virus), the aetiological agent of acquired immune deficiency syndrome (AIDS). It was mentiond that the CEM cell line infected with HTLV-III/LAV may be a better source of antigen for testing HTLV-III/LAV in patients with AIDS and AIDS-related complex (ARC).

The transmission of HTLV-III isolates in several T4⁺ permanent cell lines, including CCRF-CEM, was reported first by our laboratory[2-4]. The transmission of HTLV-III isolates into those T4⁺ cell lines, including CEM, was the subject of a patent application made in early 1984 and now pending.

The fact that we had in our possession electron microscopic pictures of transiently transmitted LAV in Hut-78 and Ti7.4 cell lines should not be surprising. The LAV sample was obtained as a tissue culture supernatant from Dr Montagnier with the express understanding that it could be used for biomedical, biological and molecular biological studies. In accordance with this understanding, we had transiently transmitted LAV into the Hut-78 and Ti7.4 cell lines. Prior to the development of specific reagents for the detection of HTLV-III, the presence of retroviruses other than HTLV-I and HTLV-II could be detected in cultures from AIDS or ARC patients only by reverse transcriptase assay and electron microscopic examination.

Table 1 Summary of the chronological isolation of HTLV-III from patients with AIDS and ARC

No.	Patient samples	Date rec'd	Source	RT	EM	Immunological reactivities HTLV-I p19	HTLV-I p24	AIDS sera	HTLV-III p19	HTLV-III p24

Abbreviations used: G.W., C.C., M.A., etc., patients' initials; RT, reverse transcriptase; EM, electron microscopy; ND, not done.
*Patient C.C. was infected with both HTLV-III and HTLV-I.

At the time we obtained LAV it was the contention of several experts on virus morphology that the particles shown in the electron micrograph published in *Science*[5] by Barre-Sinoussi *et al.* was an arena virus. Naturally we wanted to check the material received from Dr Montagnier by electron microscopy to check this contention. Before receipt of LAV, we had detected reverse transcriptase activity in a number of cultures from AIDS and ARC patients which showed no cross-reaction with HTLV-I or HTLV-II reagents, thus indicating the presence of a new retrovirus. In a number of cases electron microscopic examination showed the presence of virus particles with a cylindrical core, characteristic of HTLV-III (Table 1, Fig. 1). A chronological identification of some of these virus particles from cultures obtained from AIDS and ARC patients by our laboratory beginning in December 1982 is summarized in Table 1 and Fig. 1.

The experimental results shown were obtained shortly after receipt of the samples, usually a matter of weeks. We had evidence for the presence of a new retrovirus in AIDS and ARC patients long before the LAV particles were sent to us and even before the publication of the results by Barre-Sinoussi *et al.* in 1983. Since we considered the mere detection of virus particles in cultures from AIDS and ARC patients to be insufficient to confirm scientifically our hypothesis that such particles were implicated in the aetiology of the disease, we decided first to obtain specific reagents against the new virus in order to publish definitive results concerning AIDS aetiology. The results presented in our four papers provided clearcut evidence that the aetiology of AIDS and ARC was the new lymphotropic retrovirus, HTLV-III[2,3,6,7]. In addition, for the first time the virus was produced in large quantities, specific reagents to the virus were made, and a reliable blood test to protect the blood supply and prevent blood transfusion-associated AIDS was now available.

SIR—I wish to take issue with a comment by Tim Beardsley on the LAV/HTLV-III controversy[1]. Gilden *et al.* clearly state in their correction letter to *Science*[2] that I am not responsible for the erroneous mixing up of LAV and HTLV-III electron micrographs that appeared as part of a composite electron micrograph picture in my paper to *Science*[3]. Nevertheless, the first paragraph of Beardsley's comment evokes the impression that I am to be blamed for this embarrassing error. In fact, my work described in that *Science* paper dealt exclusively with serological and biochemical aspects of the new retrovirus. My drafts did not contain the controversial composite and neither R.V. Gilden nor M.A. Gonda were proposed as

co-authors. It was solely R.C. Gallo's decision that the composite be shifted from another paper to mine.

Keeping supercomputers under control

SIR—The Purdue Water Resources Reseach Center in conjunction with the Office of Health and Environmental Research of the US Department of Energy recently co-sponsored a meeting on the current uses of, and future needs for, supercomputers in hydrology. 'Supercomputers in Hydrology: Future Directions', the first meeting of its kind, aimed to evaluate the need for large-scale vector and parallel processing machines and their peripherals in the hydrologic sciences, especially in subsurface hydraulics. While the charge of the seminar was to specifically deal with hydrologic applications of supercomputers, the conclusions drawn at the meeting apply equally well to many other fields of science and technology.

Almost all technical issues involving the use of supercomputers were presented either by a computer scientist, a programmer or an applied mathematician. Because the architecture of most supercomputers is radically different from scalar processing machines, this is no surprise. The real importance of this observation is the implied increase in the need for multidisciplinary research teams to solve major ecological problems. Unfortunately, in the United States, many of the larger supercomputer funding initiatives do not address this issue at all.

This defect in the supercomputer initiatives leads to two major problems: scientists not doing 'science' and the inefficient use of supercomputers. If funds were available to support programmers with expertise on a machine of a certain architecture, the scientist would only need to communicate effectively with the programmer. The projected changes in architecture affect the programmer and not the scientist; hence the scientist is free to do science.

An alternative to long-run funding of programmer-consultants is for the initiatives to increase their effort in the development of very high level languages. Rice of Purdue's Computer Science Department gave a talk on projected advances in hardware and software over the next 10 years. From 1975 to 1985 computing speed increased by a factor of 25. Between 1985 and 1995 the speed is projected to increase by a factor of 2,000. On the other hand, from 1975 to 1985, computer languages have been improved by a factor of only 1.4. Unless more funding is made available for the development of high-level languages, improvement in ease of coding is not expected to increase nearly as fast as machine computational power. In fact, because of radical changes in architecture, programming may well become more difficult.

Another important point brought out at the seminar is that advances in science should not be overpowered by advances in computational capability. Do we really improve our fundamental understanding of science by looking at larger and larger computational problems? Many would argue that the understanding of complex chemical and physical interactions in the subsurface and the ability to estimate parameters is so poor that the large supercomputer models may in fact be totally incorrect. In this instance, supercomputer modelling efforts may turn out to be a greater obstacle to real progress than no model at all.

So there is clearly a role for supercomputers, but the extent of this role will depend on the availability of high level languages, expert programmer consultants working closely with multidisciplinary teams, exposure to different computational systems, and a judicious choice of problems with the aim of advancing our understanding of science.

Are light head loads carried free?

SIR—Geoffrey Maloiy and his colleagues (*Nature* **319**, 668; 1986) have shown conclusively that experienced African women can carry head loads at remarkably low energy cost. However, I cannot accept their conclusion that loads of less than 20 per cent of body mass are carried free, on the basis of the evidence they present. They performed no measurements in the load range 0 to 20 per cent: their conclusion is based on the backward extrapolation of a straight regression line fitted to the range of about 24 to 70 per cent of body mass. Extrapolation of a regression line always is risky, and in their case particularly so, because other data they present clearly show that the energy cost to army recruits of carrying a back pack is not a linear function of load.

Maloiy and his colleagues suggest that an explanation for the low cost is that the women achieve a gait such that the load makes little movement against gravity during the walking cycle. Though proof of this theory using accelerometers, as R. McNeill Alexander proposes in his *News and Views* piece on the paper (*Nature* **319**, 623; 1986), would be elegant, my observations of African women carrying head loads leads me to believe that they are right. Many South African women can carry small objects like individual oranges or bottles on their heads with grace and ease; some do so by choice even when their hands are free. While it is possible to carry a metastable object like a bottle on one's head even when one's head is moving up and down, the women appear to reduce or eliminate all vertical and transverse head movements when doing so. Given the human anatomy, I think that stabilizing the head necessarily must stabilize the centre of gravity of the whole body too. Since fuelling of cyclic vertical movements of the centre of gravity constitutes one component of the energy cost of walking, elimination of such movements should reduce the energy cost. Thus, the cost of walking with a light load on the head, in people experienced in the skill, might be less than the cost of walking with no load.

We need the missing measurements.

SIR—As supporting evidence for Maloiy *et al.*'s suggestion (*Nature* **319**, 668; 1986) about the steadiness of a head load, I cite the observation that even small children can carry liquid loads on their heads without spilling from the container. A woman carrying a bucket of water home from the well is surely one of the commonest sights; and I would think a good substitute for the suggested experiment of attaching an accelerometer to the head load.

It is interesting that it is possible to carry a much heavier load on the head than the bearer can lift unaided. It is normal to see two people lifting a burden and settling it comfortably on the head of a third, who then walks off with it. One of the most impressive, if macabre, sights I ever saw was when a farmer had died in the field, and another carried the corpse, by then rigid, to the village on his head.

State of preservation of the Dead Sea Scrolls

SIR—The article "Dead Sea Scroll parchments: unfolding of the collagen molecules and racemization of aspartic acid"[1] is of interest since any method which will improve on our knowledge of vellum fragments is important. The study on the condition and deterioration of vellum which is known to be approximately 2,000 years old is interesting in itself, although the identification into goat, calf or sheep as to origin of the material examined[2,3] would improve the information resulting from their tests. This could be accomplished by a comparison made from samples of the scrolls known to be of goat skin and that of modern goat skin prepared as we believe the scrolls to have been prepared[3]. In this way Weiner *et al.* could make a column to their Table 1 identifying the skin of each scroll as well as the patches and other additions. As the authors state in their paper[1] "Using different skins in one scroll and/or various parchment preparation treatments could conceivably influence the C:G index and the D/L aspartic ratios".

If, however, any relationship is to be drawn to the age of the samples and the agents of deterioration, then the tests they carried out gave insufficient evidence, as we have seen even within the scrolls there is variation. There must be a more comprehensive sampling to form a basis for comparison, which Weiner *et al.* acknowledge. A modern rat tail and a seventeenth century book cover do not provide a varied series, though the authors use them as comparative materials to the scroll samples. An adequate sample basis must be developed on a wider range of material both ancient and modern; this could be accomplished by application of the tests on samples which have a known documentation between the first and sixteenth centuries AD which would include changes in parchment preparation both in Europe and the Near East[1-4].

When considering the condition of materials found in the Qumran caves, it may be of interest that most scholars, given the methods of examination at the time, believed the two scrolls offered to the British Museum in the 1880's by M.W. Schapira to be forgeries based partly on the fact that their condition was throughout so superlative compared to known fragments[5]. There is now little doubt that the Schapira Scrolls came from the Dead Sea caves[6].

It is unfortunate that Weiner *et al.* did not examine the agents of deterioration of vellum to gelatin by controlled testing, and then subject their samples to the collagen/gelatin and D/L testing. Such testing of modern and ancient samples (combined with accelerated aging tests) would give information of a positive and precise nature on the causes of the variations found on Dead Sea Scroll samples (some on the same fragments) which undermine their study. As the authors note, we know damage has occurred, but its cause, and when it occurred are unknown. Plenderleith[7] found during the unrolling of Dead Sea Scroll fragments of cave 1 that certain fragments were permeated with a black bituminous substance which he identified as a decomposition product of the skin. During the unrolling he found it necessary to dampen the Scrolls which caused this substance to become sticky. This black substance apparently was gelatin. This incident brings up a very important topic, that of the interventions made necessary by the fragile and rolled nature of the scrolls. Careful identification of the location from which each sample was taken should have been presented by Weiner *et al.* This information could have been correlated with published data on the condition of the fragments as they were found and treated. Both Plenderleith[7] and Cross[8] report extensive treatments with moisture and oils to remove clay and/or relax the skins[9]. The materials used in the treatments and the originally adherent substance could have altered analytic results.

This consideration of the condition of each fragment and their individual histories, including methods of skin preparation of which Stambolov[10] has prepared a thorough survey and Poole and Reed[3] a precise analysis, is of great importance. Some of the skins were found in the same cave, some scattered on the surface, others buried and some appear to have been discovered several centuries ago and been exposed to quite varied climatic conditions[11-13].

Others were preserved for longer periods as whole scrolls rolled in linen and placed in jars encased in tar. Varied histories of the fragments should be listed and referred to when discussing the results of testing. Rapid deterioration can occur in organic material transferred from one environment to another. Fragments taken from the dry conditions in the caves to a humid environment or one with rapid or frequent variation could cause severe and immediate damage. It is of interest to note that the authors are continuing their research with specific attention to the climatic effects of the transition of collagen to gelatin (S. Weiner, personal communication).

Given the problems with amino acid dating, especially the variation with regard to radiometric methods[15-17], examination of rates of decay from amino acid D/L values should be considered very relative, especially with regard to natural and human interventions. Nevertheless, its use as a source of approximate time during which collagen has changed to gelatin may prove to be of great value

WEINER *et al.* reply—In our study, we reported the development of a new method for assessing the extent to which collagen has transformed to gelatin in ancient parchments and we tried to estimate the approximate time that elapsed since the transformation took place. We applied these methods to the analysis of some 40 parchment fragments from the Dead Sea Scrolls. We agree with Kahle and Caldararo that a thorough study, which includes more background information on the pieces analysed as well as controlled studies of parchments of different ages, prepared in various ways and subjected to a range of temperature and humidity conditions, would be the most helpful. Incidentally, some of the background information can be ascertained from the literature using the information supplied in our Table 1. We took care to emphasize in our original publication that the transformation of collagen to gelatin may be only one of several different degradative processes that occur in ancient parchments. Thus caution must be exercised when correlations between some parchment property and collagen:gelatin proportions and/or D/L ratios are made, as Kahle and Caldararo are suggesting. We also noted that the

wide range of D/L aspartic acid ratios, even from a single parchment fragment probably precludes the use of this technique for absolute age determination of parchment.

Nuclear winter and the greenhouse effect

SIR—Ever since its original publication[1], the nuclear winter concept has been in dire need of some form of experimental verification. So great has its need for independent corroboration been, in fact, that when challenged on this point[2,3], the concept's creators responded by grasping at some very strange straws. For one thing, they stated that the climate model they used to develop the concept was only partly calibrated, and that this calibration was accomplished by means of the possible collision of an asteroid or cometary nucleus with Earth at the time of the Cretaceous/Tertiary transition and by research on martian dust storms[4]. To my mind, a much more timely and down-to-earth phenomenon to use as a means of calibration is the CO_2 greenhouse effect; for it pertains to our own planet, is supposed to be happening now, and is itself predicted by the same climate models that produced the nuclear winter concept.

What are the fruits of such a calibration exercise? From data and equations in the US National Research Council's most recent review of the CO_2/climate connection[5], it can be calculated[6] that between 1880 and 1980 the northern third of the Earth (the most climatically sensitive region) should have warmed by about 3°C due to atmospheric CO_2 increases experienced over that period. However, the true model-predicted warming over this time span is actually 6°C; for an important study of the past year[7] has clearly demonstrated that increases in other trace gases over the past 100 years should have had just as great an effect on the Earth's climate as did increases in CO_2 during that time.

So how does this 6°C warming prediction compare with reality? Recent studies of Arctic and Northern Hemisphere temperature trends of the past century[8-10] show that the prediction is fully an order-of-magnitude too large, so it is logical to assume that the nuclear winter prediction is similarly overestimated.

Additional support for this conclusion comes from several climate modelling studies of the past two years, which have shown that when more realistic parameterizations of several real-world processes are included in the models, the climate sensitivity of the Earth is greatly reduced. Somerville and Remer[11], for instance, have introduced a cloud liquid water content effect which halves climate sensitivity; while Spelman and Manable[12] and Wang *et al.*[13] have improved upon the treatment of feedbacks from meridional and vertical dynamical heat fluxes, including ocean currents, reducing it by a factor of four. Finally, Ou and Liou[14] have improved on the treatment of cumulus convection, reducing the climate sensitivity by another 40 per cent. Taken together, these independent model improvements lead to the same order-of-magnitude reduction in the strength of the CO_2 greenhouse effect that is suggested by the temperature history of the Earth.

Why do we not see reference to these developments in the public dialogue over the CO_2/climate question? Is it because their acknowledgement would cast doubt on the nuclear winter hypothesis? These are questions that all who are truly concerned about mankind's future on our fragile planet must ask themselves. As Maddox[3] has rightly said with respect to the effort to avert nuclear war, "by clouding the case with disputable predictions, they [the nuclear winter protagonists] are in danger of weakening it".

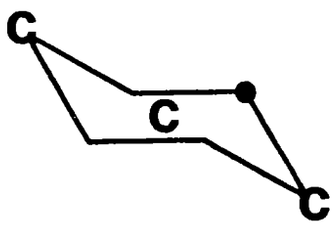
Competition amongst desert perennials

SIR—In his *News and Views* article on regularity in the desert shrub *Larrea tridentata*, Silvertown[1] ignores some areas of current debate and seems to draw spurious analogies between intra-specific competition in plants and inter-specific competition in animals. Intra-specific interactions amongst animals may sometimes create regular spacing[2,3].

King and Woodell[4] explicitly stated how the competition hypothesis could account for regularity in desert perennials. The elimination of small individuals by root competition with neighbours could convert a clumped population first to a random and then to a regular pattern. Silvertown not only ignores this hypothesis but also states that no hypothesis was provided to explain regularly-spaced clumps. King and Woodell[4] added that some regular patterns may have originated during long droughts, when intra-specific competition for water would be at its most intense. This is not 'acknowledging the importance of other factors'[1] as drought will inevitably intensify competition for water.

Larrea tridentata populations develop over such long time spans[5] that the hypothesis that regularity is largely due to competition for water will be difficult to disprove. Genets of *Larrea* can live for up to 11,000 years[6], the shrub grows slowly, and intense droughts are sporadic. Thus the lack of major change in the patterns of *L. tridentata* over 45 years in an area of fairly high rainfall[7] is unremarkable and provides no evidence for or against any of the hypotheses which suggest how regular patterns might arise.



The effects of factors other than competition for water on pattern in *Larrea*, such as allelopathy[8] and run-off[9], have been discussed for a long time. Nevertheless, there is regularity in single-species populations of other dryland perennials[10]. It has been shown that adjacent shrubs of *L. tridentata* compete for water[11,12]. Any refinement of the hypothesis must include (1) the clonal growth pattern of *L. tridentata* in certain sites, (2) the possibility that seedlings become preferentially established on mounds remaining after clumps have died, thus perpetuating existing patterns[13,14] and (3) protection of young plants by older plants against freezing[14].

At some sites clumps which consist of mixtures of genets may have been classified as individuals. The regularity of the clumps still needs an explanation, however, whether a clump consists of one genet or several.

COMPLEX CARBOHYDRATE CORPORATION

"Let us help you with your complex carbohydrate science"

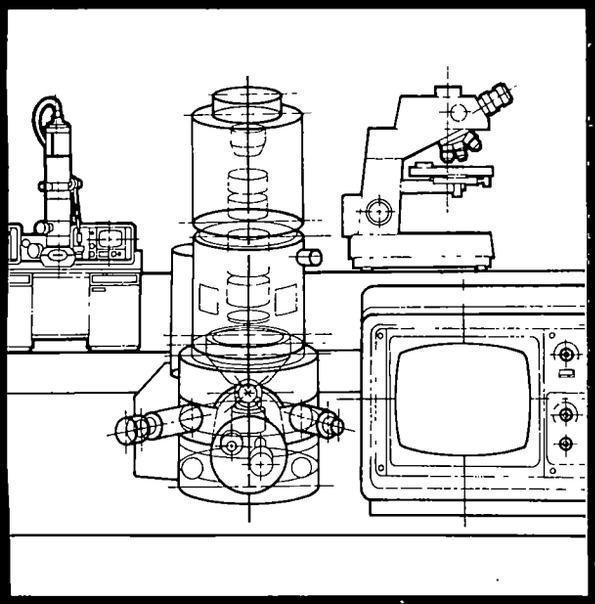
We have determined the structures of the complex carbohydrates of:

- glycoproteins
- glycolipids
- glycosaminoglycans
- cell wall polysaccharides
- extracellular (capsular) polysaccharides
- lipopolysaccharides

Analyses we can now provide:

- glycosyl composition
- glycosyl-linkage composition
- glycosyl sequence
- identification of non-glycosyl substituents
- points of attachment of non-glycosyl moieties
- absolute configuration
- anomeric configuration
- conformations in solution
- complete primary structure

In addition to consulting, the following services are offered:



- gas chromatography
- liquid chromatography
- combined g.c.-m.s. (e.i. and c.i.)
- combined l.c.-m.s. (thermospray direct inlet, moving belt)
- high-mass f.a.b.-m.s.
- ultra-high-field ^{1}H– and ^{13}C-n.m.r. spectroscopy (all 1-D and 2-D techniques
- metabolic profiling

For more information, call (404) 546-3153, or write

New volumes from

Handbook of Experimental Pharmacology

Volume 79

New Neuromuscular Blocking Agents

Basic and Applied Aspects

Editor: **D. A. Kharkevich,** Moscow
1986. 128 figures. XXIV, 741 pages. Hard cover DM 780,–
ISBN 3-540-15771-9

This volume is devoted to the applied and fundamental aspects of the studies of new neuromuscular blocking agents. It contains valuable data that until now has been insufficiently reviewed or not elucidated at all, and reflects the up-to-date state of the art of the field together with promising indications of further developments.

Volume 78

The Tetracyclines

Editors: **J. J. Hlavka,** Pearl River; **J. H. Boothe,** Ocean Gate
1985. 77 figures. XIV, 451 pages. Hard cover DM 490,–
ISBN 3-540-15259-8

The editors have compiled a comprehensive review of the tetracyclines, ranging from their discovery to the present and including all the major subdivisions of these chemically important and clinically useful antibiotics.

Volume 77

Chemotherapy of Gastrointestinal Helminths

Editors: **H. Vanden Bossche, D. Thienpont,** Beerse; **P. G. Janssens,** Schilde
1985. 62 figures. XXI, 719 pages. Hard cover DM 660,–
ISBN 3-540-13111-6

In this volume the editors and authors have critically evaluated the immense amount of data on anthelmintic drugs that is scattered throughout the literature. This review is not limited to an evaluation of the therapeutic efficacy of the more important anthelmintics, but also includes information on their pharmacology, pharmacokinetics, toxicity, and mode of action.

Volume 76

Clinical Pharmacology of Antianginal Drugs

Editor: **U. Abshagen,** Mannheim
1985. 81 figures. XVI, 552 pages. Hard cover DM 460,–
ISBN 3-540-13110-8

This volume reviews the epidemiology, pathophysiology and treatment of coronary heart disease. The emphasis placed on clinical pharmacology and research is of immediate relevance for therapeutics. Thus, the volume provides not only the pharmacological basis for treatment, but also the principles of therapy and the rational methods for its assessment.

MACMILLAN DICTIONARIES

DESIGNED FOR STUDENTS

The paperback *Macmillan Dictionary Series* combines new and established works of teaching and reference with an attractive series format.

* authoritative definitions and explanations of all current terminology written by experts
* lucidly written entries with thorough cross referencing
* regular new editions keep the student up to date with the latest research, practice and technology
* a clear layout for easy reference
* prices range from just £7.95 to £9.95

Growth into smallness

Nicholas Kemmer

Inward Bound: Of Matter and Forces in the Physical World. By Abraham Pais. *Oxford University Press:1986. Pp.637. £20, $24.95.*

Inward Bound is an account of how, since the beginning of this century, physicists have progressed towards the understanding of natural phenomena in ever-decreasing dimensions of space. The author, Abraham Pais, can look back on a long and creative career in theoretical physics, towards the end of which his biography of Einstein (*Subtle is the Lord*, published by Oxford University Press in 1982) revealed that he is a remarkably gifted writer. Now he has presented us with a book in which even more varied talents are in evidence.

Pais's mastery of the whole field of elementary particle physics is manifest on every page. In addition, his insight into the personalities of the actors in the story is remarkable. In the case of the earliest of these there is evidence of deep study of the widest range of relevant literature, but it may surprise younger readers that so many persons, whom they only know as famous names from the past, were real people in Pais's life. In particular he had the good fortune to work beside Niels Bohr in Copenhagen *and* Albert Einstein in Princeton. The many personal facts — sometimes of real relevance, sometimes just anecdotal — are a feature of the book, which is also enlivened by occasional spurts of impish humour. (Just one example: early on Pais tells us of speculations that radioactivity might be a property of *all* matter, and writes, "... the conjecture was not heard of again until... the 1970's..., see Chapter 22, which the reader will have time to reach without fear of prior disintegration".)

The scope and level of *Inward Bound* are clearly and extensively stated in its opening chapter, entitled "Purpose and Plan". No reader should skip it. All the chapters are divided into sections, and Section (a) of Chapter 1 is headed "From X to Z"; X is the X-ray and Z is the particle discovered by CERN in 1983, the two objects that are the termini of Pais's inward-bound journey. He explains here why that journey is broken into "A History" (*c.* 400 pages) and "A Memoir" (*c.* 175 pages). With the pace and volume of physics research increasing so enormously over the near-century covered in the book, it is hardly surprising that it was necessary to change the nature of the presentation at a particular moment. No break could be more natural than the end of the Second World War, which also happened to coincide with the start of the author's own career in the United States. Thus the first part covers all that for Pais was there at the start, while the second is what he witnessed and helped to shape.

Even with this break, it is quite astonishing how, in spite of the explosive growth of the subject, Pais has managed to knit events into a unified flow of narrative. This is to a large part due to the way he has chosen to unfold his story. It is not chronological, but rather topic by topic. Each of these is a strand, usually a single section, in a chapter that binds several strands together. Some of these are quite short — one might be on instrumentation, another on some general topic peripheral to the main narrative (there are for instance a few pages on physicists during the First World War) — but others are parts of long threads that can be traced almost right through the whole book, the puzzles of β-decay being an outstanding example. It is as if Pais were guiding the reader's eye along the colours in the weave of a beautiful tapestry. (I am tempted to misapply the current jargon word *fibre-bundle* to what I am trying to describe!) A feature of this particular tapestry is, of course, how it widens and thickens as one looks along it; at one end it displays all the physics that then existed, while at the other all we are following is a single, narrow strip in a huge field of activity.

From *Inward Bound*

Talk of physics: (left to right) Robert Oppenheimer, Paul Dirac and Abraham Pais.

In illustration, a closer look at Chapter 2 may be useful. Section (a) focuses on Roentgen in his environment at Würzburg, on how his accidental discovery came about in the wake of the introduction of cathode rays by Hertz and Lenard, on how his discovery was received and on its impact on the very private and shy discoverer. Section (b) then concentrates on Becquerel, or rather the Becquerel dynasty, to start with. H. Becquerel's discovery is described against this background, and with it Chapter 2 ends. However, Chapter 3 carries this second strand further, in the story of the Curies linked to that of Rutherford and his α- and β-rays. These relatively short chapters are followed by a longer fourth, entitled "The First Particle", in which the figure of J.J Thomson naturally enters, but not at the start. The previous, accidental discoveries (with Rutherford's work taken no further than the analysis of α- and β-*radiation*) did not need a great deal of background. Here, when the notion of elementary particles moves from speculation into physics, Pais needs to present more prehistory. So the first strand deals with the experimental tools that Thomson (not primarily an experimenter) owed to Geissler and Rühmkorff, and the next two with the ideas that were in the air for Thomson to bring to fruition. Section (b) is entitled "Faraday, Maxwell and the Atomicity of Charge", and Section (c) "Of Rowland, Zeeman and Lorentz". Only then does Section (d) get on to Thomson by way of Wiechert and Kaufmann. This still doesn't terminate this particular strand of narrative; Section (e), "β-rays are Electrons", ties it to what we learnt about before, and then, finally, as a link with what is to come, we have Section (f), "Relativistic Kinematics".

At this point one might well ask how a book of this size can say anything meaningful about Faraday, Maxwell, Lorentz and Einstein, all in a few pages? The answer is in part that the exposition is a model of how clarity can be combined with brevity, but also — and this is an outstanding strength of the whole book — that every section ends with a detailed set of references to books, review articles and papers, positively inviting further study

Having described the early chapters in such detail, I must be brief with the rest We hear of the struggle to understand radioactivity before the picture of the nuclear atom had been thought of. Then the first piece of the story of β-decay is presented, followed by a chapter entitled "Atomic Structure and Spectral Lines" where Rutherford, Bohr and the nucleus enter the scene. A short chapter then looks briefly at how the failure of classical mechanics brought confusion into the minds of physicists, and how a generation of young men emerged, poised to sort things out. Then quantum mechanics arrives. In a chapter labelled "An Essay", Pais states emphatically that here the reader should turn to good textbooks for

complete guidance, but this does not prevent him from writing a brilliant account in which the central ideas — and equations — are presented in the midst of much on the personal side.

This is the point where the split of physics into many branches began. The narrative narrows, but an enormous amount of material nevertheless remains to be covered in the closing five chapters of the "History". It could not have been done with greater artistry. The interwoven strands tell us about quantum electrodynamics and the positron, about the continuing mystery of β-decay, leading up to the neutrino, about the merging concepts of fields and of particles that are born and die, and how a deepening understanding of symmetries has proved to be the most reliable guide to progress. In all this Pauli and Dirac, among others, are most vividly portrayed.

Inevitably, much prominence has to be given to the great shadow cast on physics by the knowledge that the theoretical structures used at the time were quite unsound mathematically, and that the necessarily approximate calculations were completely unreliable. The "History" was bound to end on such an unhappy note, but Pais has waited to its last chapter to pick up a final, more optimistic theme, going back to 1932 and the discovery of the neutron. At last there was then a convincing picture of nuclear structure to develop, into which Fermi managed to inject an at least provisionally acceptable description of β-decay. It was from there that the search for an account of nuclear forces started and, to close the story, we hear how Anderson's discovery of the muon and Yukawa's theory of the pion (as they were later to be called) seemed to open new vistas. It is left to the subsequent "Memoir" to tell us how wrong our ideas at that time were. I say "our" because this last episode of the "History" is the first of what might have been "Memoir" for me. I can vouch for the complete authenticity of the story.

The "Memoir" starts with the entirely new situation in physics after the Second World War. Many techniques, many young trained minds and large resources become available, in particular in the United States. Having survived years of danger and tragedy in his native Netherlands, Pais is there to take part in the explosive growth of his subject. The "Memoir" is the story of his life in physics and with physicists, in the centre of unprecedented developments in both experiment and theory. These Pais manages to absorb and to reproduce for the reader, still vividly but inevitably in a more technical manner than many readers (including trained physicists not on the inward-bound track) will only be able to follow in detail thanks to the extensive references.

There are just four chapters in the "Memoir" and it would be difficult to enumerate everything in them. The "strand" structure is as before, the first three chapters telling the story up to 1960. We learn of the transformation of theoretical thinking with the arrival of the idea of renormalization and its success in explaining observed facts in electrodynamics; of the impact of the big machines and of their characteristics; of the discovery of many new particles and of the new symmetries that help to put some order into the picture; of the shock when long-cherished old symmetries turn out to be violated; and of many other avenues that are explored, some fruitlessly.

How Pais manages to fit in an account of the still-more-turbulent developments from 1960 onwards into one chapter of a mere 70 pages (with eight pages of references to end with) is almost miraculous. He shoots the discoveries and ideas at the reader with machine-gun rapidity — but it is still the same author writing, keeping the human side up with the technical.

If I who have lived through the whole period of the "Memoir", but with far less first-hand experience of the great events, ever attempt to get my bearings on these modern things, from quarks to the Z particle, with the description of things like colliders thrown in, I know I shall turn to Pais, both his narrative and his references. It is an inimitable work. □

Nicholas Kemmer, 35 Salisbury Road, Edinburgh EH16 5AA, UK, is Emeritus Professor of Mathematical Physics at the University of Edinburgh.

Membrane steps

Miles Houslay

Reconstitutions of Transporters, Receptors, and Pathological States. By Efraim Racker. *Academic: 1985. Pp. 271. Hbk $28, £24.50; pbk $12.95, £12.*

EFRAIM Racker is one of the founding fathers of membrane reconstitution, and the prospect of reading his book on the subject rather intrigued me. What would be his perception of the past, present and future of membrane biology? In the preface Racker says that the book is based on a lecture series he was used to giving, which sounds promising. Each of the lectures (12 in all) is dedicated to putting over a series of 34 "lessons" varying from good general advice to homespun philosophy. A certain amount of sound advice is indeed to be welcomed by the aspiring "reconstitutor", as taking membranes apart and putting them back together is like gardening, and requires the equivalent of green fingers and a certain feel for the subject.

Lectures 1 and 2 have the central theme of "how to solubilize the protein that you've chosen". Here Racker makes the important point that what works for one protein may well not succeed for another (that is, you often have "to suck it and see"), and lists a variety of parameters of which one has to be aware. He makes it abundantly clear that there is no self-evident set of rules to follow: there are too many parameters and we have too little basic appreciation of how individual membrane proteins are glued into bilayers.

However, having said all this, the reader is then offered little or no constructive help. We are advised to take account of "critical micellar concentrations" and hydrophil–lipophil balances, but without even being told what they are, never mind how such values may be of use to tease proteins out of their membrane home. Purification of membrane proteins, which is after all the main goal of many people interested in this field, gets a desultory page without any references to different ways of coping with this key problem. A series of general methods for reconstitution then follows, with lists of some reconstituted systems and their "activities". These lists (again innocent of references) are of little use except to give a broad view of the variety of systems that the author has got hold of and stuck back into liposomes, though the accompanying, anecdotal text does convey some idea of the principles involved.

The succeeding chapters all suffer from similar drawbacks. The section headings identify important points that should be investigated or considered, but the monologue that follows is superficial and jumps haphazardly from one system to another. One can have a degree of sympathy with such an approach in the introduction, but after three chapters one finds oneself desperately hoping to come across a logical presentation of hard facts. As it is, over the next seven chapters we are led a merry dance around a variety of membrane systems. The penultimate lecture is about cancer; it raises a few interesting points about glycolysis but is largely an indulgence, as is the final lecture centring on the author's current predilections.

I am afraid to say that after having had such high hopes for this book I found it difficult to read to the end; it lacks both substance and cohesion. Further, although Racker apologizes for all those people he has not mentioned, the number of self and selective citations in places leads to history being re-written. I would not recommend the book to students, but lecturers running courses on membranes, or sociologists of science, might find it of some interest. □

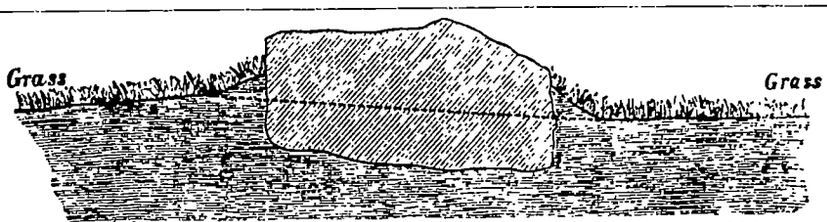
Illusion in ascent

Peter J. Bowler

Taking Darwin Seriously: A Naturalistic Approach to Philosophy. By Michael Ruse. *Basil Blackwell: 1986. Pp.303. £22.50, $24.95.*



MICHAEL Ruse believes that scarcely anyone *has* taken Darwin seriously up to now. Efforts to apply evolutionism to the problems of philosophy have failed, largely because of a refusal to acknowledge the central tenet of Darwinism: the non-progressive character of natural selection. Whatever one's opinion of Darwinism (Ruse, of course, accepts it as the basis of all legitimate evolutionary thinking), the claim that the theory has seldom been taken seriously can certainly be endorsed by the historian. To depict the growth of evolution theory as a simple ascent from Darwinism to the Modern Synthesis is to fall into the worst kind of Whig history, ignoring the large number of thinkers, including scientists, who have found the principles of natural selection unacceptable. As Ruse points out, modern Darwinists from Julian Huxley to E.O. Wilson have also found it difficult to accept the non-progressionist character of the theory.

Ruse's purpose here is to address the philosophical, not the historical issues. He criticizes evolutionary approaches to the problem of knowledge, from Herbert Spencer to Karl Popper. Drawing a simple analogy between evolution and the growth of science does not work, he says, because science is progressive and evolution is not. He looks instead at the kind of reasoning that we might expect natural selection to have programmed into our ancestors so that they could deal successfully with the real world. We believe that an effect *must* follow its cause, because any of our ancestors who did not have this mental reinforcement to back up their perception of causal regularities would soon have disappeared. The intellectual ancestor of this approach is David Hume, who realized that we read necessity into nature even though we have no philosophically satisfactory guarantee that there is anything corresponding to that necessity "out there". If the analytical philosophers are not satisfied with this, Ruse tells them that they will have to go away disappointed. The philosophers will presumably not be happy with a viewpoint that threatens to put them out of work, but anyone who has lost patience with the apparently endless wrangling of academic philosophy can only applaud.

On the question of morality, Ruse is critical of "social Darwinism" and other efforts to deduce ethical standards from evolution, precisely because they invariably assume that nature is progressing towards some ultimate good. His own approach starts from the principles of sociobiology, but attempts to purge the remnants of progressionism from the work of Wilson and others. Natural selection will have endowed us with epigenetic rules inclining us to behave in a socially responsible manner, when this is to our (reproductive) advantage. The special status we accord to moral laws is nature's way of ensuring that we have a strong tendency to obey them even when they violate our immediate preferences. As a result, we *feel* that moral laws are objective — and our desire to live in an orderly society ensures that we have no interest in rejecting the laws even when we realize that this feeling is an illusion. Once again, Ruse identifies Hume as the philosophical progenitor of this position.

It will be interesting to see how the opponents of sociobiology respond to this book. Far from justifying a harsh social policy, Ruse explains why we feel so strongly about traditional moral values. Those who wish to argue that human beings are infinitely malleable by culture will object to this — but in so doing they will have to accept that we have no built-in moral values at all. If we concede that our evolutionary heritage may have imposed at least some constraints on how we think and behave, Ruse offers us a way of trying to understand the character of such restraints. As we move into a world that differs ever more radically from that in which our ancestors evolved, such insights may help us to come to terms with the philosophical problems that confront us. □

Work of worms — section through a fallen Druidical stone at Stonehenge, indicating how much it has sunk into the ground through the undermining action of earthworms. Depth of the stone is c. 30 cm. The illustration is taken from a new paperback edition of *Charles Darwin's* The Formation of Vegetable Mould, through the Action of Worms *(1881), published by University of Chicago Press. Price is $12, £10.25. For review see* Nature *24, 553–556 (1881).*

New journals review

On 25 September *Nature* will publish the sixth annual review supplement devoted to science journals.

Criteria for inclusion of a journal in the 1986 issue are that:

(i) the first number appeared, or the journal was retitled, *between June 1984 and May 1985* (the second cut-off date allows at least three issues of a journal to have been published, the minimum number on which a reasonable judgement can be based).

(ii) it is published at least three times a year;

(iii) the main language used is English

Publishers and learned societies are invited to send *four different issues of each suitable periodical, including the first and most recent numbers* (if from outside the United Kingdom, by air mail) to The Review Editor, *Nature*, 4 Little Essex Street, London WC2R 3LF, England. Subscription details for both 1986 and 1987 should be included.

Parallel promises in computing

Igor Aleksander

The Connection Machine. By W. Daniel Hillis. *MIT Press:1986. Pp.190. $22.50, £22.50.*

THE jacket of this book heralds "the connection machine" as "the second state in the evolution of digital computers"; the first sentence reads "Someday, perhaps soon, we will build a machine that will be able to perform the functions of the human mind, a thinking machine". It must be said immediately that while the concept of the connection machine is intriguing, and the book tells us a lot about the engineering behind it, any reference to "thinking machines" is thoroughly misleading.

The primary characteristic of the connection machine is parallelism. The prototype discussed by Hillis contains approximately 64,000 simple processors that may be linked in large parallel groups, and it is one of the strengths of the book that the author discusses his design decisions with great clarity. The main attraction of the machine is that it allows a user to research the behaviour of different "shapes" of parallel machines; for example, the properties of processors connected in a ring are very different from those of processors connected in a matrix, and the connection machine may be configured into these structures and many more. It almost becomes possible to believe the claim that the machine marks a new era in digital computing, as the possibility of working with different "shapes" of parallel structure is awkward (that is, slow) on conventional computers.

Hillis's main problem, in common with that of designers of similar machines, was to devise schemes that allow processors to be selected from a pool, and then to provide a sufficiently rich set of pre-defined connections so that the user's desired structure can be realized. Clearly, alternatives had to be found to the obvious solution of connecting every processor to every other one: that would require just too many connections, most of which would be unused during the execution of a particular task. Hillis lucidly reviews the various options and describes why he settled on a "Boolean n-cube topology" (the details of which might interest the topologist as an engineer's choice among theoretical alternatives). The end result of the parallel/serial compromise is an achievement of 1,000 million instructions per second (Mips) — the average modern machine in a research laboratory probably delivers about *one* Mip. Another achievement is that this machine may be programmed by means of an extension of LISP, easily mastered by those who use the language anyway. Hillis goes to some pains to argue that this is an arbitrary choice and advanced features of the machine could equally be applied to other languages.

But what scientific advances are likely to follow from the application of the connection machine? As is often the case with innovators in engineering, Hillis is less comfortable with the answer to this question than he is with the technical description of his machine. He points principally to questions arising in research on artificial intelligence, and suggests that image-processing could benefit by arranging the processors into two-dimensional arrays. Although this is true, and possibly useful, processor arrays have been built for some time; for example, Michael Duff's CLIP machines at University College London have been doing workmanlike tasks in practical image-processing for about 15 years, and those who have used them have probably discovered most of the principles that such methodology is likely to reveal.

Closer to the heart of AI, Hillis suggests that the connection machine might implement knowledge stores called "semantic networks". Here, two processors might have respective labels such as "lemon" and "sour", with a connection leading from the former to the latter and labelled as "tastes". The methodology was first introduced by Patrick Winston in 1970 and it is a matter of debate whether the lack of applications of such schemes in more recent research is solely due to the lack of a sufficiently parallel machine. Away from AI, Hillis proposes that the connection machine might be used to simulate silicon circuits (very large scale integrated systems), but at the rate of one processor (containing thousands of transistors) for each simulated transistor this has an air of overkill about it.

All this talk of application only occupies a few pages in the first chapter and is evidently not central to the author's interest. Hillis perhaps gets closer to the real potential for the connection machine in the last two pages of the book, where he suggests that through such "granular" computers of ever-decreasing grain-size, computational theory will extend its explanational powers to an increasing number of natural phenomena. This is where the payoff may really be found. The natural phenomena which, in my opinion, are most in need of attention are those concerning brain-like networks of cells, and the connection machine is an ideal simulation tool for such work. But despite the references to "thinking machines", Hillis does not actually discuss this possibility. The bibliography, although extensive, mostly bears little relation to the text and is notable for its omissions. The most serious of these is notice of the modelling of brain-like systems that has been pursued by Geoffrey Hinton at Carnegie Mellon University since the late 1970s. Exciting discoveries are being made about the way in which cellular learning systems can learn to "understand" concepts such as the shape of objects "seen" through a television camera, or build internal representations of "Italian name" against "English name" in a telephone directory database *without* having been programmed to do so directly. Investigations of this kind have much to do with what is meant by the word "thinking" and, if carried out through the connection machine, will contribute a great deal to understanding the functions of the brain. Indeed, simulations of Hinton's work are clumsy and counter-productive on conventional machines, and it is in this sense that the connection machine provides a useful tool with which "thinking" may be researched. To confuse this with the creation of a "thinking machine" is a category mistake of textbook quality. Moreover, despite the author's implication that the MIT-associated connection machine is unique, it must be seen as taking its place among a number of similar developments such as the "Non-Von" machine at Columbia University and John Darlington's ALICE machine at Imperial College, London.

The Connection Machine will be appreciated best by those who require a lucid description of a computer design that is truly ingenious and indicative of the trend in computer science hardware research towards massive parallelism. It is not for those with no knowledge of computer engineering at all, nor for others who hope to be enlightened on what a "thinking machine" might be. □

The real Frederick Soddy*

*As a number of people have pointed out, the photograph supporting the review of the collection of essays on Soddy (*Nature* **320**, 691; 1986) was in fact of Ernest Rutherford.

Muon-catalysed fusion revisited

Steven Earl Jones

Department of Physics and Astronomy, Brigham Young University, Provo, Utah 84602, USA

Muons introduced into relatively cold, dense deuterium–tritium mixtures can replace the atomic electrons and form muonic molecules which participate readily in nuclear fusion reactions. Catalysis yields of ~150 fusions per muon have been achieved, renewing interest in muon-catalysed fusion as a possible source of energy.

MUON-CATALYSED fusion can be viewed as a series of reactions induced by negative muons in cold hydrogen leading to nuclear fusion and a release of energy. For example, when a negative muon enters a mixture of deuterium and tritium (heavy isotopes of hydrogen):

$$\mu + t + d \tag{1}$$

The muon replaces an electron to form a $t\mu$ atom:

$$\rightarrow t\mu + d \tag{2}$$

A molecule bound by the muon may then form:

$$\rightarrow dt\mu \tag{3}$$

which leads to deuteron–triton (d–t) fusion, freeing the muon to repeat the cycle:

$$\rightarrow \alpha + n + \mu \tag{4a}$$

Occasionally the muon is captured by the α-particle following fusion:

$$\rightarrow \alpha\mu + n \tag{4b}$$

The key to this remarkable sequence of reaction lies in the large mass of the muon, which is 207 times that of the electron. A negative muon admitted into a high-density mixture of deuterium and tritium gases (step 1) quickly replaces the lighter electron to form a muonic atom (step 2). The reaction is energetically favourable and rapid because the muon greatly outweighs the electron. The same holds true for the succeeding step (3), formation of a $dt\mu$ molecule held together by the muon. The muonic molecule is ~200 times smaller than an ordinary heavy hydrogen molecule (such as DT, bound by electrons). Thus, the muon confines the d–t nuclei to a very tiny volume. Although the rest of the gas may be near room temperature, conditions inside the muonic molecule are similar to those found inside a white dwarf star[1]. In such conditions nuclear fusion (step 4) will occur, just as it does in stars. Indeed, d–t fusion occurs in $\sim 10^{-12}$ s in the $dt\mu$ molecule[2].

Without the use of external magnetic fields or lasers, we can thus achieve local star-like conditions by simply adding negative muons to a mixture of hydrogen gases. Each muon can spontaneously induce a number of fusion reactions, so that it serves as a catalyst for nuclear fusion.

In his 1968 Nobel prize acceptance lecture, Luis Alvarez[3] described the excitement generated by the first observation[4] in 1956 of this fascinating phenomenon for muons stopped in liquid hydrogen (H) plus deuterium (D):

> "We had a short but exhilarating experience when we thought we had solved all of the fuel problems of mankind for the rest of time. A few hasty calculations indicated that in liquid HD a single negative muon would catalyse enough fusion reactions before it decayed to supply the energy to operate an accelerator to produce more muons, with energy left over after making the liquid HD from sea water. While everyone else had been trying to solve this problem by heating hydrogen plasmas to millions of degrees, we had apparently stumbled on the solution, involving very low temperatures instead."

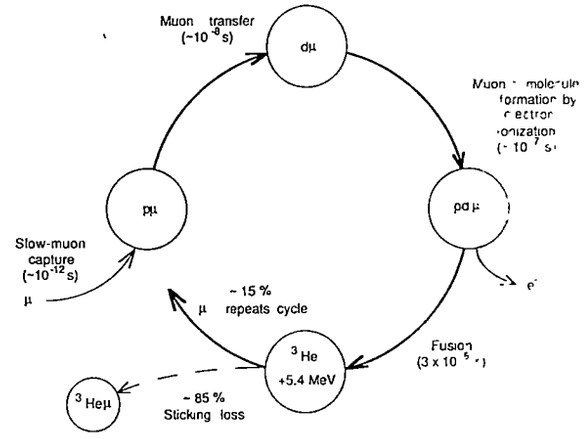

Fig. 1 The muon catalysis cycle for liquid hydrogen containing 1% deuterium. Approximate reaction times are shown[8,9]. Because the mean time required for muon-induced fusion to occur in the $pd\mu$ molecule (3 μs) exceeds the mean muon lifetime (2.2 μs), the muon usually decays before it can repeat the $pd\mu$ fusion cycle

Excitement quickly waned, however, following theoretical predictions that very few fusions could be catalysed by a single muon. Indeed, in experiments performed by Alvarez and others using hydrogen and deuterium, only rarely was a muon observed to induce more than one fusion reaction.

In mixtures of deuterium and tritium, the situation is strikingly different, for reasons which are as yet only partially understood. Within the past few years, we have demonstrated that a single muon can complete the reaction sequence (1)–(4) many times, catalysing many d–t fusions. It is fitting on this thirtieth anniversary to announce the achievement at the Los Alamos Meson Physics Facility of 150 fusions per muon (average) in dense deuterium–tritium mixtures[5]. These yields exceed theoretical expectations, and have stimulated speculation regarding muon-catalysed fusion as a source of energy.

Muon-catalysed fusion research encompasses many disciplines, including atomic, molecular, nuclear and particle physics, chemistry, accelerator technology, and possibly fusion energetics. This review, which is intended to be accessible to scientists in diverse fields, highlights the most recent discoveries which have stimulated renewed interest in muon-catalysed fusion.

Muon-catalysed p–d fusion

The first type of muon-catalysed fusion to be discussed theoretically[6,7] and observed experimentally[3,4] was proton–deuteron (p–d) fusion:

$$\mu + p + d \rightarrow {}^3He + \mu + 5.4\ \text{MeV} \tag{5}$$

The first observation of muon-induced fusion came as a great

surprise[3,4]. Alvarez and his colleagues at Berkeley noticed in their liquid-hydrogen bubble chamber a number of mysterious muon tracks having a characteristic 1.7-cm length. Furthermore, a gap frequently appeared between the 1.7-cm track and the stopping point of the incoming muon.

Unaware of earlier theoretical work by Frank[6], A. D. Sakharov and P. N. Lebedev[54] and Zel'dovich[7], the Berkeley physicists inferred the phenomenon of muon-catalysed fusion from their data. The principal clue was the 1.7-cm range of the muons, which corresponds to an energy of 5.4 MeV—just the energy released in proton-deuteron fusion. It was quickly realized that a muon could form a muonic ($d\mu p$) molecule, and then, "in such a 'molecule', the proton and deuteron would be brought together in such a close proximity for such a long time that they would fuse into ^{3}He, and could deliver their fusion energy to the muon by the process of internal conversions"[3].

The mystery of the observed gap between the stopped and ejected muons was solved by Edward Teller[3,4]. He correctly surmised that the muon would be initially captured by a proton, the nucleus of the predominant isotope of hydrogen in the bubble chamber, to make a muonic $p\mu$ atom. Although the fraction of deuterons in naturally occurring hydrogen is only 1 in 5,000, the muon could transfer rapidly and irreversibly to a deuteron to make a $d\mu$ atom:

$$p\mu + d \rightarrow d\mu + p \qquad (6)$$

because the binding energy for the ground-state $d\mu$ atom is 135 eV greater than that of the $p\mu$ atom. The neutral $d\mu$ atom could then recoil some distance, producing the observed gap, followed by $d\mu p$ molecule formation and fusion. The ability of the $d\mu$ atom to travel a few millimetres in liquid hydrogen before stopping (that is, before becoming thermalized) provides an interesting example of the Ramsauer-Townsend effect[8].

The sequence of reactions just discussed is shown in Fig. 1, along with some observed reaction times[8,9]. A major limiting factor in the process is the likelihood that the negative muon will be captured by the positive ^{3}He ion synthesized during proton-deuteron fusion; another is the long time spent by the muon in the $pd\mu$ molecule before fusion occurs. These factors limit the number of muon catalysis cycles in liquid hydrogen containing ~1% detuterium to an average of less than one fusion per muon.

Muon catalysis in pure deuterium

The Alvarez group and others[8] extended the study of muon catalysis to the case of pure liquid deuterium, observing the reactions

$$\mu + d + d \rightarrow d\mu d \rightarrow {}^3\mathrm{He} + n + \mu + 3.3\ \mathrm{MeV} \qquad (7)$$

and

$$\mu + d + d \rightarrow d\mu d \rightarrow t + p + \mu + 4\ \mathrm{MeV} \qquad (8)$$

Experimental results, shown in Fig. 2, were consistent with expectations based on studies of hydrogen-deuterium mixtures. The relatively slow formation rate of the muonic molecule and the loss of muons due to ^{3}He ion capture limited the average number of fusions per muon to less than one. It thus appeared that muon-catalysed fusion reactions in hydrogen isotopes were rather well understood and quite useless as an energy source[8,10,11].

Persistent research in the Soviet Union, however, led to a revival of interest in muon catalysis[12]. Dzhelepov *et al.*[13] first showed experimentally that the rate at which $dd\mu$ muonic molecules form depends strongly on temperature. In fact, the $dd\mu$ formation rate in deuterium at room temperature was found to be 10 times greater than the rate at liquid-deuterium temperatures (~30 K). That the deuterium temperature could strongly affect the formation rate of $d\mu d$ molecules came as a complete surprise.

In 1967, following an earlier suggestion of Zel'dovich[7],

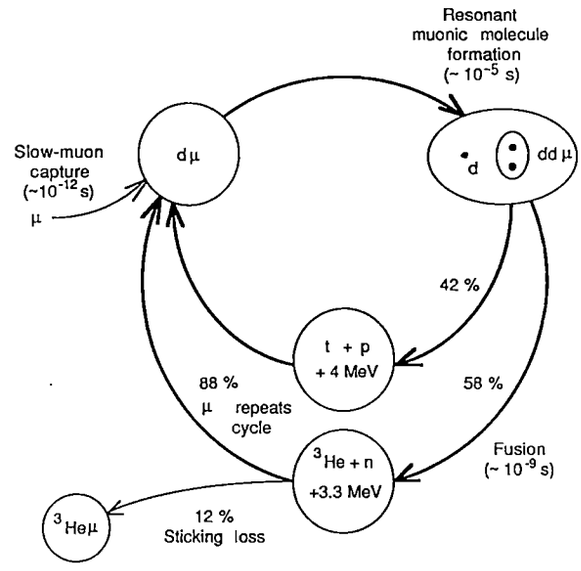

Fig. 2 The major reactions which occur when a muon is admitted into liquid deuterium. Resonant formation of a $dd\mu$ molecular ion within an electronic molecule (without emission of an electron) can occur when a $d\mu$ atom penetrates a D_2 molecule. However, the $dd\mu$ molecular formation process is slow relative to the muon lifetime so that the muon often does not survive to repeat the $dd\mu$ catalysis cycle.

Vesman[14] advanced the notion that the muonic $d\mu d$ molecule could form within a D_2 host molecule, as shown in Fig. 2. Note that the $(d\mu d)^+$ ion serves as one of two nuclear centres in the complex new molecule. For this process to occur, the energy released as the muonic molecule forms ($d\mu d$ binding energy, E_b, plus the initial kinetic energy of the $d\mu$ atom, E_K) must be small enough to be absorbed in the vibrational and rotational excitation ΔE of the host molecule:

$$E_b + E_k = \Delta E \qquad (9)$$

Because the energy levels of the complex molecule are quantized, equation (9) expresses a resonance condition; that is, the muonic molecule forms most rapidly when equation (9) is exactly satisfied. The temperature dependence of the process derives from the E_k term.

Precise calculations showed that there exists an excited state of the muonic $d\mu d$ molecule that has a binding energy of only 1.9 eV, which is small enough to be absorbed by the electronic molecule without causing it to break apart. Furthermore, the temperature dependence of the $d\mu d$ formation rate could be accounted for by the resonance requirement[15,16].

A startling prediction followed from this theoretical model: the formation of muonic $dt\mu$ molecules should also be resonant, and resonant $dt\mu$ formation at 540 K (the expected optimum temperature) should exceed the fastest $d\mu d$ formation rate by two orders of magnitude[17]. In addition, muon capture by the helium ion synthesized during deuteron-triton fusion had been predicted to be ~0.9%[10], much less than the corresponding loss term for proton-deuteron or deuteron-deuteron fusion. Thus, in late 1977 Gershtein and Ponomarev[17] declared:

> "It means that every μ^- meson in the mixture deuterium and tritium can produce ~10^2 of the nuclear fusion reaction and release ~2 GeV which is 20 times the rest mass of muon. We leave the question open about the possibilities of practical applications of the phenomenon discovered...
>
> The reactions [in deuterium plus tritium] are not yet studied experimentally. We hope that such experiments will soon be performed despite the technical difficulties involved."

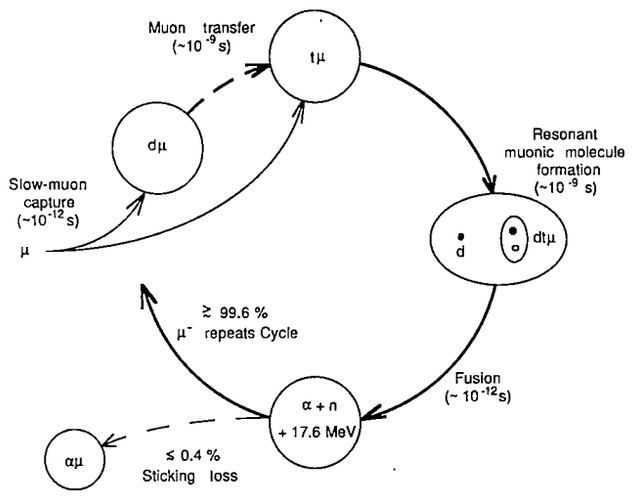

Fig. 3 The major processes which occur when a muon stops in a liquid mixture of deuterium and tritium in roughly equal proportions. The reaction times are very short, compared with the muon lifetime (2.2 μs). In addition, the probability of muon retention by the α-particle synthesized during d-t fusion is small. Thus, the muon-catalysed d-t fusion cycle can easily be repeated more than 100 times.

Experiments were soon mounted. As we shall see, some results were as startling as the predictions. Muon-catalysed fusion was not a closed subject after all.

Muon catalysis in D–T mixtures

Resonant dtμ formation. Bystritsky *et al.*[18,19] set out in 1979 to test predictions that the dtμ molecule could form in ~0.5% of the muon lifetime and that this formation rate would increase with increasing deuterium–tritium (D–T) gas temperature. They showed that dtμ molecules may form at least as fast as predicted by the new resonance model (shown in Figs 2 and 3), and four orders of magnitude faster than expected from the electron-emission process (shown in Fig. 1). The experiment allowed only a lower limit to be set for the dtμ formation rate.

However, no temperature dependence of the dtμ formation process was detected, even though the D–T gas was cooled to 93 K and heated to 613 K. Rapid dtμ formation appeared consistent with the resonance model, but where was the expected temperature dependence? Unfortunately, the Dubna accelerator was closed for refurbishment in 1979 and the Soviet experimenters were unable to pursue their research. (The machine is expected to return to operation soon. Related experiments recently began at the Gatchina facility of the Leningrad Nuclear Physics Institute.)

An experiment was begun in 1982 at the Los Alamos Meson Physics Facility (LAMPF) by our group, with the intention of exploring in depth the muon catalysis cycle in D–T mixtures[5,20–23]. Vessels capable of holding deuterium and tritium gases at pressures up to 1,000 atm (later, 3,000 atm) were developed at the Idaho National Engineering Laboratory (INEL) to allow near-liquid-hydrogen densities to be maintained over a broad temperature range (13–800 K). The experimental team consists of scientists from Brigham Young University (BYU), INEL and the Los Alamos National Laboratory (LANL).

Early one morning in November 1982, we cooled a target containing equal amounts of deuterium and tritium from room temperature to 100 K: the number of fusion neutrons decreased significantly as the gas was cooled. Although in qualitative agreement with the resonance model prediction, the result was surprising because no temperature dependence had been detected in the earlier Dubna experiment. The rest of the night was spent checking the electronics for a malfunction, but nothing was wrong. As the D–T mixture was heated the following day, the fusion yield grew larger. Resonance model predictions of temperature dependence enunciated by Ponomarev and colleagues were finally confirmed.

However, virtually no temperature dependence was seen when a target composed of 10% tritium and 90% deuterium was used. This result was consistent with the Dubna experiment, in which the D–T mixture contained ≤8% tritium. The experiments soon demonstrated that for low tritium fractions, the muon catalysis cycle was dominated by the muon transfer reaction

$$d\mu + t \rightarrow t\mu + d \qquad (10)$$

This reaction, analagous to reaction (6), is nearly independent of temperature. These two facts explain why no temperature dependence was seen in the low-tritium-fraction experiments at Dubna. For tritium fractions ≥30% at LAMPF, the temperature-dependent dtμ formation rate became evident[5,20–23].

With several hundred million muon-catalysed fusion events now recorded in the continuing BYU/INEL/LANL experiments, along with continued theoretical efforts, a consistent picture of the resonant formation of dtμ molecules is emerging. The important features are:

(1) The dtμ-formation rate rises with increasing temperature, as expected[20–23].

(2) The rate does not peak at ~540 K as predicted[15,16]. Instead, it continues to climb at 800 K, the highest temperature reached to date. There are now theoretical reasons to expect the rate to reach a maximum near 1,200 K[24]. Note that the resonance process depends on the presence of intact molecules to host the $(dt\mu)^+$ ion (see Fig. 3). As hydrogen molecules begin to decompose into atoms at temperatures ≥5,000 K, the resonance formation mechanism becomes unavailable so that dtμ formation must decline precipitously. Moreover, muon-catalysed fusion cannot be used in conjunction with plasmas; in particular, it cannot be used for thermonuclear weapons. The term 'cold fusion' is therefore quite appropriate for the process.

(3) The dtμ formation rate depends on whether the host is a D_2 or DT molecule[5,20–23]. In particular, the reaction

$$t\mu + D_2 \rightarrow [(dt\mu)d2e]^* \qquad (11)$$

proceeds more rapidly over a broad range of density and temperature than does the reaction

$$t\mu + DT \rightarrow [(dt\mu)t2e]^* \qquad (12)$$

This host-dependence arises from the different energy levels which are available in the two compound molecules, in keeping with the resonance model[24].

(4) While the rate of reaction (12) scales linearly with density as anticipated, the rate of reaction (11) increases faster than linearly with density[5]. The resonance model implies that $t\mu + D_2$ collisions are special, in having their strongest resonances just below threshold. A third body can allow these resonances to contribute by absorbing some kinetic energy in a reaction such as

$$t\mu + D_2 + T_2 \rightarrow [(dt\mu)d2e]^* + T_2' + \Delta E \qquad (13)$$

Thus, the density dependence of reaction (11) observed at LAMPF provides evidence for significant resonant dtμ formation involving three-body collisions[5,25], although other explanations for the phenomenon cannot be ruled out[26].

Muon capture by the fusion α-particle. Experiments thus demonstrate that dtμ molecules do form extremely rapidly, nearly three orders of magnitude faster than pdμ or ddμ molecules. In fact, owing to the extraordinary resonance in dtμ formation, a muon could catalyse many hundreds of d–t fusions during its lifetime, were it not for muon capture by the synthesized helium nucleus (see equation (4b)). We have seen that muon loss in this way constitutes a dead-end in the p–d and d–d catalysis

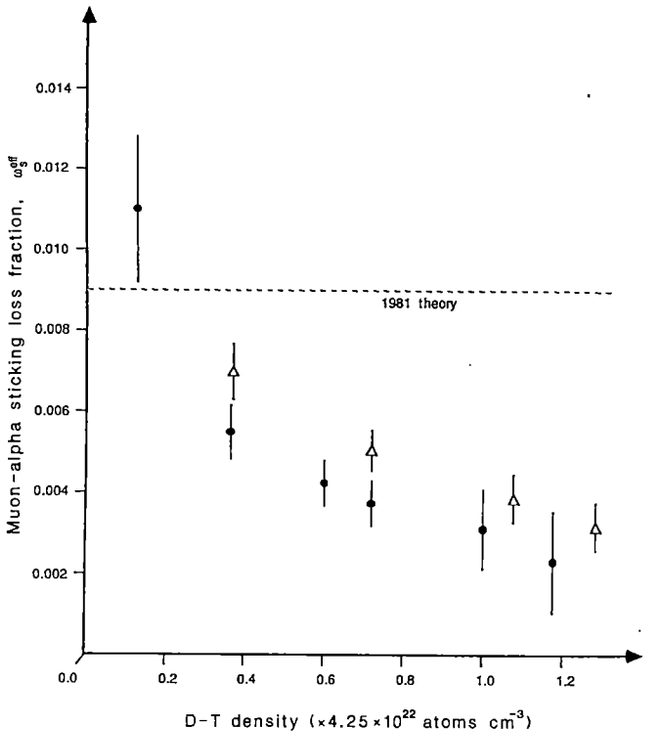

Fig. 4 Data from LAMPF showing the decrease in the deduced μ–α sticking fraction as the density of the duterium–tritium mixture is increased, for 50% tritium/50% deuterium (dots) and 30% tritium/70% deuterium (triangles). At high target densities, the μ–α sticking probability is clearly much lower than was predicted before the experiments were performed.

cycles (Figs 1 and 2); does this feature persist in d-t fusion?

Before 1985, theorists[1,10,27] predicted that the muon would be captured by the fusion-synthesized α-particle in $\omega_s^0 \simeq 1.2\%$ of muon-induced fusion reactions. Then, as the $\alpha\mu$ ion moves rapidly through the surrounding gas, there is a probability $R \simeq 24\%$ that the muon will be collisionally stripped from the α particle and thereby freed to continue the cycle. Thus, after slowing down in the gas, the muon would remain bound to the α-particle with probability $\omega_s = \omega_s^0(1-R) \simeq 0.9\%$. Muon loss due to capture by the synthesized α-particle is cumulative, so that the maximum number of d-t fusions which a muon could possibly catalyse would be $1/\omega_s \simeq 110$ (ref. 10). This limit would apply even if the muon were stable. Thus, the μ–α sticking probability ω_s was perceived to be the ultimate limit on the fusion yield from the muon catalysis cycle[1,10,17].

The only published measurements of ω_s are from the BYU/INEL/LANL experiments[5,20–23]. The deduced quantity ω_s^{eff} (expected to represent ω_s (ref. 5)) is shown in Fig. 4; the results were totally unexpected. Note the striking dependence of the apparent μ–α sticking loss fraction on the density of the D-T mixture. Moreover, the magnitude of ω_s at high gas density is approximately one-third the theoretical prediction of 0.9%. A possible dependence on tritium fraction is also suggested by the data but is statistically inconclusive.

Neither the smallness of ω_s nor its apparent density dependence is understood. Perhaps the muon stripping fraction R depends strongly on density and attains large values for dense D-T mixtures. Then $\omega_s = \omega_s^0(1-R)$ could become small for high densities. Although theorists are now re-examining muon stripping probabilities, this explanation does not appear promising. Or perhaps ω_s^0 itself varies with density; for example, ω_s^0 may depend on the state of the dtμ molecule from which fusion occurs (C.-Y. Hu, in preparation), which in turn could depend on density. It has also been suggested that a certain fraction of muons may be significantly delayed as the dtμ molecule cascades down from the excited state in which it is formed, thus increasing ω_s^{eff} above a small initial value[28]. Two years after the initial observation of this phenomenon at LAMPF, the puzzle persists. It is appropriate to emphasize that no independent confirmation of the LAMPF results has yet been published.

Interestingly, theoretical estimates of values ω_s have decreased significantly since small ω_s values were reported in 1984[21,23]. Jackson, who first calculated ω_s^0 using the Born–Oppenheimer approximation in 1957[10], estimated that corrections to that approximation would reduce ω_s^0 by ~25%[29]. In agreement with this estimate, a precision Monte Carlo calculation by Ceperley and Alder[30] yielded $\omega_s = 0.6\%$. These recent calculations are, however, still larger than the (high-density) experimental values. Mueller and Rafelski[31] argue that the (resonant) nuclear d–t interaction, neglected in other calculations, is capable of affecting the wave function describing the three-body dtμ system. This may have the effect of reducing the initial sticking to $\omega_s^0 \simeq 0.1\%$—a remarkably small value.

Although not yet understood, the BYU/INEL/LANL results clearly point to small ω_s values (Fig. 4). Thus, >300 fusions per muon may be possible in deuterium–tritium mixtures. In the past few years there has been a steady rise in the average number of d–t fusions per muon achieved at LAMPF: 20 in 1982, 80 in 1983 and 150 in 1984. Each step reflects an increased understanding of the rich physics underlying muon-catalysed fusion.

Hyperfine effects. In addition to the research in the Soviet Union and the United States, an experiment on muon-catalysed d–t fusion is in progress at the Swiss Institute for Nuclear Research (SIN). The work by Breunlich *et al.*[32] has so far focused on the fascinating possibility of hyperfine-structure effects.

It was recognized long ago that the reactions in muon catalysis could be influenced by the spin states of muonic atoms and molecules. Indeed, experiments at Columbia University[33] in the early 1960s showed that hyperfine transitions take place in muonic atoms, according to the reaction

$$d\mu(\uparrow\uparrow) + d(\downarrow) \rightarrow d\mu(\downarrow\uparrow) + d(\uparrow) \qquad (14)$$

By increasing the deuterium concentration in a liquid hydrogen target from 0.7 to 25%, Lederman and collaborators enhanced the population of $d\mu(\downarrow\uparrow)$ atoms. This in turn increased the population of those pdμ molecules in which fusion is most rapid, and the number of proton–deuteron fusions per muon increased by ~17% (Wolfenstein–Gershtein effect)[33]. Of course, the average yield was still less than one p–d fusion per muon.

Interest in hyperfine effects, as in muon catalysis generally, was stimulated by the discovery of the resonant formation of ddμ and dtμ molecules discussed above. Breunlich and coworkers repeated studies of hyperfine effects in hydrogen–deuterium mixtures[9], and then observed hyperfine effects in pure deuterium[34]. In particular, they found that the rate of resonant ddμ formation in $d\mu + D_2$ collisions depends strongly on the hyperfine state of the dμ atom. The experimental results can be described within the framework of the resonance formation model for ddμ molecules. Indeed, a rather complete picture of the energy levels of the muonic ddμ molecule, including hyperfine splitting, is anticipated from these experiments.

However, results of experiments conducted at SIN with mixtures of deuterium and tritium appeared to contradict theory. Time spectra of the fusion neutrons gave evidence of two distinct dtμ formation rates[32]. (This effect is also reported in the LAMPF experiments[22].) When the SIN experimenters interpreted their data in terms of hyperfine effects, the results were contrary to theoretical expectations. For instance, the evaluated rate of the spin-flip reaction

$$t\mu(\uparrow\uparrow) + t(\downarrow) \rightarrow t\mu(\uparrow\downarrow) + t(\uparrow) \qquad (15)$$

was much smaller than predicted and displayed an unexpected and strong dependence on temperature. Moreover, very little

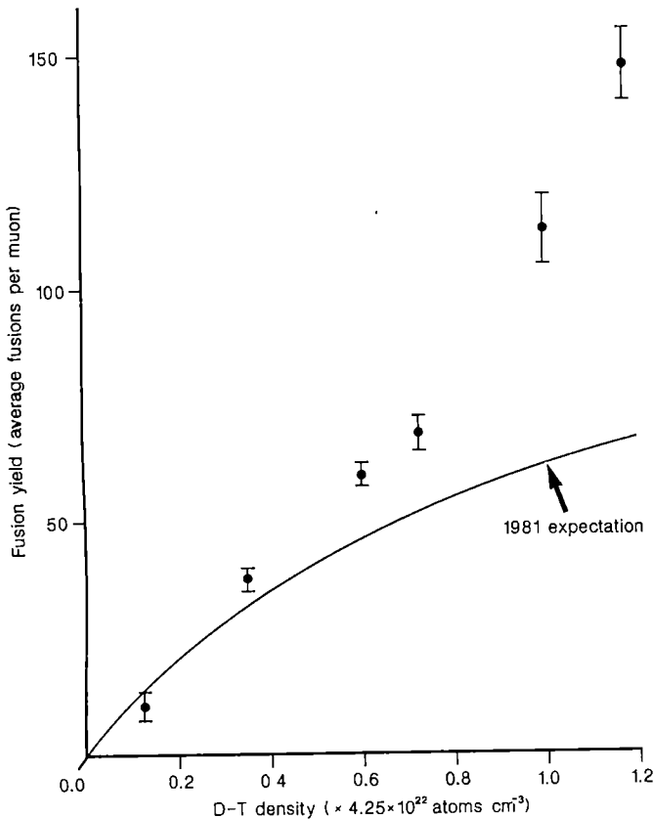

Fig. 5 The average number of muon-catalysed d-t fusion cycles observed by the BYU/INEL/LANL collaboration as a function of target density for cold ($T \lesssim 100$ K), equimolar deuterium-tritium mixtures. The solid line is based on experimental data[18,19] and theoretical predictions[37] as of 1981.

temperature dependence of the dtμ formation rate emerged from the analysis of the SIN data[32].

An alternative explanation has been recently advanced[24,35]: perhaps the data reflect different dtμ formation rates for thermalized or 'stopped' tμ atoms than for 'hot' recoiling tμ atoms. This is reminiscent of the way in which the recoil of dμ atoms accounted for the peculiar gaps observed in the Alvarez experiments. In the present case, a strong resonance for 'hot' tμ atoms colliding with D_2 or DT molecules would account for a very large dtμ formation rate. (This suggests the interesting possibility that if the gas were heated to ~1,200 K, dtμ formation would occur extremely rapidly[24].) The 'hot atom' model accounts for the observed density dependence of the neutron time spectra[22], among other features, and is now generally favoured over the hyperfine-effects interpretation. With this explanation, the fusion-neutron time spectra observed at LAMPF and SIN appear consistent with the resonant dtμ molecule formation model. Clearly, hyperfine effects will be more difficult to extract in dtμ catalysis than in ddμ and pdμ catalysis. In any case, only the lower-energy hyperfine state t$\mu(\uparrow\downarrow)$ should be significantly populated for tritium fractions $\geq$10% and densities $\geq 0.1 \times$ liquid-hydrogen density, because of the rapidity of the spin-flip reaction (15)[36].

Summary. The physics of muon catalysis in mixtures of deuterium and tritium is unexpectedly rich. The major processes and experimental values now thought to describe muon-catalysed d-t fusion are displayed in Fig. 3. By comparing Figs 1–3, one sees why the fusion yield for the muon-catalysed d-t fusion cycle greatly exceeds fusion yields in the p-d and d-d catalysis cycles. The average number of d-t fusion cycles per muon measured at LAMPF by the BYU/INEL/LANL collaboration is shown in Fig. 5. The observed yields at high D-T mixture densities exceed even the optimistic (resonance model) predictions[37], reflecting the discovery of a very small μ-α sticking probability[5].

Other reactions

Can muons induce fusion reactions involving elements heavier than hydrogen? The following reactions, for example, are appealing because there are no neutrons in the final state:

$$d + {}^3He \rightarrow {}^4He + p + 18.3\ MeV \quad (16a)$$

$$d + {}^6Li \rightarrow {}^4He + {}^4He + 22.4\ MeV \quad (16b)$$

A muonic molecule must form before muon catalysis can proceed[8,10] and the rates for d$\mu{}^6$Li and d$\mu{}^3$He formation have been calculated to be rapid relative to muon decay[38–40]. However, Coulomb repulsion in such cases is large, as is the nuclear separation, so the fusion rate is small[10,37]. The normal fate of the muon is to become irretrievably bound to the heavier isotope as the molecules dissociate in picoseconds[38–40].

Muon catalysis experiments involving hydrogen isotopes contaminated with ^{3}He (refs 20–23) or ^{4}He (refs 41, 42) provide a test of these predictions. Helium isotopes, are, in fact, observed to scavenge muons rapidly, thus poisoning the muon catalysis cycle. Consequently, it is desirable to keep helium and other non-hydrogen impurities at a low level[8]. It is intriguing that muon-catalysed fusion proceeds rapidly only for deuterium tritium mixtures.

Energy applications

In experiments performed by the BYU/INEL/LANL collaboration at LAMPF, an average fusion energy release of ~3 GeV per muon has been achieved and larger yields are expected[5]. The achieved fusion energy yield is 25 times greater than the total energy of the muon which drives the fusion reactions. However, muon-catalysed fusion as an energy source suffers from the lack of an efficient way to generate the muon catalysts. It appears that ~5 GeV must be invested to produce one negative muon by advanced techniques[43–48].

In 1980, Petrov[43,44] presented a clever scheme for a power reactor based on muon-catalysed fusion combined with nuclear fission processes and found that a commercial reactor would require ~100 fusions per muon. Others have examined and amplified the fusion/fission hybrid scheme and concluded that 100–300 fusions per muon would suffice for a power plant[45,46]. The LAMPF experiments demonstrate that such yields are indeed possible (see Fig. 5). A pure fusion reactor might require 1,000 fusions per muon, based on current ideas for efficient muon generation[51].

Figure 6 shows a schematic outline of a conceptual muon-catalysed fusion system based on the recent work of Eliezer *et al.*[50]. The first step is to form a beam of high-energy tritium nuclei using an efficient particle accelerator; the development of the radio-frequency (r.f.) quadrupole during the last decade represents a relative advance in accelerator technology. Grid-to-beam power conversion efficiencies as high as 60% appear achievable, along with high beam intensities (~200 mA)[53]. Dramatic progress in superconducting r.f. cavities for particle accelerators[52] may also find application here.

The high-energy (~1 GeV/nucleon) triton beam enters one or more pressurized D-T gas targets. Negative pions are copiously produced in ensuing nuclear collisions and these rapidly decay into muons. (The ratio of negative-to-positive pions and muons is enhanced through the use of neutron-rich tritium nuclei in the beam and the target[43,44,49].) Eliezer *et al.*[50] calculate pion/muon production and stopping rates in the D-T gas; a magnetic mirror effectively confines the charged particles to a small volume (~0.1 m^3). The muons are produced and stopped in the D-T fuel itself, which proves to be much simpler and more efficient than forming intermediate pion and muon beams as is conventionally done at accelerator laboratories, even

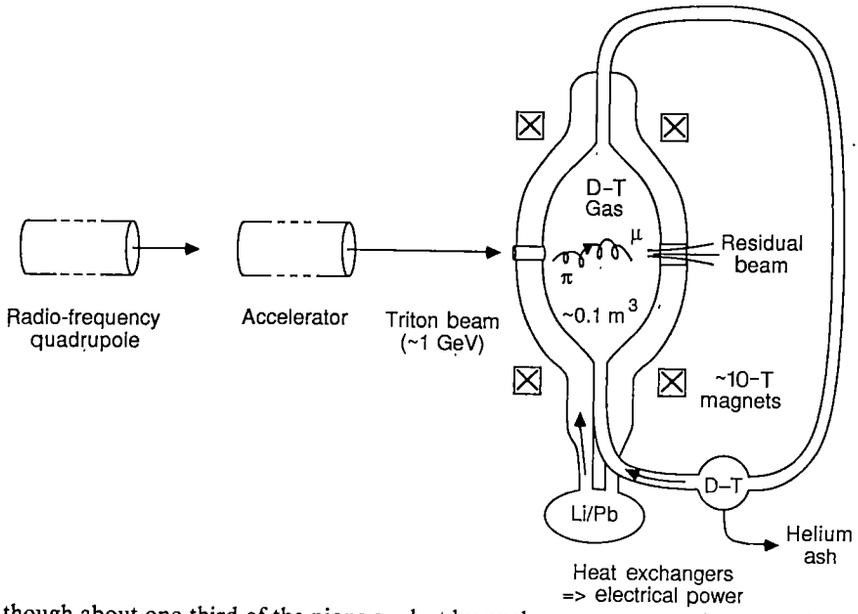

Fig. 6 A conceptual muon-catalysed fusion system, showing detail of a modular reaction vessel where muon-catalysed d-t fusion occurs.

though about one-third of the pions are lost by nuclear capture processes in the D-T gas.

Muons then spontaneously and rapidly catalyse fusion reactions in the D-T fuel as we have discussed, producing energetic α-particles and neutrons. The α particles stop within ~1 mm in the dense gas which protects the vessel walls from α-bombardment. The gas must be circulated to extract heat and ^{4}He, the inert product of the fusion reaction. Note that in a reactor environment, thermal neutrons would consume ^{3}He arising from tritium decay by the reaction (^{3}He+n→p+t)[53].

The energetic neutrons enter a lithium-lead eutectic melt, where they deposit heat and produce tritium by the reactions (n+^{6}Li→α+t) and (n+^{7}Li→n+α+t). A fertile isotope such as thorium could be used in the blanket to greatly amplify the energy gain from the muon-catalysed fusion neutrons[43–50].

A few researchers have studied ways of recovering the significant energy remaining in the form of energetic protons and neutrons following muon production[43–50]. One approach is to use the residual beam to breed fissile fuel; for example, spent fuel rods from fission reactors could be renewed without chemical reprocessing. Alternatively, the energy of charged particles could be recovered directly; neutrons would first produce energetic protons through inelastic collisions (G. Chapline, personal communication). Alvarez (personal communication; see also ref. 49) and Eliezer *et al.*[50] have independently suggested that beam particles which do not interact strongly with the target could be collected, re-accelerated and re-circulated into the reaction chamber.

The scheme of Fig. 6 can be characterized as a power amplifier, with input power to the accelerator ultimately driving the muon-catalysed fusion reactor. There is neither plasma to heat nor danger of thermal runaway. However, it is clear that for such a scheme to succeed: (1) hundreds of fusions per muon must be achieved; (2) muons must be produced cheaply (<10 GeV per muon); and (3) many engineering problems must be solved. Research now centres on the first issue: we are surprised to observe so many catalysed d-t fusions per muon (see Fig. 5) and we are exploring the limits of the process. A better understanding of the physics may suggest ways to further enhance the cold fusion process. The research could thus lead to the serious consideration of muon-catalysed fusion as an energy source.

Conclusion

A resonance which allows muonic dtμ molecules to form in less than one-thousandth of the muonic lifetime is indeed a remarkable phenomenon. The resonant process has been observed when negative muons are stopped in 'cold' mixtures of deuterium and tritium gases and leads to rapidly induced nuclear fusion reactions. This effect could hardly have been predicted from the studies of muon reactions in liquid hydrogen and deuterium 30 years ago. The discovery of this resonance in the last few years has reawakened interest in muon-catalysed fusion.

On top of this surprise comes another: the retention of muons by α-particles synthesized during d-t fusion is much less severe than expected. Muon catalysis research now focuses on confirming and understanding this discovery. Together these phenomena imply that each muon may catalyse hundreds of d-t fusion reactions, releasing a great deal of fusion energy. Not surprisingly, these discoveries, along with advances in accelerator technology, have renewed interest in muon-catalysed fusion as a potential energy source. One might say that muon-catalysed fusion is an idea whose time has come—again.

My colleagues deserve recognition for years of dedicated effort: Alan Anderson, James Bradbury, Gus Caffrey, James Cohen, Peter Gram, Mel Leon, Richard Maltrud, Michael Paciotti, Clinton Van Siclen and Kenneth Watts. I particularly acknowledge also the support of early pioneers in muon catalysis research, Luis Alvarez, David Jackson, David Judd, and Leon Lederman, and of recent bold thinkers such as Leonid Ponomarev, Johann Rafelski and Marshall Rosenbluth. Finally, I thank Ryszard Gajewski of the US Department of Energy, Division of Advanced Energy Projects, for financial support and encouragement.

Note added in proof: Results of the SIN experiment[55] confirm that μ–α sticking is small: $\omega_s^0 = (0.45 \mp 0.05)\%$ for liquid D-T mixture, in good agreement with LAMPF result (Fig. 4).

Splice-site selection by a self-splicing RNA of *Tetrahymena*

Richard B. Waring*§, Paul Towner*, Stephen J. Minter*† & R. Wayne Davies°†‡

* Department of Biochemistry and Applied Molecular Biology, University of Manchester Institute of Science and Technology, PO Box 88, Manchester M60 1QD, UK

† Allelix Inc., 6850 Goreway Drive, Mississauga, Ontario, Canada L4V 1P1

5′ Splice-site selection by the self-splicing Tetrahymena *ribosomal RNA precursor requires the formation of a particular RNA helix by base pairing between an intron 'guide sequence' and bases surrounding the 5′ splice junction. Part of the guide sequence subsequently holds and positions the 3′ end of the cut 5′ exon to attack the 3′ splice junction.*

THE way in which splice sites are selected so precisely is a central question for all systems in which RNA splicing occurs, for a particular phosphodiester bond must be singled out from thousands of bonds that are chemically nearly identical. This specificity can be conferred only by higher-order molecular structure. The intron of the large ribosomal RNA precursor of *Tetrahymena thermophila* is excised, and the flanking exons ligated together in the absence of proteins[1,2]. In this case, the splice junctions are defined, and catalysis carried out, by elements of RNA structure only. The capacity to form a particular set of RNA helices, including several involving distant RNA sequences, is conserved throughout the class of introns to which the *Tetrahymena* intron belongs[3]. Davies *et al.*[3] showed that the capacity for exon sequences near the 5′ and 3′ splice junctions to base pair with an intron 'internal guide sequence' was also conserved, and proposed that these RNA helices could be important for defining the splice junctions and bringing both ends into the active site. We have used second-site suppression as a genetic tool to investigate the roles of these RNA structural elements in this RNA-catalysed RNA splicing reaction.

The RNA self-splicing reaction can be regarded as consisting of two subreactions, one at the 5′ and one at the 3′ splice junction—a simultaneous cleavage and ligation reaction in which phosphodiester bond energy is conserved—occurring via *trans*-esterification (phosphoester transfer)[1,2]. The intron RNA takes up a very specific structure[3-9], binds a guanosine cofactor[10] and can then catalyse the RNA splicing reaction if magnesium ions are present[1]. The intron is excised as a unique linear molecule with the guanosine added to the 5′ end, and subsequently autocyclizes[11-15]. All genetic[16-20] and biochemical[21] evidence is consistent with an RNA secondary structure closely related to that shown in Fig. 1*A*[3,5]. The *Tetrahymena* ribosomal RNA intron is the biochemically best-studied member of a widespread class of introns (class I of fungal mitochondria) all of which are potentially self-splicing and have this RNA structure[5,6,8]. Two mitochondrial introns of this class have been shown to be self-splicing[22,23].

Each subreaction involves an attacking hydroxyl group and a target phosphodiester bond. We show that the formation of a short RNA helix involving an intron '5′ guide sequence' and bases around the 5′ splice junction is essential for 5′ splicing. The structure of this helix and its position within the complete RNA structure define which phosphodiester bond is the 5′ splice site. Part of the 5′ guide sequence has a further role, positioning the attacking hydroxyl group in the 3′ subreaction, which can be separated from the 5′ subreaction. We are thus able to begin to dissect the RNA splicing reaction, and provide the first direct evidence that identifies elements of the mechanism by which a splice junction is selected.

Role of base pairing

A definitive way of demonstrating that interaction occurs between distant portions of RNA (or protein) molecules is to obtain second-site revertants of mutations that affect function. If, in an RNA molecule, the suppression of the original mutant phenotype by the second-site mutation is correlated with the restoration of the capacity to form a base pair disrupted by the first mutation, it follows that the capacity to form this base pair is important for the function that is altered in the mutant phenotype. The base-paired region may be a semi-permanent feature of the RNA structure, or may form transiently but still

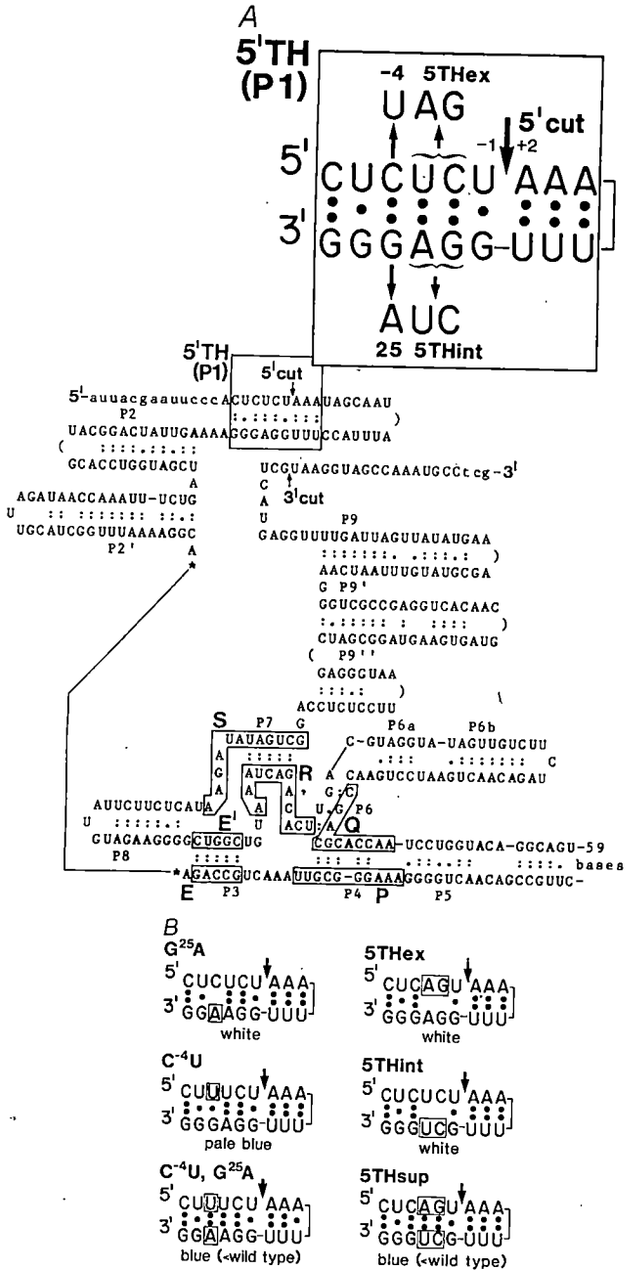

Fig. 1 Wild-type and mutant forms of the *Tetrahymena thermophila* rRNA intron. ***A***, RNA secondary structure of the wild-type intron[5] according to the model of Davies *et al.*[3] as given in ref. 34, showing mutations introduced into the P1 (5′TH) structure. *Tetrahymena* sequence is in upper-case letters and β-gal and M13 polylinker sequence derived from the constructions of Waring *et al.*[18] are in lower-case letters. M.TET.14 (ref. 18) contains 17 *Tetrahymena* exon bases in the 3′ exon. Splice sites are indicated by arrows and all features have been described previously[3,5,8]. P, Q, R and S are conserved sequences found in all introns of this class[3,8]. 'P' in P2–P9 indicates a pairing region; only a part of each conserved sequence is involved in base pairing (P4 for P–Q; P7 for R–S). The P10 pairing[3] between the internal guide sequence and 3′ exon bases is not found in all introns of this class[8], and is therefore not shown here. Its role in RNA self-splicing by the *Tetrahymena* RNA intron will be discussed separately (R.B.W. and R.W.D., in preparation). E and E′ are non-conserved sequence elements that are always able to form a conserved long-range pairing (P3). Genetic evidence for the functional importance of the P–Q, E–E′ and R–S pairings are described in refs 18–20, respectively. The P2′, P9′ and P9″ stem–loop structures are not found in typical class I introns[8], which only have single P2 and P9 stem–loops. Asterisks indicate the point where the structure has been broken in order to be able to display all key base-paired regions. Bases are numbered by taking the 5′ cut site as 0, numbering 5′ exon bases in the 3′ to 5′ direction starting with −1 next to the 5′ cut site, and numbering intron bases in 5′ to 3′ order as in the excised intron, so that base 1 (5′) is the G derived from the guanosine cofactor and is not present in the non-excised intron in the RNA precursor. G^{25} is thus seen as the 24th base 3′ to the 5′ cut site in ***A***. ***B***, Model 5′ splicing target helix structures for the mutant introns. Oligonucleotide site-directed mutagenesis was performed as described by Zoller and Smith[35]. All mutants were sequenced from the *Eco*RI to the *Hin*dIII sites[18] of M83.TET.14 to ensure that no other mutations were obtained during the mutagenesis procedure. Mutant phenotypes were scored from at least four independent mutations.

be functionally important. Davies *et al.*[3] noted that a particular region of RNA near the 5′ end of class I introns[8], including the *Tetrahymena* rRNA intron (the internal guide sequence), is always capable of base pairing with both exon and intron bases flanking the 5′ splice junction, and usually[8] can also use adjacent bases to base pair with 3′ exon bases near the 3′ splice junction. The pairing of the internal guide sequence with bases at the 5′ end of the intron and at the 3′ end of the 5′ exon would form a particular RNA helix called P1, with the phosphodiester bond that is the target for 5′ cleavage in one strand within the helix. Our starting point was the hypothesis that the formation and structure of this helix provide the information that identifies the 5′ splice junction.

We have made two sets of mutations in the short RNA helix named P1, which we now refer to as the 5′ splicing target helix (5′TH) (see Fig. 1). Mutations affecting splicing were easily identified using the system of Waring *et al.*[18]. M83.TET.14 is an M13mp8.3 bacteriophage derivative, with the *Tetrahymena* intron (and short sections of the flanking exons) inserted so that the synthesis of the β-galactosidase α-fragment is prevented unless the intron excises itself *in vivo* in *Escherichia coli*. Phages carrying wild-type introns, which self-excise, make β-galactosidase and give blue plaques on Xgal-containing medium, whereas phages carrying introns defective for RNA splicing produce white plaques. One mutation in the 5′ exon component of 5′TH was picked up as a pale blue plaque in screening phage M83.TET.14[18] for spontaneous splicing-deficient mutants. This $C^{-4}U$ mutation (see Fig. 1 legend for the numbering convention) would form a 5′TH that has lost one of its three key G·C base pairs, but still has a weak U·G base pair rather than no base pair at all at this site. This mutation produces a Phe-to-Ser exchange in the extreme amino-terminal region of the β-galactosidase α-fragment. The steady-state level of excised intron in M83.TET.14$C^{-4}U$-infected *E. coli* is approximately 10% of that found in M83.TET.14-infected *E. coli*, showing that intron excision in this mutant is impaired.

Oligonucleotide-directed *in vitro* mutagenesis was used to generate the intron mutation $G^{25}A$. The $G^{25}A$ mutant itself gives a white plaque on minimal medium (Fig. 2) and is therefore more defective than the $C^{-4}U$ mutant. The double mutant $C^{-4}U$,$G^{25}A$ has a plaque colour phenotype sightly less blue than that of the wild type (Fig. 2), indicating that the $C^{-4}U$ mutation

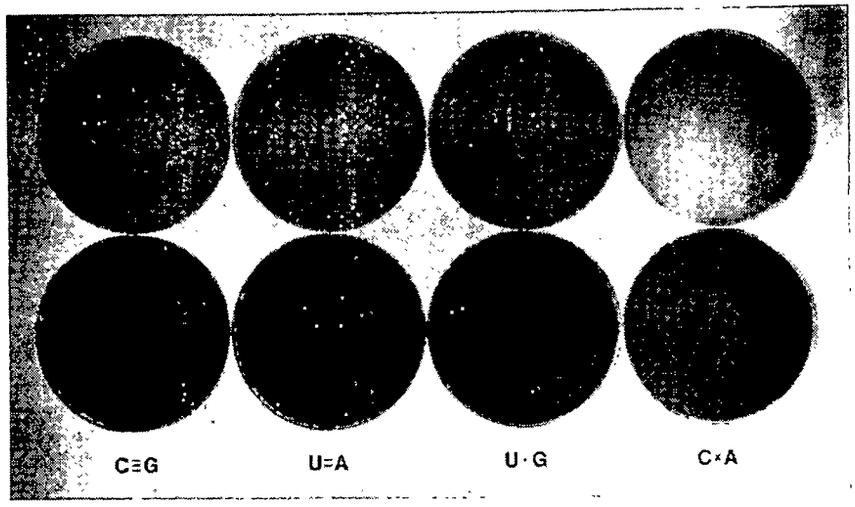

Fig. 2 Plaque phenotypes of M83.TET.14 and M83.TET.14 carrying mutants in the 5′ splicing target helix. The base pair present at position −4 in 5′TH (P1; Fig. 1) is given in each case to show the corelation between phenotype and the stability of 5′TH. From left to right, the phages are M83.TET.14 (C≡G), $C^{-4}UG^{25}A$ (U=A), $C^{-4}U$ (U·G) and $G^{25}A$ (C/A). The top row of plates are of minimal medium, the lower row of YT medium. More intron excision is needed on YT than on minimal medium to produce the same plaque phenotype, which helps to distinguish between partial mutations[18]. For example, $C^{-4}U$ and $C^{-4}UG^{25}A$ are both a fairly similar pale blue on minimal medium, but $C^{-4}U$ is virtually white on YT and $C^{-4}UG^{25}A$ still pale blue.

suppresses the phenotype of the $G^{25}A$ mutation and vice versa; the only reasonable explanation for this is that C^{-4} and G^{25} are normally base paired, that $C^{-4}U$ and $G^{25}A$ weaken or destroy this base pair, and that $C^{-4}U,G^{25}A$ replaces the original C·G base pair with a U·A base pair. The plaque phenotypes of these four phages, and therefore the efficiency of intron excision, are precisely in the order of the known strength of the base pair that each phage has in the −4 position of 5′TH—C≡G> U=A>U·G>C/A (Fig. 2)—as would be expected if base pairing underlies the function affected.

A second set of mutations (Fig. 1*B*) affecting different bases also predicted[3] to be involved in forming 5′TH was made by *in vitro* mutagenesis, with two adjacent bases being altered for generating more extreme phenotypes, so as to facilitate *in vitro* RNA splicing analysis. The mutant phages are M83.TET.14 $U^{-3}A$, $C^{-2}G$ (5THex; Fig. 1*B*) and $G^{23}C$, $A^{24}U$ (5THint; Fig. 1*B*), both of which give white (intron excision-defective) plaques on minimal medium. The predicted second-site revertant combination (5THsup; Fig. 1*B*) would have a 5′TH containing the same base pairs as the wild type, in the same order, but with the purine–pyrimidine positions reversed (Fig. 1*B*). 5THsup plaques are almost as blue as wild-type plaques. Therefore, the pairs of double base-changes suppress each other's effects on intron excision. The occurrence of second-site suppression shows that any effects due to alteration of the β-galactosidase sequence by the exon mutants are not of primary importance, and that the capacity of the affected sequences to base pair is essential for normal intron function.

The phenotypes of these mutants were examined further in *in vitro* RNA splicing assays. Introns (with flanking exons as in Fig. 3*A*) carrying 5THex, 5THint or 5THsup mutations were subcloned into pSP65 (Fig. 3*A*) and transcribed *in vitro*; RNA was prepared and *in vitro* RNA splicing reactions were performed. Figure 3*B* shows the results of a typical *in vitro* RNA splicing experiment. The relevant data here are the levels of excised intron (IVS) and ligated exons (5E3E) produced; the origin of the novel products Y and Z is described below. The 5THex mutant is completely defective, producing no excised intron at all; clearly, this mutant is blocked in the very first step of RNA splicing. The 5THint mutant is slightly less defective, producing a very low but detectable amount of excised intron only in the presence of GTP; the GTP dependence of this reaction shows that the excised intron RNA is produced by the standard splicing reaction, and not by some side reaction. 5THsup produces a significant amount of excised intron in a GTP-dependent reaction, showing that the splicing defects of 5THex and 5THint are suppressed *in vitro*. The level of intron excised is not fully that of the wild type, and significant amounts of the novel products Y and Z generated by the 5THint mutant are still made by 5THsup, so that suppression is not total.

These results show that if we alter the capacity of a particular intron sequence—which we refer to as the 5′ guide sequence (5′GS:5′UUUGGAGGG3′; Fig. 1*A*)—to base pair with the exon sequence adjacent to the 5′ splice junction, RNA splicing is severely blocked. As all the base pairs affected are precisely those that would be centrally located in 5′TH (Fig. 1*A*), it follows that the capacity to form 5′TH is crucial for at least the 5′ cleavage and ligation reaction. There is corroborative *in vivo* genetic evidence from yeast mitochondrial class I introns, as splicing-defective 5′ exon mutations that would affect the 5′THs of cytochrome *b* introns 4 (refs 16, 24) and 5 (P. S. Perlman, personal communication) have been isolated, and one of the classes of revertants of the *cobI4* mutation is in 5′GS and would restore base pairing in 5′TH.

Factors influencing splicing rate

To determine the extent of phenotypic suppression in the 5THsup intron, a time course of the *in vitro* splicing reactions of wild-type and mutant introns (Fig. 4) was carried out. If the base pairing in 5′TH is restored, the splicing defect is suppressed, but splicing is still slow *in vitro*, reaching in 48 min less than half the level of excised intron produced by wild type in 1 min. This is not a result of depletion of the precursor by the reaction yielding Y and Z, as the generation of these products is particularly favoured in RNA transcripts generated from *Pvu*II-cut pSP65 (see below), and RNA splicing of 5THsup in transcripts from *Hin*dIII-cut pSP65, which produce very little Y, occurs at much the same rate (data not shown). The number of hydrogen bonds that can be formed between bases in the wild-type and 5THsup 5′ splicing target helices is the same, so that it is the alteration in the sequence of base pairs in 5′TH that changes the rate of RNA splicing. Moreover, 5THint produced some excised intron and ligated exons but 5THex did not.

Separable 5′ and 3′ reactions

A striking property of the 5THint mutant is the production of large amounts of two completely new RNA species, bands Y and Z, in a GTP-independent reaction. Because the guanosine cofactor is required[1] for the nucleophilic attack that initiates the 5′ cutting reaction, Y and Z must be produced by a reaction that bypasses 5′ cutting, such as a novel version of the 3′ cleavage–ligation reaction. Also, the function affected by the 5THint mutant is a function of the intron strand involved in the formation of 5′TH, and not of the exon strand of 5′TH or 5′TH itself. Both 5THint and 5THex mutations (Fig. 1*A*) disrupt the same two base pairs of 5′TH, yet 5THint makes large amounts of Y and Z, whereas wild-type and 5THex make no Z and very little Y (Fig. 3*B*). The structure of Y and Z reveals the nature of the bypass reaction. Y behaves as a linear molecule in different gel conditions, and is 437 nucleotides long, which corresponds

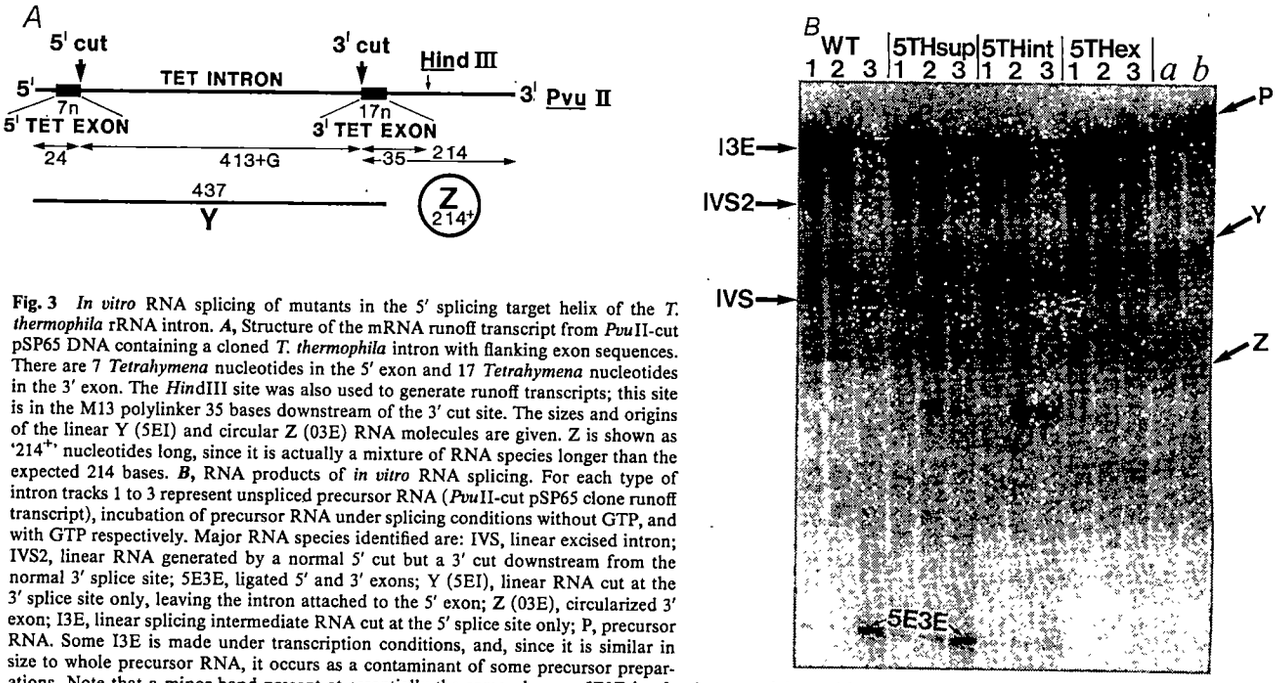

Fig. 3 *In vitro* RNA splicing of mutants in the 5′ splicing target helix of the *T. thermophila* rRNA intron. ***A***, Structure of the mRNA runoff transcript from *Pvu*II-cut pSP65 DNA containing a cloned *T. thermophila* intron with flanking exon sequences. There are 7 *Tetrahymena* nucleotides in the 5′ exon and 17 *Tetrahymena* nucleotides in the 3′ exon. The *Hin*dIII site was also used to generate runoff transcripts; this site is in the M13 polylinker 35 bases downstream of the 3′ cut site. The sizes and origins of the linear Y (5EI) and circular Z (03E) RNA molecules are given. Z is shown as '214^{+}' nucleotides long, since it is actually a mixture of RNA species longer than the expected 214 bases. ***B***, RNA products of *in vitro* RNA splicing. For each type of intron tracks 1 to 3 represent unspliced precursor RNA (*Pvu*II-cut pSP65 clone runoff transcript), incubation of precursor RNA under splicing conditions without GTP, and with GTP respectively. Major RNA species identified are: IVS, linear excised intron; IVS2, linear RNA generated by a normal 5′ cut but a 3′ cut downstream from the normal 3′ splice site; 5E3E, ligated 5′ and 3′ exons; Y (5EI), linear RNA cut at the 3′ splice site only, leaving the intron attached to the 5′ exon; Z (03E), circularized 3′ exon; I3E, linear splicing intermediate RNA cut at the 5′ splice site only; P, precursor RNA. Some I3E is made under transcription conditions, and, since it is similar in size to whole precursor RNA, it occurs as a contaminant of some precursor preparations. Note that a minor band present at essentially the same place as 5E3E is of unknown origin, and is present in precursor preparations. The low levels of 5EI (Y) which occur in wild type (WT) and the 5THex mutant probably result from the known tendency of this intron to undergo hydrolysis at the 3′ splice junction at a low rate[15]. The two tracks on the far right are *in vitro* RNA splicing with precursors of mutant 29 (track *a*) which produces more 5EI/03E than wild type, but has a wild-type 5′TH (R.B.W. and R.W.D., unpublished), and the 5THex mutant (track *b*), incubated under splicing conditions with no GTP and 4 mM spermidine, showing stimulation of 5EI and 03E production by spermidine, which can stabilize weak RNA helices[26,27].

Methods. The 458-bp *Eco*RI–*Hin*dIII fragments from M83.TET.14 mutants were purified and shuttled into the pSP65 transcription vector[25]. pSP65 clones were linearized with *Pvu*II, phenolized and ethanol-precipitated. RNA was synthesized by incubating 2 μg of DNA in the recommended buffer[25] including 4 mM spermidine (which promotes transcription, but partially inhibits splicing[1]), bovine serum albumin (100 μg ml^{-1}), RNasin[25] and 5 U of SP6 RNA polymerase at 37 °C in a final volume of 50 μl. ^{32}P-GTP (20 μCi, 400 Ci mmol^{-1}; Amersham) in the presence of 20–50 μM GTP was used to label the RNA, which was then phenolized, ethanol-precipitated, resuspended in water and loaded onto a 7 M urea/5% polyacrylamide gel after the addition of at least 1 vol. of loading dye (deionized formamide containing 40 mM EDTA, 0.1% bromophenol blue). The gel was made and run exactly as a DNA sequencing gel[36]. *Hin*fI-digested M13mp8 was used as a size marker. RNA was located by autoradiography. Acrylamide strips were cut out, crushed and the RNA eluted overnight in 0.3 M Na-acetate, 20 mM Tris *p*H 8.0, 1 mM EDTA at 4 °C. Gel fragments were removed by centrifugation or filtration through siliconized glass wool and the RNA was then ethanol-precipitated twice at −20 °C. Attempts to clean RNA preparations using a variety of affinity chromatographic media, reverse-phase chromatography and Sephadex G-50 did not increase the initial rate of splicing and frequently reduced yields. RNA was stored frozen at −20 °C in 10 mM Tris *p*H 7.4, 0.1 mM EDTA. Unless otherwise indicated, splicing reactions[1] were performed in siliconized 0.5-ml Eppendorf tubes in 10 mM $(NH_4)_2SO_4$, 30 mM Tris *p*H 7.5, 5 mM $MgCl_2$ and 0.2 mM GTP at 37 °C for 30 min. Splicing was stopped by addition of at least 1 vol. formamide loading dye[36]. Samples were run on polyacrylamide gels as described above. Gels were fixed and usually exposed at room temperature without an intensifier screen.

precisely to the size of molecule consisting of the joined 5′ exon and intron, '5EI'. The presence of the 5′ exon in Y was confirmed by generating a complementary DNA runoff transcript of the expected size using an oligonucleotide that primes only 18 bases downstream of the 5′ splice junction within the intron. The mobility of Z varies with the strength of the polyacrylamide gels, as is typical of circular molecules. Purified Z, when nicked, gives two linear molecules 215 and 216 nucleotides long in roughly equal proportions, corresponding to the expected length (Fig. 3*A*) of the 3′ exon plus one or two nucleotides respectively. As sequencing (Fig. 5) established that the 3′ end of the precursor transcript had been joined to the first base of the 3′ exon, Z must be the circularized 3′ exon, '03E'. 03E contains either one or two extra nucleotides at the circularization point which are not in the DNA template. The runoff transcript itself (and all derivatives of it which contain the 3′ exon) is an approximately equal mixture of RNA molecules with one or two additional nucleotides which must be at the 3′ end and are presumably added spontaneously by SP6 polymerase, an effect observed previously[25]. Thus, the bypass reaction is a cleavage and ligation reaction involving cleavage at the normal 3′ splice site, with ligation of the free 3′ end of the RNA precursor to the 5′ end of the cut 3′ exon, producing a circular 3′ exon (Z, 03E) and a linear molecule comprising the intron joined to the 5′ exon (Y, 5EI).

The generation of 5EI and 03E by the 5THint mutant is 1/10th to 1/20th as rapid as normal splicing by the wild-type intron, and thus 5THint RNA carries out a rapid 3′ splicing reaction analogue while it is almost completely blocked for 5′ cleavage and ligation. 5EI molecules, which lack the 3′ exon, also undergo 5′ cleavage in the absence of a 3′ reaction, and the relative rates of 5′ cleavage for molecules with wild-type, 5THint, 5THex and 5THsup sequences are as expected from the above results (data not shown). The 5′ and 3′ cleavage and ligation reactions are separable, and 5′TH is involved only in the 5′ subreaction.

Positioning of attacking group

The fact that the high 03E and 5EI production results from the 5THint mutation means that the intron sequence altered by this mutation must be involved. In the runoff transcript from *Pvu*II-cut template, the RNA precursor should end in 5′CCAG3′ (actually it ends with 5′ CCAGN(N′)3′; Fig. 5), which can pair precisely with the sequence 5′CUGG3′ containing the double base change (GA→CU) of 5THint compared with wild type. The 3′ end of the transcript can then substitute for the cut 5′ exon. This hypothesis predicts that the phenomenon will be specific to DNA transcripts containing a *Pvu*II end, since sequences adjacent to other restriction enzyme sites will not pair as well with the 5′TH intron strand of 5THint. Table 1 shows that this is the case; the reaction generating 5EI and 03E is much less frequent using runoff transcripts from templates containing *Hin*dIII, *Hpa*II or *Hin*fI ends. The amounts of 5EI and 03E produced actually correlate well with the strength of potential pairing between the end of the RNA transcript and the key region of intron RNA (Table 1), and their amounts are increased

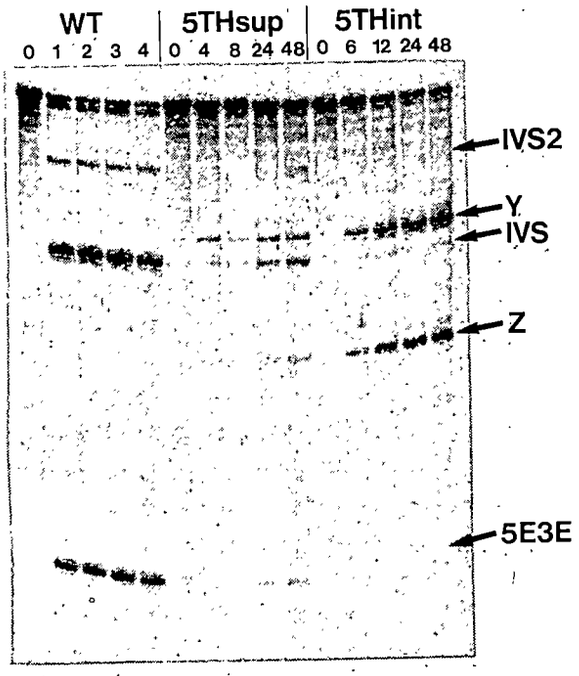

Fig. 4 Time course of *in vitro* RNA splicing of mutant and wild-type *Tetrahymena* rRNA introns. Numbers above each track indicate the time in minutes at which samples were taken. Runoff transcripts from *Pvu*II-cut pSP65 clones were generated, purified and incubated under splicing conditions as described for Fig. 3*B*, except that splicing was performed at 30 °C, rather than 37 °C. Major RNA species are labelled as in Fig. 3*B*.

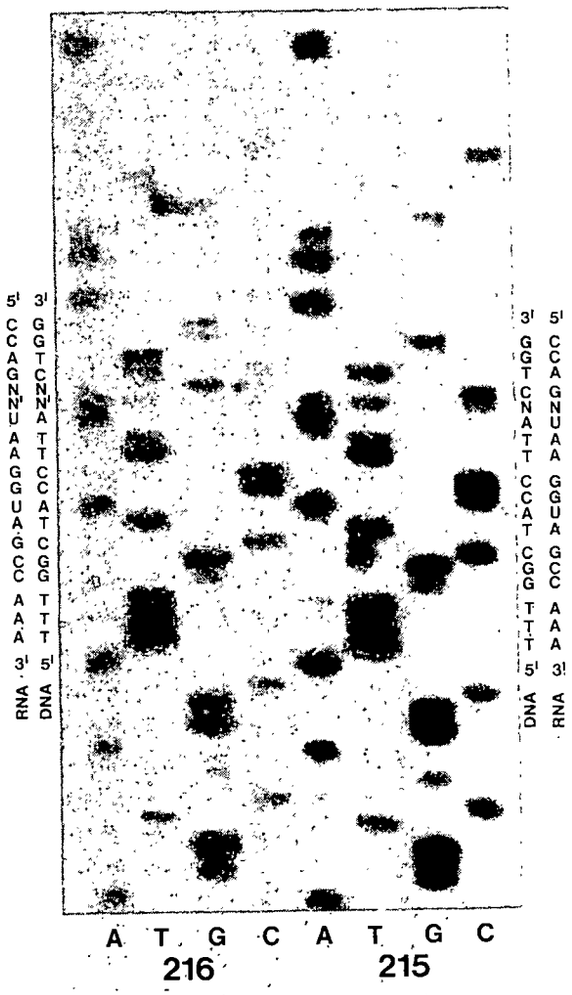

Fig. 5 Nucleotide sequencing of the circularization site of the circular 3′ exon (03E). The two 03E bands (215 and 216 nucleotides long) were separated, and the sequences of both are shown side by side; note that the sequences run parallel until the circularization site, where they shift 1 base out of phase. DNA sequences read directly from the gels are shown alongside, together with the RNA complement which is the true sequence of the 03E molecule in this region. The sequence appears to become unclear after the circularization point; this is because the two 03E species could not be obtained completely without cross-contamination, and their sequences are, of course, shifted by 1 base relative to each other after the circularization point. The 215 03E has one extra base at the circularization site, the 216 03E has two. In the RNA, N is A > U > G ≫ C in the 215-nucleotide 03E. In the 216-nucleotide 03E, N is C > A, U, G, N′ is U > A ≫ C ≥ G.

Methods. RNA was purified as described for Fig. 3. Sequencing was carried out using the dideoxy procedure with reverse transcriptase at 42 °C and priming from ^{32}P-end-labelled M13 reverse sequencing primer (Amersham), which pairs with the downstream exon. The reaction mixes were treated with RNase before boiling and loading onto gels. 03E RNA was produced in sufficient amounts for this experiment by incubating precursor transcript from a pSP65 clone of the 5THint mutant intron under splicing conditions for 1 h. More than 90% of the precursor was converted to 5EI and 03E in this time.

in the presence of spermidine, which stabilizes weak RNA helices[26,27].

Our experiments identify the binding site within the catalytic RNA molecule for the nucleotide sequence (normally the 3′ end of the cut 5′ exon) that carries the 3′ hydroxyl attacking group for the second (3′) step in the RNA splicing reaction; we will refer to the binding site as the 3′ attack site (3′AS). The nucleotides making up 3′AS are a subset of those in the 5′ guide sequence. In the 5THint mutant the sequence of 3′AS is 5′(G)CUGG3′; the wild-type equivalent is 5′(G)GAGG3′. Figure 6 outlines the role of 3′AS in the generation of 5EI and 03E. The reaction described here ('3′ end invasion') is intramolecular, but a clear prediction is that any RNA fragment or oligonucleotide that can pair with the bases 5′[G]GAGG[G]3′ to place a 3′ hydroxyl end correctly will be used as an alternative to the cut 5′ exon if provided in sufficient concentration ('oligonucleotide invasion'). This is consistent with the recent results of Cech and co-workers[28]. Mutants with a weak, unstable 5′TH will be particularly susceptible to oligonucleotide invasion, which would lead to *trans* activity of this RNA catalyst.

Conclusions

Our results lead us to draw three major conclusions about the mechanism of RNA splicing for self-splicing class I introns: (1) the formation, at least transiently, of a short RNA helix (5′TH; 5′ splicing target helix) between an intron 5′ guide sequence and bases surrounding the 5′ splice junction, is essential for the selection of the 5′ splice site and for 5′ cleavage and ligation; (2) the 5′ and 3′ cleavage and ligation reactions are completely separable; (3) a subset of the intron bases in the guide sequence (those that pair with 5′ exon bases) serves to retain and position the cut 5′ exon, or any externally supplied partner sequence with a free 3′ OH end, to attack the 3′ splice junction. In Fig. 6 these conclusions are incorporated into the present understanding of the RNA-catalysed splicing reaction.

As the 3′ splicing bypass reaction occurs at a significant rate (1/10th that of normal splicing), some detailed inferences concerning the structures involved can be drawn. First, the nature of the last base of the cut 5′ exon is not crucial for 3′ cutting, as this base is highly variable on the 3′ end of the precursor transcript due to the semi-random addition of nucleotides by SP6 RNA polymerase. Also, the hydroxyl that attacks the 3′

The potential to form 5′TH or 3′AS-RNA 3′ end structures is correlated with the production of normal splicing products (I/5E3E) and unusual RNA molecules derived by 3′ cleavage and ligation only (5EI, Y; 03E, Z) in *in vitro* RNA splicing reactions. 5′TH, 5′ splicing target helix (P1 in refs 3, 5, 8, 9); 3′AS, 3′ attack site; 5EI, linear fused 5′ exon and intron; 03E, circular 3′ exon; I, excised intron; 5E3E, ligated 5′ and 3′ exons. 5′TH is essential for 5′ cleavage–ligation, and the 3′AS–RNA 3′ end pairing is proposed as the basis of the 3′ end invasion reaction that generates 5EI and 03E. The strongest base pairing possible is given in all cases, whether or not such a pairing is potentially stable. The arrow in 5′TH indicates the 5′ splice junction. The 3′ end of the RNA transcript is shown with one or two semi-randomly added nucleotides, as described in Fig. 5 legend. 5THint, 5THex and 5THsup mutants are described in the text; bases differing from wild type are underlined. *Pvu*II, *Hpa*II and *Hin*fI refer to the restriction enzymes used to cut the pSP65 clone DNA template, which determines the end of the runoff transcript. The lengths of the 3′ exons, not including bases added by SP6 polymerase, are: *Hin*dIII, 35; *Hpa*II, 110; *Pvu*II, 214; *Hin*fI, 228. Data for transcripts from *Hin*dIII-cut DNA are not included here, as the very small 03E from this reaction was not identified clearly. Production of various RNA molecules is scored semi-quantitatively on a scale of 0(−) to 5(+++++), based on data obtained under standard splicing conditions. Symbols in parentheses refer to data obtained in the presence of 4 mM spermidine under normal splicing conditions. The production of 03E is the crucial indicator of the 3′ end invasion reaction, as low background levels of 5EI are produced by spontaneous scission at the 3′ splice site[15]. The relative success of the normal 5′ splicing and 3′ end invasion reaction depends on: (1) the potential for base-pairing between the 3′ end of the transcript and 3′AS; (2) the relative stability of 5′TH, the 3′AS–5′ exon pairing, and the 3′AS–RNA 3′end pairing. With 5THint in a transcript from *Pvu*II-cut DNA, normal splicing is rare because of the defective 5′TH, but the bypass reaction is frequent because of the pairing of the 5′CUGG3 sequence with the 3′ end of the RNA transcript. In wild type, 5′TH is strong and the alternative pairing with the end of the transcript is weak so that the bypass reaction rarely if ever occurs; in 5T-ex, which has a wild-type intron strand, 03E production is detectable when the weak alternative pairing is stabilized by spermidine (Fig. 3*B*). 5THsup can form as good a pairing with the transcript's 3′ end as 5THint, but has a much stronger 5′TH, so that 5EI/03E generation is reduced and normal splicing increased in 5THsup over 5THint. Note that the presentation of the 3′ attacking group is achieved adequately by two very different short helices in the wild-type/cut 5′ exon and 5THint/RNA 3′ end combinations. In the role of 3′AS the 5′GGAGGG3′ sequence primarily determines the position of the 3′ hydroxyl group, placing it in close proximity to its target, the 3′ splice junction, and is thus truly acting as an internal guide sequence as proposed by Davies *et al.*[3].

splice junction can be at least one base beyond the usual position, since the '+2' transcript directs 3′ splicing. Finally, the U carrying the hydroxyl that attacks the 3′ splice junction in the 'normal pathway' (Fig. 6) need not be paired with G as in 5′TH because the '+1' structure has a 3′A^{OH} that is unpaired yet gives good 3′ splicing.

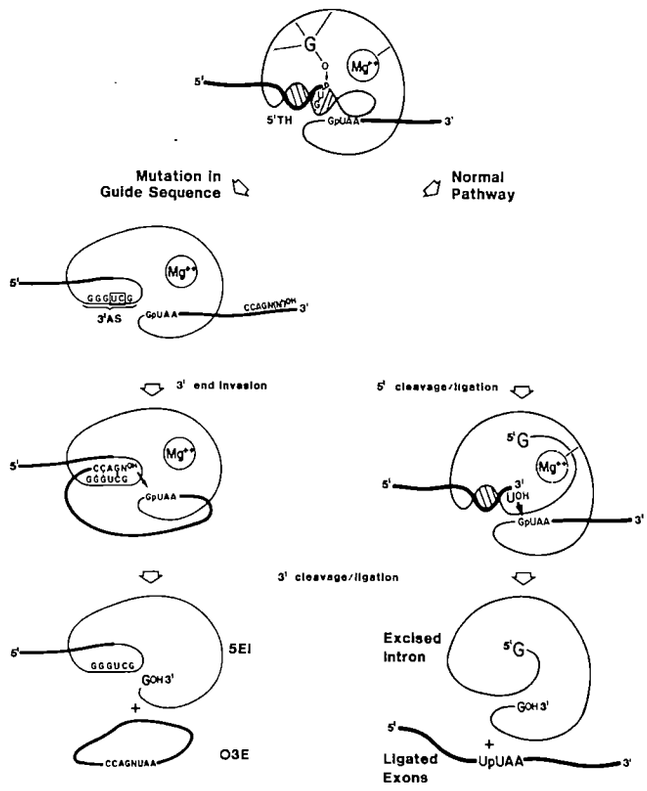

Fig. 6 Diagram of the steps in the RNA splicing reaction catalysed by the intron of the rRNA precursor of *T. thermophila*, and the events leading to the generation of 5EI and 03E by the 3′ end invasion reaction in mutants that alter the sequence of the 5′ guide sequence, such as 5THint. The boxed bases are the mutated bases in the guide sequence of the 5THint mutant, 5′CU3′ replacing the 5′GA3′ of wild type. The RNA precursor shown is an *in vitro* transcript from *Pvu*II-cut DNA of a clone of the 5THint mutant *T. thermophila* rRNA intron. Exon RNA is shown as a thick line, intron RNA as a thin line. 3′AS, 3′ attack site; 5′TH, 5′ splicing target helix; G, guanosine cofactor. The figure is based on conclusions from the present paper and the experiments of T. R. Cech and co-workers[1,2,10,15].

The formation of 5′TH is necessary but not sufficient for effective 5′ splicing, since particular series of base pairs in this helix allow much more rapid reaction than others. It seems unlikely that the difference in stacking energy between the wild-type 5′TH and the 5THsup 5′TH is actually significant enough to account for the difference in behaviour of 5THsup and wild type in terms of stability of 5′TH. The sequence of 5′TH may be a factor in positioning the helix via tertiary interactions between exposed groups on bases in 5′TH and other parts of the RNA catalyst, and/or in determining the susceptibility to cleavage of the phosphodiester bond at the 5′ splice site. Recent work on the crystal structure of A-form DNA helices containing T·G base pairs[29] suggests that U·G base pairs may introduce novel features into RNA helices, changing the availability of groups for tertiary interaction and altering local stacking. A U·G base pair is found in 5′TH next to the 5′ splice site in all but one class I intron[8]. The purine–pyrimidine asymmetry of the *Tetrahymena* 5′TH, which switches strands precisely at the 5′ splice site, may also be significant for this intron, but is not a general feature of class I introns. Either of these features could influence the lability of the bond at the 5′ splice junction, and would be affected by local alterations in the structure of 5′TH.

Pairing of the 3′ end of the RNA precursor with the 3′AS in 5THint would be regarded as unstable on the basis of the rules generally used to establish the stability of RNA structures[30].

Also, in some introns of this class, noticeably the third and fourth introns of the yeast cytochrome oxidase gene and the fourth intron of the yeast apocytochrome *b* gene, 5′TH is very short[3,8], consisting of 4,3 and 4 base pairs (bp), respectively. A role for protein factors such as maturases[31] in stabilizing or directing the folding of RNA can be envisaged; indeed, the intron specificity of maturases could be explained if they stabilize guide sequence-exon interactions rather than other parts of the molecule where conserved sequences underlie the structure. In addition, the RNA structure must be viewed as being dynamic rather than static. The 5THsup mutant RNA is a clear example of this; during the long interval that elapses before a significant proportion of the molecules are cut at the 5′ splice junction (due to the aberrant nucleotide sequence in 5′TH), the 3′ end of the RNA transcript is able to find the intron strand of 5′TH unpaired often enough to generate a considerable level of the 3′ cleavage bypass reaction. Interactions involving only 3 bp have been shown to result in 'reverse cyclization' of the excised intron[32], and CpU can act as a 5′ exon[28], presumably by pairing with the 5′ end GG of 3′AS. In a dynamic, rather than a static, RNA structure, the concept of stability must be used more flexibly, and the establishment of classical 'stable pairings' should not necessarily be used as a prerequisite when seeking to determine the structural elements important in dynamic processes such as RNA splicing or ribosome function.

We have presented here the first direct evidence concerning the mechanism of splice-site selection in a ribosomal or messenger RNA precursor, identifying key elements of RNA structure involved in 5′ and 3′ cleavage and ligation. These elements, within the context of the whole RNA molecule, provide the information that defines particular phosphodiester bonds as the targets for cleavage and ligation. The sequence of 5′TH and its position relative to the attacking guanosine 3′ hydroxyl and the Mg^{2+} ion determines the 5′ splice junction. The 3′AS/cut 5′ exon helix positions the attacking hydroxyl group at the end of the 5′ exon correctly relative to the Mg^{2+} ion and the 3′ splice junction. Similar elements of RNA structure may define splice junctions in nuclear mRNA precursors. An intact 5′ end of the RNA moiety of U1snRNA is essential for splicing[33], and this RNA sequence can pair with bases near 5′ splice junctions to produce a structure similar to 5′TH. Precise understanding of splice-site selection requires crystal structures of 5′TH and the whole RNA.

High-resolution imaging from Mauna Kea: the triple quasar in 0.3-arc s seeing

J. Patrick Henry & J. N. Heasley

University of Hawaii at Manoa, Institute for Astronomy, 2680 Woodlawn Drive, Honolulu, Hawaii 96822, USA

The 'triple' quasar, PG1115+08 (which actually contains at least four objects: A_1, A_2, B and C) was the second gravitational lens object to be found[1]. But because of its small angular scale (<2.5 arc s separation between components) and lack of detectable radio emission, which precludes the use of high-resolution interferometric radio techniques, not much is known about this object. In particular, the lensing object(s) have not been identified. Here we report imaging observations made on a night of exceptional seeing, as well as spectroscopy of two galaxies near the quasar. We find that there is a galaxy centred approximately midway between the two A components. The properties of this galaxy are consistent with it being the brightest member of a small group at a group redshift of 0.305. Although detailed modelling is required, it is likely that the galaxy and its group are the lenses.

Previous imaging of PG1115+08 has been either by direct photography or speckle interferometry[2-6]; in all cases components B and C have been unresolved. Component A is resolved into two subcomponents (termed A_1 and A_2, north and south, respectively) separated by ~0.5 arc s at a position angle of ~20°. The intensity ratio is ~1. All observations have failed to detect a lens galaxy, which must be fainter than $V = 22$ (visual magnitude) or be ≤1 arc s from a component. Furthermore, there is no cluster in the field brighter than a Thuan-Gunn *r* magnitude of 25 (ref. 2). The only objects previously known to be near PG1115+08 are three galaxies 12-24 arc s to the south-west, whose redshifts have not been measured until now.

We made direct imaging observations of PG1115+08 on 9 April 1983 UT (Universal Time) at an airmass of between 1.02 and 1.07. These observations were obtained with an RCA C33063 image intensifier mounted behind a Barlow lens and a Schott GG 475 filter at the Cassegrain focus of the University of Hawaii 2.2-m telescope on Mauna Kea. This combination yielded a bandpass of ~4,750-6,000 Å and a scale of 4.1 arc s per mm. The data were recorded on a roll of IIa-O film which was mounted in a camera capable of taking many sequential exposures of specified length while automatically advancing the film. From a previous run we determined that 2 s was the minimum exposure time that would record the faintest (B) component. We obtained 285 2-s exposures, 105 3-s exposures and 230 10-s exposures. The sky was well exposed on the 10-s exposures. Only the 2-s exposures were used for imaging because the seeing was noticeably worse on the 3-s exposures.

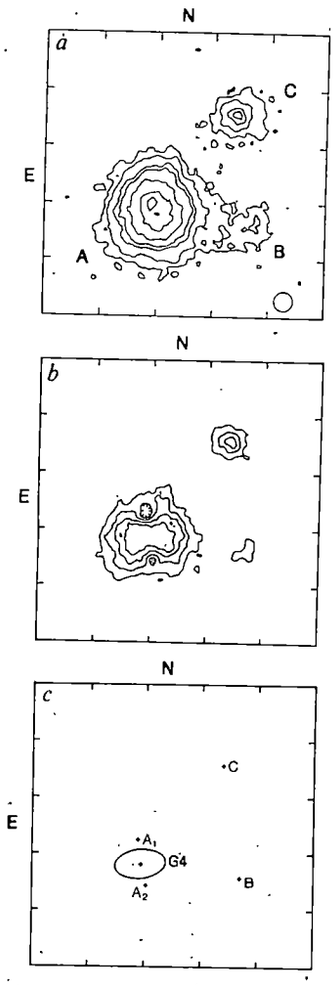

Fig. 1 Diagrams of the PG1115+08 field. The tick marks along the axes are at 1 arc s intervals. *a*, Contours of surface brightness in the 9 April 1983 summed image (see text for details). The contours are at 0.9, 0.8, 0.6, 0.4, 0.3, 0.15 and 0.07 of the peak. If component C did not vary during the one month between our observation and that of ref. 4 (our crude photometry verifies this assumption to 0.2 mag), then the peak surface brightness is $\mu_V = 16.8$ mag (arc s)$^{-2}$. The resolution of this image is shown by the circle at the lower right which indicates the FWHM; it is slightly larger than that of the raw data because of the light smoothing to attenuate the high-frequency noise. *b*, Contour diagram after subtracting the best-fitting point sources in the two point source + galaxy model. The contours are at 0.8, 0.6, 0.4 and 0.2 of the galaxy brightness peak, which, under the assumptions given in *a*, is $\mu_V = 17.1$ mag (arc s)$^{-2}$. Contours with tick marks indicate local minima in the surface brightness at the locations of the imperfectly subtracted point sources. *c*, Schematic diagram of the objects in the PG115+08 field. The outline of the galaxy (G4) is at one core radius.

We examined all the exposures and selected the best 19 for further analysis. These images were scanned on a PDS 1010A microdensitometer; the aperture used was 12 × 12 μm, scanned in 12-μm steps; that is, a pixel size of 0.049 arc s. The maximum density anywhere in the field was only 1.2 density units. The digitized images were then converted to intensities using a calibration curve derived from a step exposure through the image tube onto the same roll of film, developed at the same time as the imaging data. We determined the full width at half maximum (FWHM) of component C in each of these 19 images. The best five were co-aligned and summed to produce our final data set.

During times of extremely good seeing at Mauna Kea, the image consists of a tiny spot dancing within a circle of diameter

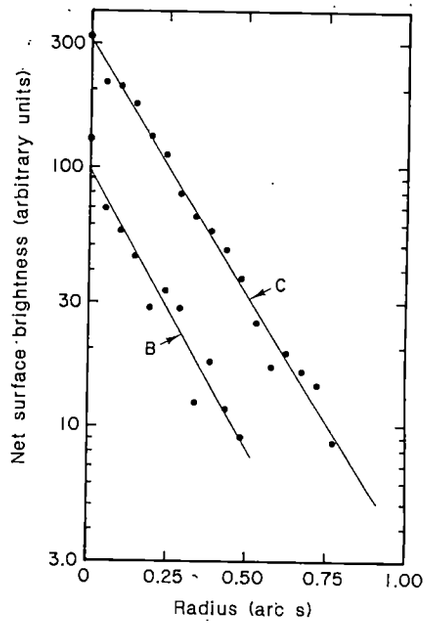

Fig. 2 Azimuthally averaged surface brightness of the B and C components.

~1 arc s; the above procedure was designed to remove the image jitter, leaving only the tiny spot. We show a contour diagram of the final image (slightly smoothed) in Fig. 1*a*.

Azimuthally-averaged profiles for components B and C are shown in Fig. 2. Fitting an exponential to the data yields a point spread function proportional to $\exp(-\theta/0.23 \text{ arc s})$ (C) and $\exp(-\theta/0.21 \text{ arc s})$ (B), implying FWHMs of 0.31 and 0.29 arc s, respectively. In what follows we adopt the point spread function determined from C because it has a higher signal-to-noise ratio. As the two point spread functions are virtually the same, it seems reasonable to assume that the same function will also be applicable to the region of component A. Although most previous descriptions of the seeing function have used a gaussian distribution, at least at small radii (see, for example, ref. 7), such a function does not fit our data, probably because we have eliminated the image motion. Integrating over such motion probably produces a gaussian point spread function by way of the central limit theorem.

The parameters of a nonlinear least-squares fit to a two-dimensional array of data around components B and C yielded the results given in Table 1, which also includes the results of previous measurements. The only significant difference is in the intensity (flux) ratios; in particular, there is a change in the ratio f_B/f_A on a timescale of a month between our data and those of ref. 4. Crude photometry, using the sky as a zero point, indicates that the B component weakened by ~0.5 mag during that time.

Figure 1*a* shows that A must be more complicated than the two equal-intensity point sources separated by 0.5 arc s detected previously. The intensity is approximately constant in an area 0.5 arc s in diameter at the peak, yet we should easily resolve the point sources if they were the only contributors to A. To quantify these statements, and also to better understand the structure of the A component, we have fitted a variety of models to our data. Our intensity data are unlikely to have a Poisson distribution, because of the nonlinearity of the photographic process; therefore, the usual goodness-of-fit tests cannot be used. Yet we need to know when to stop adding free parameters to the models. We adopt the following criterion, which seems reasonable, but is certainly not rigorous: A model for the A component will be considered acceptable if the root-mean-

† Number in parentheses is the error in the last digit.

square (r.m.s.) sum of residuals from it is of the order of the mean of the fluctuations in the A peak (72) and the background (30); that is, 50.

Table 2 contains the results of fits of two models to the A component data. As expected, a model containing just two point sources has unacceptably large residuals, although the best-fitting parameters are virtually identical to those given in refs 4-6. We then tried a model with two point sources and a galaxy. The galaxy was modelled as having an elliptical surface brightness of major axis a, and ellipticity $\epsilon = 1-$(minor axis/major axis). The surface brightness was assumed to fall off as $(1+r^2/a^2)^{-1}$ along the major axis and correspondingly at other position angles. This form accurately approximates a King[8] model in the core. Since the integrated surface brightness of this model diverges logarithmically, we give the light within the core when describing the galaxy brightness. Best-fitting parameters are given in Table 2. The residuals to this second model are acceptably small, although they do exhibit some systematic trends, such as the negative-going contours at the location of A_1 and A_2, shown in Fig. 1*b* (tick marks). A schematic diagram of the various objects in the field is shown in Fig. 1*c*, where the galaxy is labelled 'G4'.

Several tests can be made of the existence of G4. First, do other simple models substantially reduce the residuals? We have tried four additional models: three point sources, three point sources and a galaxy, and two 2 point+galaxy models with broader point spread functions (0.4 and 0.5 arc s). The lowest r.m.s. residual from these four models was 50 (3 points+galaxy). This reduction in the residuals is not large compared with that achieved by going from 2 points to 2 point+galaxy models, so we consider the latter to be a reasonble representation of the data. Second, will a broader point spread function eliminate the galaxy? We find that in order to decrease the galaxy intensity to near zero, it is necessary to increase the FWHM of the point response to 0.5 arc s, which certainly does not fit the data of B and C (see Fig. 2). Third, with a galaxy as bright as we claim, why was it not detected previously? We have better spatial resolution, which facilitates the detection, but in addition our observations were made when the quasar was significantly fainter (by 0.6 mag, according to ref. 4). From the fraction of galaxy light that we observe in the A component ($f_{G4}/f_A = 0.46$, Table 2), we calculate that the corresponding fraction was only 0.26 in 1980 and 1981. Fourth, why are the colours of A not redder than those of B or C? The best constraint is from ref. 2, which gives the $g-r$ of A as 0.05 ± 0.06 mag bluer than that of C. An Scd galaxy at a redshift of 0.3 (see below for this choice of redshift), contributing 26% of the total light of A (the measurements of ref. 2 weremade in 1980) would make A 0.09 mag redder than C in $g-r$. Similar contributions would arise from earlier type galaxies at smaller redshifts. We regard these colour data as the most stringent requirement that the putative galaxy must meet, but given the dispersion of ~0.1 mag in the colours of a galaxy as a function of its Hubble type, such a galaxy is not ruled out by existing data.

In addition to the fitting procedures described above, we have attempted to detect the imaging galaxy directly, by removing the effects of the seeing in the data using a nonlinear deconvolution procedure. The deconvolution procedure used was the Jansson-Van Cittert algorithm as described by Heasley[9]. The results of the deconvolution are shown in Fig. 3. Although A_1 and A_2 are resolved from each other for the first time, there is only a hint of structure aligned with the major axis of G4 (compare Fig. 1*c*). The emission between components A and B, visible in the raw data (Fig. 1*a*), remains after the deconvolution, possibly indicating yet another object.

We made spectroscopic observations of galaxies G1 and G2 (ref. 2) on 25 March 1985 UT with the Hawaii grism (grating/prism) spectrograph and Galileo/IFA CCD (charge-coupled device) mounted at the Cassegrain focus of the Canada-

Table 3 Rest-frame properties of G4 and M104

† Derived from a de-Vacouleurs-law effective radius of 14.2 kpc using core radius = effective radius/13.2 (ref. 14).
‡ Assuming the brightness of component C was unchanged from ref. 4 (our crude photometry using the sky as a zero point shows this assumption to be true to within 0.2 mag) and using a k-correction appropriate to an Sab galaxy of 0.76 mag.
§ Hubble constant $H_0 = 100\,h$.
‖ Core light only.

France-Hawaii Telescope. Exposures of 57 and 31 min were made of G1 and G2, respectively, through holes in thick clouds. The spectra are normal. Reshifts derived from spectral lines Ca II H, K, Hδ and G for G1 and the 4,000-Å break for G2 are 0.306 ± 0.002 and 0.304 ± 0.005, respectively. Thus these galaxies form a small group at redshift 0.3, which may also contain G3.

It is possible that G4 is the brightest member of this group. Table 3 lists the properties of G4 if it is at redshift $z = 0.3$ and compares those properties with those of M104, a massive spiral galaxy. From the simulations presented by Schweizer[10], the seeing corrections to the core radius and central surface brightness are ~20% if G4 follows a King model and the point spread function is gaussian. We have not applied these corrections to our data because our point spread function is not gaussian, and corrections of this order will not affect our conclusions. G4 and M104 are very similar. Of course, the redshift of G4 may not be the same as that of G1 and G2, but until a spectrum can be obtained, this is a reasonable assumption.

It is obvious that G4 will contribute substantially to the gravitational focusing. If it is the brightest member of the group, it is a massive galaxy. However, the rest of the group must also make some contribution. The only quantitative models[11] of the gravitational focusing explain PG1115+08 using a single flattened galaxy roughly equidistant from all four components, rather than midway between A_1 and A_2. However those models did not incorporate the galaxy group, so it is as yet unclear whether their combined effects can produce the observed configuration. A spectrum of G4 and additional lens modelling, particularly incorporating a possibly nonspherical group, are required for further progress.

After this paper was written we received a preprint from Shaklan and Hege[12] in which they report a flux excess above

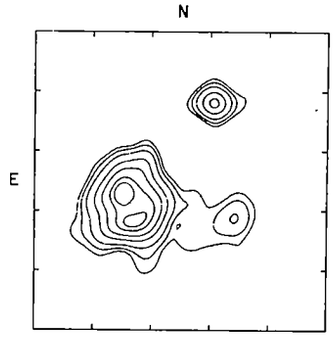

Fig. 3 Contour diagram of the PG1115+08 field after image deconvolution. The tick marks along the axes are at 1 arc s intervals. Contours are at 0.9, 0.8, 0.6, 0.4, 0.2, 0.1 and 0.05 of the peak.

that from the four usual components that is located at ~65% of the distance between A and B and closer to B. We can apparently confirm this report, (see Fig. 3), although our nominal brightness is greater by at least 1 mag. Our resolution of the component may explain the small value of f_B/f_A that we observe.

This research was supported in part by University of Hawaii Research and Training Fund grants to Alan Stockton to adapt the rapid-exposure film camera for use with the image intensifier, and to J.P.H. for observing expenses. We thank John MacKenty for writing the PDS scanning programs, and Robert Hlivak for keeping our CCD in good condition. J.P.H. was a Visiting Astronomer at the Canada-France-Hawaii Telescope, operated by Canadian NRC, the French CNRS and the University of Hawaii.

We report here observations which confirm Paczynski's speculation[1] that the previously known[2] pair of 19th magnitude quasars 1146+111B,C are actually two images of a single object produced by a gravitational lens. The image splitting is 157 arc s, more than 20 times greater than any previously reported[3], thus indicating an exceptionally massive lensing object. The data supporting the lens hypothesis are remarkably similar, high signal-to-noise, moderate-resolution spectra of the two components. Both spectra show strong Mg II λ2,798 emission at $z = 1.012 \pm 0.001$ with indistinguishable redshifts ($\Delta v = 126 \pm 309$ km s^{-1}), widths (FWHM = 64 ± 4 Å) and detailed profile shapes. Both spectra also show broad troughs at λ6,180 and several weaker continuum features. Neither object exhibits the [O II] λ3,727 line which is frequently strong in Mg II emission objects. If the foreground galaxy clustering apparent in a deep R band charge-coupled device (CCD) image proves insufficient to explain the large image splitting, other possibilities such as massive dark objects (for example, a ~10^{15} $M_\odot$ black hole) or a cosmic string may be indicated.

In 1979, Hazard *et al.*[4] reported a 'concentration' of quasars in a field at $\alpha = 11$ h 46 min 14 s and $\delta = 11°11'42''$ (1950). Subsequently, Arp and Hazard[2] gave redshifts based on slit spectra for nine confirmed quasars in the field. Among these, two quasars (B and C) were determined to have redshifts of 1.01, equal within their measuring errors. Arp and Hazard[2] dismissed the possibility that these were a pair of gravitational lens images on the grounds of an implausibly large image separation. Recently, Paczynski[1] again called attention to this system along with four others as possible examples of large splitting gravitational lenses and noted that such systems might result from an intervening cosmic string[5,6].

We obtained spectra of 1146+111B and C on the night of 5 March 1986 UT with the Cryogenic Camera[7] and the R-C spectrograph on the Kitt Peak National Observatory 4-m telescope of the National Optical Astronomy Observatories (NOAO). A 2.5 arc s × 4.4 arc min slit was used to illuminate a 300-line per millimetre grism (grating/prism). An 800 × 800 TI CCD camera recorded the first-order spectra through a GG420 filter giving 15 Å resolution in the λλ4,600-7,800 range with a 4.3-Å per pixel sampling. Two 1,800-s exposures of each object

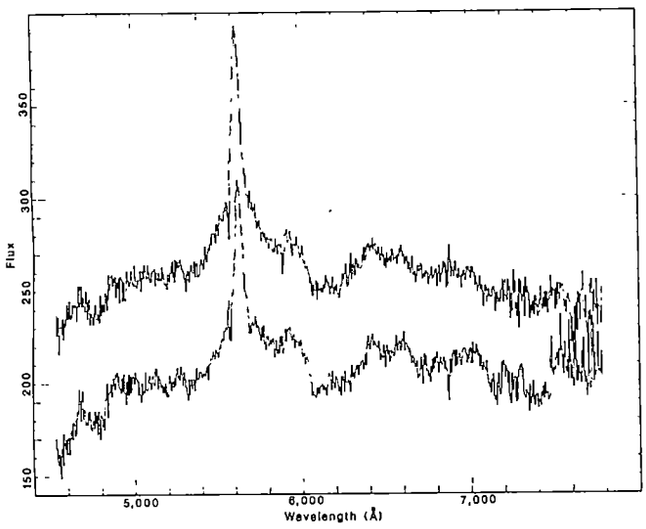

Fig. 1 The spectra of 1146+111B and C. The vertical axis is a linear flux scale in arbitrary units. The upper spectrum is of object B; the lower, of object C (70 counts per channel were added to B to displace it from C). The identification of the strong emission feature as Mg II λ2,798 is primarily based on Arp and Hazard's[2] detection of C III λ1,909. Note the correspondence of the emission feature, the deep trough, and several weaker continuum dips and bumps in the two spectra.

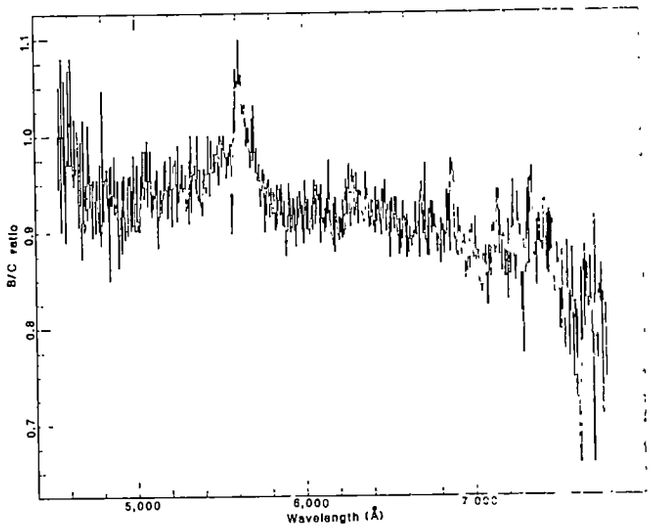

Fig. 2 The ratio of the spectrum of 1146+111B to that of 1146+111C. The feature in this ratio at the wavelength of the Mg II emission indicates that the line-to-continuum ratio in the two objects is slightly different. The smooth variation in the ratio from blue to red indicates that C has a redder detected continuum than B. The absence of other significant features in this ratio demonstrates the detailed match in shape and amplitude between respective emission and absorption features in the two spectra.

were obtained along with interspersed quartz lamp flat fields and He-Ne-Ar comparison arcs. A spectrum of the flux calibrator GD 140 was also obtained to remove the instrumental response function and atmospheric absorption bands. The data frames were reduced individually using the CASSANDRA image processing package and the resulting spectra of each object were then combined. They are shown in Fig. 1.

These two spectra agree precisely in their significant features. Figure 2 gives the ratio B/C of the two spectra. The Mg II line ratio is ~1.02 while the continuum ratio varies from roughly 0.96 at the blue end to around 0.83 at the red end. These small variations do not mitigate against a lens interpretation as similar small differences in line strengths and continuum slopes are observed in such confirmed lens cases as 0957+561 (ref. 8) and 2016+112 (ref. 9). They may be accounted for by a variety of explanations including source variability plus differential time delays, gravitational mini-lensing events[10], extinction by intervening material, contamination of the source spectrum by light from the lens, and systematic observational errors resulting from differential refraction effects. Overall, the spectroscopic similarity of 1146+111B and C is as strong as for any of the known (few arc second separation) lens systems.

On 7 March 1986 UT we obtained six direct images of the 1146+111B, C field, each exposed for 300 s using the TI2 CCD camera at the prime focus of the same telescope. The average of these six images is shown in Fig. 3. Profile fits to stellar images indicate a FWHM seeing of 1.2 arc s. Although accurate calibration of this image was not attempted due to non-photometric observing conditions, we believe that it reaches 23rd to 24th magnitude in the R band.

Analysis of this image shows: (1) an image separation of 156.8±0.5 arc s, (2) an R-band B/C brightness ratio of 0.93± 0.01; (3) a possible very distant rich cluster of galaxies between the two quasar images; and (4) an unusual number of fairly bright ($R \sim 18$ to 19), apparently low redshift ($z \lesssim 0.2$) galaxies in the field including one roughly between B and C. The quasar images themselves show no signs of resolution.

The importance of 1146+111B, C lies in its unprecedented large image separation and the questions and possibilities thus raised.

The first question is that of the nature of the lensing object. The most conventional candidate would be a very massive rich cluster of galaxies. If such a cluster lay at the most probable redshift of 0.32 and had an isothermal sphere mass distribution, the required one-dimensional velocity dispersion would lie near 2,200 km s^{-1} (depending weakly on q_0). If the cluster instead lay at a redshift of 0.81, which would minimize (for a constant M/L value) its visibility (assuming an elliptical galaxy k correction[11]), the requirement would be ~4,500 km s^{-1}. The former value is extreme but not entirely beyond the observed range for rich clusters[12]. Nevertheless, such a cluster would be easily detectable in deep CCD images at any redshift less than 1, so this candidate lens is subject to direct observational test. If no suitable rich cluster can be located, more exotic possibilities such as $\sim 10^{15}\ M_\odot$ black holes and cosmic strings will need to be considered. Indeed, lens systems much like 1146+111B, C are a predicted consequence of cosmic strings[1,5,6]. Of course, the possibility of a physically distinct (not lensed) pair of objects with astonishingly similar spectroscopic properties is not logically excluded by the data.

Second is the possibility that additional objects in the 1146+111 field may be multiply imaged. The large angular splitting of the B, C pair implies a large multiple imaging cross-section for most reasonable lens scenarios. Some of the other known[2] quasars in the field could well have additional, so far undetected images; D, E and K are particularly likely candidates. Even if they are not multiply imaged, lens magnification and hence flux enhancement could account for the statistically unlikely 'concentration' of quasars which originally called attention to the field. In any case, discovery of additional multiply-imaged objects would offer the opportunity to model the lens mass distribution more precisely than for other known lenses and, should this distribution prove simple, to carry out powerful cosmological tests.

Third is the large differential time delay expected for large splitting image pairs. For reasonable lens models, the 1146+111B, C time delay is of the order of 10^3 years. This offers the opportunity of observing variations in the lensed object(s) taking place over time periods well in excess of those usually accessible. If the lensing geometry is highly symmetrical, as the roughly

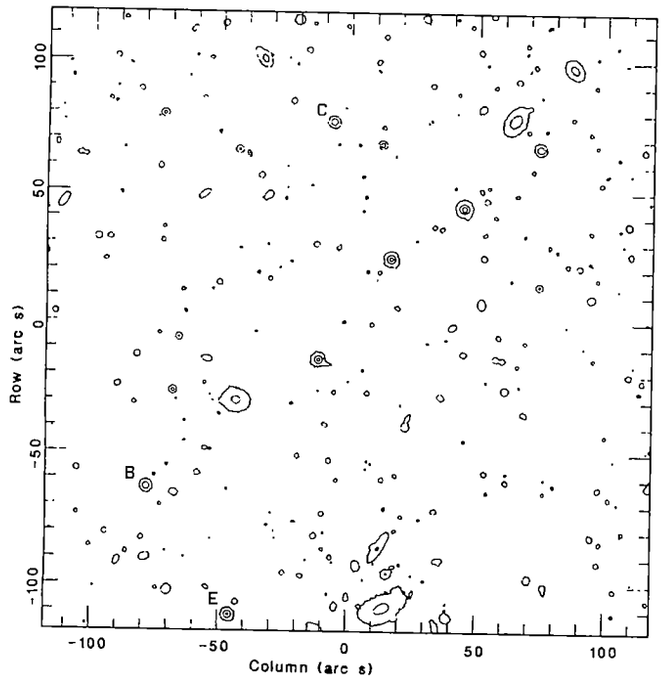

Fig. 3 A contour diagram of the R-band CCD frame of the 1146+111 field. North is at the top, east at the left. The image is 4 arc min on a side. The first contour level is 2.5 times the r.m.s. sky noise with additional contours at 3-magnitude intervals. Dots corresponding to single high pixels are probably noise in many cases; however, larger objects are likely to be real. It is estimated that the faintest objects visible are between 23rd and 24th *R* magnitude. Object B is at column, row coordinates −77.4 arc s, −61.9 arc s while object C is at −6.0 arc s, 77.7 arc s. Note that there are several bright galaxies scattered across the frame including one at −42.5 arc s, −28.7 arc s (roughly between B and C) and a concentration near the centre of the south edge of the field. Also note the arc of faint galaxies, possibly a distant cluster, extending from about −5 arc s, 26 arc s towards −74 arc s, −10 arc s.

equal brightnesses of B and C might suggest, the time delay will be substantially smaller than this 'natural' value.

1146+111B, C and the surrounding field warrant further study, and some attempts in this direction are under way. Verification of the spectral similarity of B and C at other wavelengths and searches for additional, multiply-imaged objects are of particular interest. Other candidate large splitting lenses should also be examined more carefully.

We thank B. Paczynski for a preprint and for discussions, the Kitt Peak staff for assistance with the observations and J. Ostriker for useful comments on the manuscript. Dense dust jets are expected to be encountered by the spacecraft penetrating the coma of comet Halley in March 1986. At the time of encounters, remote observations of the global distribution of coma constituents will complement the detailed *in situ* measurements. Here we report ground-based measurements of the optical brightness distribution of the coma, made in November 1985, when the comet was at a distance of 1.75 AU from the Sun. From the total brightness we deduce a dust production rate of 1.5×10^6 g s^{-1}, but our results show that cometary dust and gas production, which seem to be correlated, are strongly anisotropic and time-variable. Structures in the coma can be revealed by comparison with a physical model of the coma, but astrometry of the comet nucleus is adversely affected by the anisotropic brightness distribution in the coma.

The coma morphology and dust emission pattern of comet Halley, as revealed on photographic plates taken during the 1910 apparition[1], have been used to determine the nucleus spin vector[2]. A verification of this result and the location of active regions on the nucleus is important for the space probe missions Giotto[3] and Vega[4] currently approaching the comet. An efficient computational method has been developed[5] to analyse images of the coma and to model the dust distribution in it. Repeated observations of coma structures are necessary to determine the rotational state of the nucleus and the distribution of active regions on it.

The observations were performed using the 80-cm Schmidt telescope and the 2.2-m telescope at the German–Spanish Astronomical Center at Calar Alto, Spain. Sixteen Schmidt plates were taken during the period 9–21 November 1985, in order to study the brightness distribution of the outer coma. The following emulsion–filter combinations were used: Kodak IIIa-J plus Schott UG1 or GG495, IIIa-F plus RG610, or 103a-E without filter.

A large, curved, jet-like structure extending 21 arc min to the south of the cometary nucleus was photographed on two plates on the night of 12/13 November; the U-plate image is shown in Fig. 1. The observed structure was nearly perpendicular to the projected antisolar direction; although the projection angle is unknown, this deviation seems too large to be only a projection effect. The brighter inner part of the jet (visible on Fig. 1) is narrow and consists of three 'beams'; its wide and faint outer part looks like a fan. The U-plate (IIIa-J+UG1) has shown that this ejection very probably contained not only dust particles but also CN molecules. Jockers[6] observed a southward-pointing ion tail (CO^+) during the same night: it is thus highly likely that ion emissions contribute to the total brightness observed by us. The coma photographed 3 days earlier was symmetrical, and had a diameter of ~10 arc min (at the isophote level corresponding to the sky background). In addition to the jet, some radial rays are visible on the U-plate at the west side of the coma. On 18.0 November the outer coma appeared symmetrical again, but had expanded to ~15 arc min. In addition to the increase of the cometary brightness due to its decreasing distance from both the Earth and the Sun, the activity observed on 12/13 November

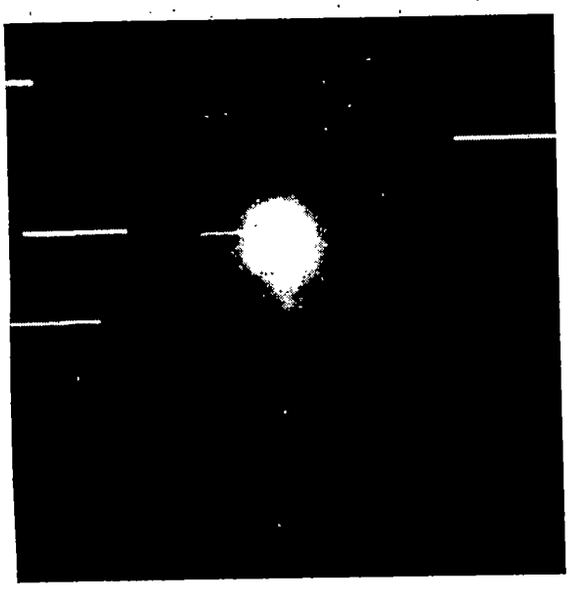

Fig. 1 Jet structure of the coma of comet Halley, observed on 13.0 November 1985 UT (Universal Time) with the 80-cm Schmidt telescope at Calar Alto. The 50-min exposure was taken on Kodak IIIa-J emulsion through a UG1 filter. The field of view is 20 × 20 arc min; north is up, east is left.

Fig. 2 Isophote representation of a CCD image taken with the 2.2-m telescope at Calar Alto on 12.9 November 1985 UT. A continuum filter at 703 nm was used. The field of view is 2 × 2 arc min; north is up, east is left.

probably increased the total brightness of the comet during the subsequent days. On plates taken on 21.0 November two jets are visible to the east (position angles 63° and 90°; the latter is the tail direction), at a distance of ~9 arc min from the nucleus.

More than 100 CCD (charge-coupled device) images have been taken with the 2.2-m telescope. The detector used was a thinned, backside-illuminated RCA CCD (type SID 510-EX), with 512 × 320 pixels. The pixel size is 30 × 30 μm, which corresponds to 0.35 arc s at the Cassegrain focus. The filters used were Johnson R, V and B and the IHW filters at 703 nm ($\Delta\lambda = 22$ nm), 684 nm ($\Delta\lambda = 9$ nm), 514 nm ($\Delta\lambda = 10$ nm) and 485 nm ($\Delta\lambda = 6$ nm). The filter at 514 nm covers a major C_2 emission; the other narrow ones are continuum filters.

Optimum pre-perihelion observation conditions (small zenith distance, large brightness and long observation intervals from a single site) occurred in November 1985. During this time the comet was ~0.7 AU from the Earth, in approximately the anti-solar direction. The comet was close to its ascending node. The required high offset speed of up to 400 arc s h^{-1} was achieved with an accuracy of better than 3 arc s h^{-1}. The exposure times to reach near-saturation in the centre ranged from 15 to 1,000 s for the wide-band and narrow-band filters, respectively.

Figure 2 shows an isophote representation of a CCD image of the coma. The image was taken on 12.9 November. The outer part of the image is elongated towards the south, whereas the centre part is more symmetrical. An image taken ~3.5 h after that shown in Fig. 2 shows that the direction of strongest emission had shifted by 10° to position angle 190°. A similar shift was observed for the jet seen on the Schmidt plates which were taken at about the same times.

To determine photometric magnitudes for Halley's central coma, a set of standard star measurements were taken in the same (photometric) night (~12 stars per waveband with magnitudes between 8.8 and 17. The sky background (per pixel and second) in the Halley frames was determined by averaging the background of three field exposures taken at about the same zenith distance, shortly before or after the respective Halley exposure. Coma magnitudes were measured by flux integration in circles of 10 and 30 arc s diameter around the brightness maximum. The measured values are $B = 12.6$ and 11.3, $V = 11.6$ and 10.4 and $R = 11.4$ and 10.2, respectively. A conservative estimate of the root-mean-square deviation of one observation is ±0.1 mag. The magnitudes were measured on 13.1 November.

Assuming that most of the coma brightness in R can be attributed to sunlight scattered by dust, one can derive the dust production rate. For the measured brightness in R of 11.4 mag we find a mean dust production rate of $\sim 1.5 \times 10^6$ g s^{-1}. We adopt an effective geometric albedo of 0.03, a grain size distribution with an exponent −4.2 in the coma and the effective emission velocity of 150 m s^{-1} according to the standard Halley model parameters proposed by Newburn and Reinhard[7]. Note, however, that the uncertainties in the assumed parameters result in an uncertainty of a factor of ~2 in the production rate.

Taking an average dust-to-gas ratio of 0.3 and a mean molecular mass of 22.3 AMU (ref. 7) we derive a gas production rate of $\sim 1.3 \times 10^{29}$ molecules s^{-1}. This is ~3 times higher than the value predicted by Newburn[8] on the basis of 1910 Halley observations and recent cometary models.

Figure 3 shows radial and azimuthal brightness profiles of the Halley coma. The radial brightness profiles at different wavelengths were obtained by averaging the surface brightness around concentric circles centred on the brightness maximum. Inside $\rho \simeq 5$ arc s (ρ being the distance from the centre) the brightness first rises more steeply than the average increase, then flattens off at $\rho < 3$ arc s. This inner part of the coma represents the seeing disk of the central brightness peak. During the observation period the seeing ranged from 2 to 5 arc s. Outside this radius the coma brightness in the continuum wavelengths decreases roughly as $1/\rho$, as would be expected from a steady stream of particles emitted isotropically at constant speed from the surface of the nucleus. In the outer part of the brightness profile, the effect of the constant sky background is recognized. The radial profiles of the C_2 brightness fall off as $\rho^{-\gamma}$, $\gamma = 0.6$–0.75. This is in good agreement with the C_2 scale length calculated for the inner coma region[9].

The azimuthal brightness profile at continuum wavelengths (Fig. 3*b*) shows deviations of up to 30% from the mean brightness at a given distance from the centre. The C_2 brightness varies azimuthally in the same way, with a smaller amplitude.

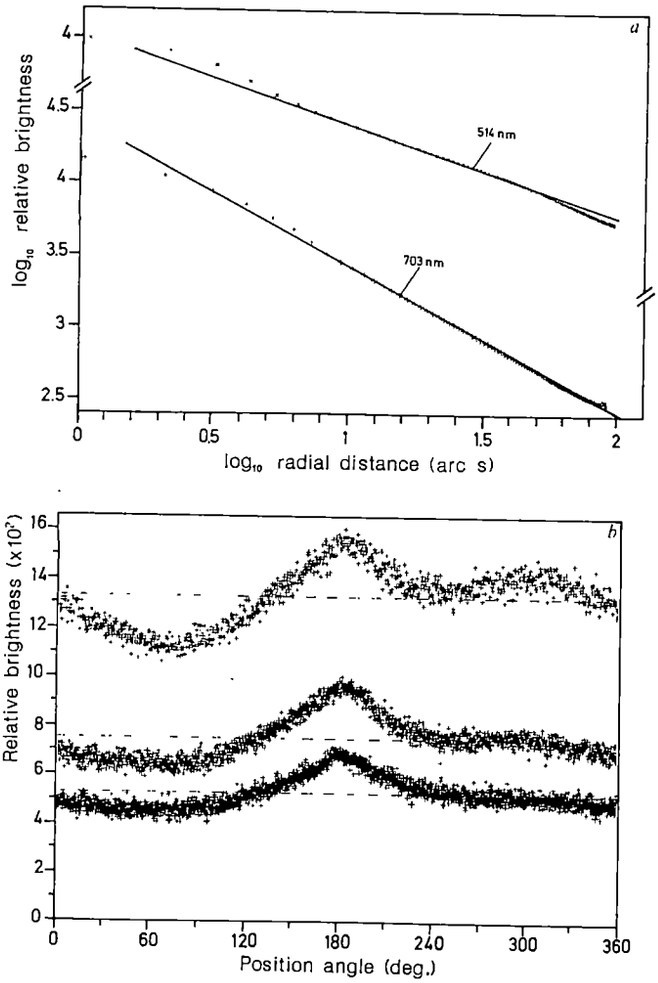

Fig. 3 Brightness profiles of CCD images of the Halley coma, taken on 12.9 November 1985 UT. *a*, Radial profiles of the continuum brightness (703 nm) and C_2 brightness (514 nm). The solid lines have slopes of −1.0 and −0.63, respectively. *b*, Azimuthal profiles of the brightness at 703 nm at radial distances of 21, 37 and 53 arc s from the brightness centre. The dashed lines represent mean brightness values at these distances.

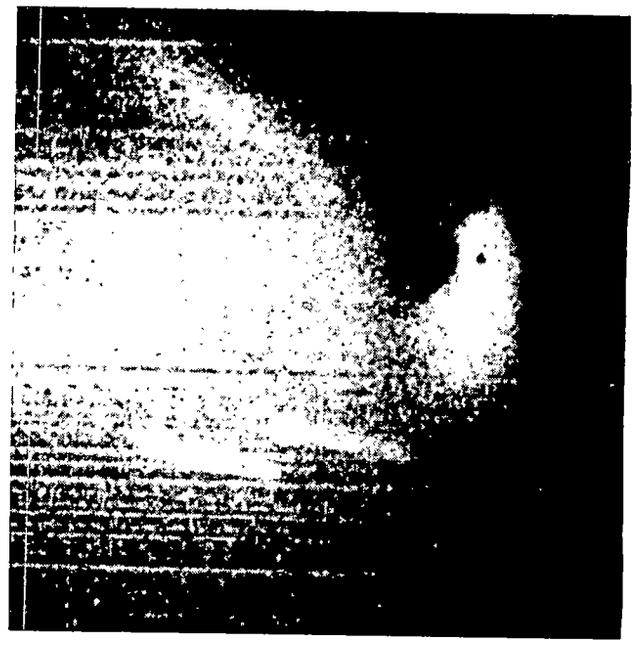

Fig. 4 Jets in Halley's inner dust coma on 21.1 November 1985 UT. This picture (at 703 nm) was obtained by normalizing the observed brightness distribution to the distribution which would be expected for an isotropically expanding coma. The centre of the original brightness distribution is marked by a dark spot in the right-hand part of the image. A major jet can be seen to the south, which bends over to the east. Another jet is visible at position angle 63°. Two star trails can be recognized in the lower part of the image. The east-west striation originates from a defect in the CCD, which could not be corrected for in all portions of the picture. The field of view is 2×2 arc min; north is up, east is left.

The strong overall radial brightness gradient hinders the recognition of local variations in brightness. To enhance the visibility of local inhomogeneities, and hence the variations in dust density, we have compared the images with a simple physical model of the dust coma. After subtraction of a constant background level the images were normalized to a $1/\rho$ brightness distribution centred on the apparent nucleus. Thus, the seeing disk is represented by a low-intensity central part and a bright ring around it. Outside this artefact the brightness distribution represents the deviation from an isotropic expanding dust emission. These deviations are due to non-isotropic emissions and bending of trajectories caused by dynamical effects. A similar method can be used to show structures in the gas coma.

Figure 4 shows a processed image, taken on 21.1 November. It also shows the main dust emission from the nucleus in the southerly direction. This time, however, it bends over to the east, which is the general tail direction. The enhancement of the outer coma in the easterly direction became increasingly dominant during the latter part of the observation period. At position angle 63°, a narrow jet is visible which continues for several arc minutes and has been simultaneously observed on Schmidt plates as described above.

We have found several independent indications that enhancements in the inner dust coma are correlated with enhancements in the gas coma, as well as with jets and perhaps even ion tails outside the coma. This observation indicates that the interaction between dust and gas, and perhaps ions, is more complicated than previously expected.

On nearly all images taken with continuum filters, a prominent emission feature is visible within ~10° of south. This feature shows no periodic orientation changes, such as are generally expected from an active area on a rotating nucleus. We suggest, therefore, that it is caused by increased gas and dust emission at the constantly sunlit rotational pole of the nucleus. Each observation then defines a plane in which the spin vector must be located. All of these planes should intersect in a common line, which is the spin vector. For three representative observations on 12/13 November and three others on 20/21 November these planes have been computed. Their common spin vector lies in the region $\phi = 0$–10° and $I = 30$–55°, following the notation of Sekanina and Larson[2]. This differs by ~40° from the direction recently proposed by Sekanina[10] on the basis of 1910 observations.

The anisotropic brightness distribution of the coma affects the determination of the nucleus position. On some images we have observed elongated seeing disks, suggesting that the deviation of the brightness centre from the nucleus position may be as large as one-third of the mean seeing-disk radius. Local dust density enhancements by about two orders of magnitude—as required to produce visible structures, according to jet simulations[5]—are also expected to occur during the space probe encounters with the comet. The observations cannot tell us whether hazardous large particles (>1 mg) are entrained in the jets, because the observed brightness is mainly due to 1–10-μm-sized particles for all reasonable size distributions.

Remote ground-based observations of the coma, similar to

those presented here, will be of great value during the spacecraft encounters with comet Halley. The remote coma observations will determine the overall structure, while *in situ* measurements provide the absolute calibration.

We thank T. A. Morley, ESOC, for providing exact Halley ephemeris data. E.G. and L.K. are visiting astronomers, German-Spanish Astronomical Center, Calar Alto, operated by the Max-Planck-Institut für Astronomie jointly with the Spanish National Commission for Astronomy.

Nitrogen dioxide emitted from space shuttle surfaces and shuttle glow

Ulf von Zahn* & Edmond Murad†

* Physikalisches Institut, Universität Bonn, 5300 Bonn 1, FRG
† Air Force Geophysics Laboratory, Hanscom AFB, Massachusetts 01731, USA

Photographs taken on early space shuttle flights have indicated the presence of a surface glow in the ram direction[1]. Examination of airglow data from the AE and DE satellites has shown the presence of a similar glow[2], suggesting that the phenomenon is general to spacecraft in low Earth orbit, with the emission being concentrated in the ram direction. Several explanations have been offered for the glow: (1) OH formed by surface reactions of fast O atoms[3]; (2) plasma discharge mechanism[4]; (3) surface-induced decomposition of N_2 followed by recombination into an excited state[5]; (4) surface emission by impact of O_2 and O (ref. 6); and (5) near-continuum emission (at a resolution of ~3.4 nm) in the region 400–800 nm from electronically excited NO_2 (ref. 7). With reference to the last hypothesis we discuss here data on the number density of NO_2 measured inside the payload bay of the shuttle orbiter. We also derive fluxes of NO_2 near shuttle surfaces. Our data are shown to be consistent with the hypothesis of the glow being caused by NO_2 emission.

Number densities of NO_2, $[NO_2]$, were measured with a neutral mass spectrometer aboard flight 41-B of the space shuttle. The instrument and its performance have been described in detail by Wulf and von Zahn[8]. The instrument was mounted near the middle of the payload bay. The data discussed here were obtained at the beginning of day 6 of the mission, when the ion source opening was pointing towards the pressure bulkhead of the astronaut cabin. Figure 1 shows the motion of the orbiter and the position of the mass spectrometer sampling orifice. Incoming ambient species bombarded the cabin bulkhead directly; however, the mass spectrometer observed only species reflected or desorbed from the shuttle surfaces, mostly from the pressure bulkhead. The orbiter maintained the attitude shown in Fig. 1 for 11 min, enough time for the signals measured in the mass spectrometer to reach a steady state. The following data were obtained at the end of this period at 290 km altitude and 27° latitude, near 03:45 LT (Local Time). $[NO_2]$ is derived

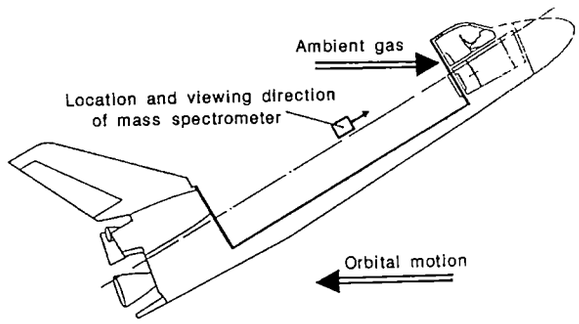

Fig. 1 Observational geometry for measurement of NO_2 density in the payload bay of the shuttle orbiter. The ambient gas strikes the orbiter surfaces with a velocity of 7.3 km s^{-1}, but the ion source of the mass spectrometer receives only species reflected or desorbed from orbiter surfaces.

from the peak at 46 AMU in the mass spectrum, after correcting for the contribution by $^{12}C^{16}O^{18}O$ (heavy CO_2), deduced from the peak at 44 AMU. We find that 43% of the observed 46 AMU peak is due to heavy CO_2. The remaining 57% we assign to NO_2 (the contribution of monomethylhydrazin to the mass 46 peak is considered to be negligible, mainly because of the strong dependence of the observed mass 46 peak on the angle of attack). To derive an absolute value for $[NO_2]$, we use the absolute sensitivity of the mass spectrometer for CO_2, as calibrated in the laboratory, multiplied by the ratio of cross-sections for electron impact ionization of NO_2 and CO_2 (refs 9, 10). This yields the NO_2 density inside the ion source of the mass spectrometer, $[NO_2]_s = (2.7 \pm 1.0) \times 10^7$ cm^{-3}. With an ion source temperature of 315 K, the flux $\Phi(NO_2)_O$ out of the ion source opening becomes $(2.5 \pm 1) \times 10^{11}$ cm^{-2} s^{-1}. The error bars reflect our estimate of an upper bound for potential contributions to the mass 46 peak from gases other than NO_2 and CO_2.

In the presumed steady-state conditions, the flux into the ion source, $\Phi(NO_2)_i$, equals the flux out of it, $\Phi(NO_2)_O$. Because of the observation geometry, $\phi(NO_2)_i$ is only ~40% of $\phi(NO_2)_b$, the flux leaving the cabin bulkhead; hence, $\Phi(NO_2)_b \simeq (6 \pm 3) \times 10^{11}$ cm^{-2} s^{-1}.

To relate this flux to a density $[NO_2]_b$ near the bulkhead we consider two extremes which have been suggested by other studies of the shuttle glow. First, NO_2 desorbs from the bulkhead with the mean thermal velocity(0.37 km s^{-1}). This results in $[NO_2]_b = 6 \times 10^7$ cm^{-3}. Second, NO_2 desorbs with a velocity of 2.5 km s^{-1} (corresponding to a kinetic energy of 1.5 eV), as suggested by Swenson *et al.*[7], based on a calculated *e*-folding distance of 20 cm (ref. 11) for the shuttle glow and a radiative lifetime of NO_2* of 80 μs (ref. 12). This velocity would lead to a considerable thermal accommodation factor for $[NO_2]$ inside the ion source, and for these circumstances $[NO_2]_b \simeq 1 \times 10^7$ cm^{-3}.

We now consider the requirements of the shuttle glow intensities, assuming that the glow arises solely from NO_2 as suggested by Swenson *et al.*[7]. The most recent estimate of the glow intensity is 10–100 kR (1R = 10^6 photons cm^{-2} s^{-1}), viewed normal to the surface[13]. This translates into a flux of excited NO_2, $\Phi(NO_2^*)$, of 10^{10}–10^{11} molecules cm^{-2} s^{-1}. The surface above which this glow is calculated consists of the shuttle tiles, which are made of silica fibres doped with a variety of materials[14]. On the other hand, a large part of the NO_2 observed by our mass spectrometer originates from the bulkhead surfaces, which are covered by Teflon-coated glass[15]. Mende and Swenson[13] reported a study of the relative glow intensities of different materials aboard shuttle mission 41-D at ~300 km altitude. Their study indicated that the glow intensity was weakest above a polyethylene sample and brightest above a material designated Z302, overcoated with silicon. If this latter material is close to that of the shuttle tiles, one would have to

draw the conclusion that the NO_2 flux close to the shuttle tiles is considerably enhanced over that near the bulkhead. Assuming that the conditions for the two flights are the same (mass spectrometer data from flight 41-B and glow data from flight 41-D), and that the glow intensity of the shuttle tiles is the same as that of Si-coated Z302, we deduce that $\Phi(NO_2^*)/\Phi(NO_2) \simeq 0.01$–$0.1$. Thus the mass spectrometer data indicate that NO_2 desorbed from the surface is present in sufficient amount to further consider NO_2 a viable candidate for causing the glow.

To pursue this analysis, let us assume that NO is present on the surfaces of the space shuttle (from the ambient, from surface reaction between N and O (ref. 16), from chemical reaction of fast O with the shuttle materials, or from contamination caused by attitude thruster firings[8]), and that O atoms striking the surface recombine with the adsorbed NO to yield NO_2^*:

$$\text{NO (adsorbed)} + \text{O (fast)} \rightarrow \text{NO}_2^* \text{ (fast)} \quad (1)$$

This is an example of the Eley-Rideal mechanism in catalysis (see ref. 17 for a discussion of this and the Langmuir-Hinshelwood mechanism). In this mechanism, the desorbed molecule is expected to carry the evolved heat of the reaction as rotational, vibrational, electronic or kinetic energy (or a mix of all these). A summary of work relevant to the shuttle glow problem is given in ref. 18. For the case under discussion, reaction (1), the excess energy is enormous: kinetic energy of O (4.5 eV, corresponding to a velocity of 7.3 km s^{-1}) + D_O(NO-O) (3.1 eV), or a total of 7.6 eV. The short wavelength cutoff of the glow is ~430 nm (ref. 7), corresponding to 2.9 eV in the form of electronic excitation. If the desorbed NO_2^* has a kinetic energy of 1.5 eV, as has been suggested[13], then the remainder (3.2 eV, or ~40% of the excess energy) must be partitioned between vibrational/rotational excitation of NO_2 and surface deposition of the excess energy. Results from beam experiments[18] and theoretical calculations[19] indicate that the amount of energy deposited into the surface is quite small. For example, in a theoretical study of the reaction of O with adsorbed carbon on platinum at 0 and 500 K, it was found that >90% of the energy released in the reaction appears in the product, CO. If the case of $O + NO_{ads}$ is analogous, then most of the remaining energy would appear in vibrational/rotational excitation of NO_2 (~2.8 eV); ~5% of the excess energy would be deposited in the surface (~0.4 eV). The implication of this argument is that the glow emitted by NO_2 may be more intense in the infrared than in the visible. The problem becomes even more serious if the velocity of the desorbed NO_2^* is less than that used above. In any case, the prediction from this mechanism is that the rate of desorption of NO_2 will increase with increasing [O], until a plateau is reached.

Another model is provided by the Langmuir-Hinshelwood mechanism, whereby fast O atoms are thermalized on the surface and then react with adsorbed NO to form NO_2:

$$\text{NO (adsorbed)} + \text{O (adsorbed)} \rightarrow \text{NO}_2 \text{ or } \text{NO}_2^* \quad (2)$$

Again, the NO_2 or NO_2^* would be expected to contain the excess energy, which is now considerably smaller than in the Eley-Rideal mechanism, namely only D_O^0(NO-O), 3.1 eV. Since the short-wavelength threshold is ~430 nm (2.9 eV), the remainder, 0.2 eV, is kinetic energy; this corresponds to a velocity of 0.9 km s^{-1} for the desorbed NO_2. If we again use a radiative lifetime of 80 μs, then the e-folding distance becomes ~7 cm, which is not far from the observed distance. If both NO and O are strongly adsorbed on the surface and if the adsorption energies are comparable, then the rate of reaction (2), and therefore the glow intensity, will go through a maximum as [O] is increased. If, on the other hand, both NO and O are weakly bound to the surface, then the reaction will be second-order in [O] (ref. 17). We cannot yet choose between the two mechanisms, although the Langmuir-Hinshelwood mechanism seems easier to reconcile with the observations. Finally, the energies and lifetimes used above represent most probable values. In reality, there will be a distribution (perhaps maxwellian) of interaction energies, which will in turn, lead to a distribution of excitation energies in the products. For the qualitative nature of this discussion, however, it is sufficient to consider the most probable values.

The question of the origin of the surface NO merits some discussion. The four sources mentioned above are all possible, and all can provide the required [NO]. We note that, for example, semi-empirical models of the thermosphere[20] predict ambient densities [O] and [N] of 5.3×10^8 cm^{-3} and 6.5×10^5 cm^{-3}, respectively, during our observational period. Hence, fluxes of ambient species onto the cabin bulkhead have been $\phi(O) = 3.4 \times 10^{14}$ cm^{-2} s^{-1} and $\Phi(N) = 4.1 \times 10^{11}$ cm^{-2} s^{-1}. $\Phi(N)$ seems only just able to balance $\phi(NO_2)_b$. However, due to local-time and latitudinal/seasonal variations in the global N distribution, $\phi(N)$ went through a local minimum at the location and time of our observation and the orbital average of $\phi(N)$ is considerably higher.

The data reported here are consistent with a glow hypothesis based on NO_2 emission. However, they do not prove this hypothesis, and a number of questions remain, concerning NO_2 as the source of the radiation.

Atmospheric CH_4, CO and OH from 1860 to 1985

Anne M. Thompson

Applied Research Corporation, Landover, Maryland 20785, USA

Ralph J. Cicerone

National Center for Atmospheric Research, Boulder, Colorado 80307, USA

Atmospheric methane, CO and the gaseous OH radical are interdependent: if CH_4, CO or OH is perturbed, background concentrations of the other two constituents are affected. Perturbations to OH alter photo-oxidation rates of numerous natural and anthropogenic trace gases and affect lifetimes of those species that pass from the Earth's surface to the free troposphere and stratosphere. It is now known that global atmospheric methane con-

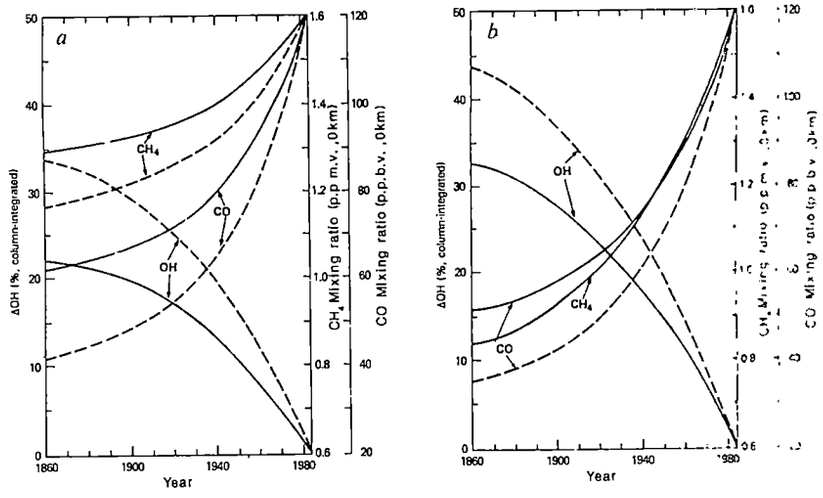

Fig. 1 Calculated ground-level methane and CO mixing ratios and per cent changes in column-integrated tropospheric OH from 1860 to 1985. Model conditions are appropriate for the mid-altitude Northern Hemisphere with low background NO_x (20–25 p.p.t.v). Calculations for low-latitude conditions (higher photolysis rates, lower O_3 and CO mixing ratios) show trends of similar magnitude, implying that the OH changes illustrated here are typical of unpolluted environments. Calculations with higher NO_x levels also show similar trends, but the magnitude of OH change is about half the increase shown here. *a*, Results from models 1 and 2 (Table 1). Methane flux is constant at all times; the calculated CH_4 increase is due solely to CO and OH changes. The solid line is from model runs with a largely anthropogenic upward flux of CO at 35% of the CO source in 1985; the dashed line assumes $flux_{CO}$ (1985) produces 65% of present-day CO. In both cases additional CO derives from CH_4 and C_2H_6 oxidation by OH and from an explicit source, S_S, representing non-methane hydrocarbon oxidation. $flux_{CO}$ and S_S vary in time as described in Table 1. *b*, Results from models 3 and 4 (Table 1). Fixed CH_4 mixing ratios follow ref. 13. Solid and broken lines as in *a*.

centrations are increasing[1–6]; less definite data suggest that carbon monoxide is also increasing[1,7–9]. Even before the measurements of refs 1–9 were made, modelling studies of CH_4–CO–OH coupling had led to predictions[10–12] of future temporal increases of CH_4 and CO. Here we look backwards in time, using a photochemical model to simulate the trace-gas composition of the unpolluted troposphere at the start of the industrial era (taken as 1860), and at intervals up to 1985. We find that the OH concentration in the background troposphere has decreased significantly and O_3 has increased due to increases of CH_4 and CO; calculated changes depend on temporal trends of NO_x ($NO_x = NO + NO_2$), for which no historical data are available. The calculations allow recent trace-gas trends affecting background chemistry and climate to be viewed in a longer-term context.

In modelling the photochemistry of the pre-industrial atmosphere it is essential to specify past concentrations of NO_x and the more stable species CH_4, CO and O_3. Before ~1960, few ambient measurements were made of these trace species, so the input to our model is based on current mixing ratios or source flux estimates extrapolated backwards in time. A summary of key species follows.

CH_4 and CO. We take two extreme methane cases: one with a minimum difference in CH_4 mixing ratio between 1860 and 1985 and one with a maximum difference. Similarly, we assume minimum and maximum temporal changes in CO and combine alternate sets of CH_4 and CO constraints to obtain four model types (Table 1). Models 1 and 2 assume a uniform CH_4 flux (constant sources) at all times, yielding 1.2–1.3 p.p.m.v. (parts per 10^6 by volume) in 1860 and 1.60 p.p.m.v. in 1985 in the models. Models 3 and 4 are based on the assumption that large differences between modern CH_4 and that extracted from ice cores[13–15] represent real changes in atmospheric composition over the past hundred years, rather than diffusive losses of trapped gases[5]. This is consistent with recently published spectroscopic measurements of past CH_4 (ref. 6). Thus, in models 3 and 4, CH_4 is present at a concentration of only 0.82 p.p.m.v. at ground level in 1860.

Choosing model input for CO is complicated because ground-level CO concentrations vary greatly, owing to the short lifetime of CO and uneven geographical distribution of CO sources[7,8]. We take 120 p.p.b.v. (parts per 10^9 by volume) CO at ground level as typical for the 1985 mid-latitude Northern Hemisphere; Southern Hemisphere CO concentrations are lower because there are fewer local sources[16,17]. Uncertainties in CO sources are treated by parameterizing two components in the model representation of the total source, $S^{total,CO}$: S_S (a surrogate for the oxidation of non-methane hydrocarbons besides C_2H_6) and $flux_{CO}$ (representing directly injected surface sources). Both S_S and $flux_{CO}$ include natural and anthropogenic contributions as described in Table 1. In ascribing 82% of present-day S_S to natural hydrocarbon sources, we follow Logan *et al.*[17], recognizing that this apportionment is still uncertain. Model runs for years before 1985 assume that natural sources contributing to S_S and $flux_{CO}$ are unchanged and anthropogenic ones scale with population or fossil-fuel usage[18]. Thus, S_S changes little in time and $flux_{CO}$ is strongly time-dependent.

Table 1 Model characteristics

Input	Model 1	Model 2	Model 3	Model 4
Past CH_4	High CH_4:constant 1985 flux		CH_4 specified from ice-core data[13]	
Past CO	Type 1-CO	Type 2-CO	Type 1-CO	Type 2-CO
Output				
1985 O_3 (0 km)	30.0 p.p.b.v.	29.8 p.p.b.v.	30.0 p.p.b.v.	29.8 p.p.b.v.
1860 O_3 (0 km)	27.7 p.p.b.v.	26.4 p.p.b.v.	25.4 p.p.b.v.	27.1 p.p.b.v.

Type 1-CO: 35% of $S^{total,CO}$ (1985) is $flux_{CO}$; type 2-CO: 65% of $S^{total,CO}$ (1985) is $flux_{CO}$. The total CO source in year t is:

$$S^{total,CO}(t) = Q_{CO}(t) + flux_{CO}(t) + S_S(t)$$

where Q_{CO}, the *in situ* photochemical formation from CH_4 and C_2H_6 oxidation, is derived from the model [$Q_{CO}(z, t)$, integrated from $z = 0$ to 15 km]; S_S (also column-integrated) explicitly represents photo-oxidation of non-methane hydrocarbons (NMHC) besides C_2H_6:

$$S_S(z, t) = S_S(z, 1985)\,[f_{NMHC,N} + r^{ff}(t) f_{NMHC,A}(1985)]$$

where $f_{NMHC,N}$ (0.82) and $f_{NMHC,A}$ (0.18 in 1985) are fractions of S_S due to oxidation of natural and anthropogenic NMHC[17]. $r^{ff}(t)$ is the ratio of fossil-fuel usage[18] in year t relative to 1985. $S_S(z, t)$ is proportional to the product of the OH number density and an exponential function with the latitude dependence of a typical OH+alkane reaction. $flux_{CO}(t)$, the model lower boundary condition for CO, signifies direct surface-injected CO sources:

$$flux_{CO}(t) = flux_{CO}(1985)\,[f_{flux,N} + r^{ff}(t) f_A^{ff}(1985) + r^{pop}(t) f_A^{nf}(1985)]$$

where $r^{pop}(t)$ is the ratio of the population in year t relative to that in 1985. f values are based on a budget[17] for Northern Hemisphere CO sources; $f_{flux,N} = 0.13$ is the natural fraction of $flux_{CO}$ (oceanic flux, emissions from plants and lightning-induced wildfires); f_A^{ff} and f_A^{nf} are fossil-fuel and non-fossil-fuel (wood fuel and biomass burning) combustion components of anthropogenic $flux_{CO}$. In all models C_2H_6 at 0 km was increased from 1.0 to 1.5 p.p.b.v. between 1860 and 1985. This has negligible effect on OH and CO changes.

O_3. Ozone concentrations vary so much in time and space, even on a short timescale, that a realistic determination of tropospheric O_3 in 1860 is impossible. For simplicity we assume identical boundary conditions for O_3 in current and past-year models: these conditions are fixed stratospheric input and fixed deposition velocity[19].

H_2O, NO_x. These species and other model parameters, for example ultraviolet and visible radiation and rainout rates, are critical in determining O_3 and OH concentrations. Water vapour, radiation fluxes and rainout rates for soluble species are fixed at constant levels[19] in all model runs. Boundary conditions for odd nitrogen (NO_x) are assumed to be uniform at all times; a stratospheric odd-nitrogen source controls NO_x in the upper and mid-troposphere and a small upward flux of NO gives 20–25 p.p.t.v. (parts per 10^{12} by volume) NO_x in the boundary layer. Although NO_x sources include a large anthropogenic component that has increased during the past century, it seems reasonable to suppose that the low levels of NO_x that determine O_3 and OH in the background troposphere are supplied by non-anthropogenic sources[20,21] (for example, stratospheric injection, lightning, weak oceanic and soil fluxes of NO) which have not changed appreciably with time.

Details of the model used in the present paper and profiles of tropospheric O_3, NO_x and OH are reported in ref. 19. The model solves for a standard complement of odd O, H, N species; CO, CH_4 and species derived from CH_4 and C_2H_6 oxidation, including peroxyacetylnitrate (PAN). Simulations are performed with a steady-state model at 10–30-yr intervals. CH_4 and CO can exhibit slower transients than would be predicted from their respective 10-yr and 2-month lifetimes[11], depending on the mix of CO sources.

Figure 1 shows ground-level CH_4 and CO mixing ratios and changes in column-integrated OH (0–15 km) from 1860 to 1985. Figure 1*a* shows results assuming minimum CH_4 change between 1860 and 1985 (models 1 and 2), and Fig. 1*b* assumes maximum CH_4 change (models 3 and 4). Tropospheric OH decreases as CO and CH_4 increase, with the greatest change occurring when both CO and CH_4 undergo maximum change (model 4). In that case CH_4, CO and fractional OH increases in 1950 (relative to 1985) are similar to those presented by Levine *et al.*[22], although our NO_x level is much lower. When we calculate perturbed CH_4–CO–OH cycles at higher NO_x levels (1 p.p.b.v. at 0 km) we find that increased CH_4 and CO cause near-surface OH to increase, but total tropospheric OH decreases as in Fig. 1 (although by only half as much).

Changes in atmospheric lifetimes of hundreds of trace gases, for example, reactive hydrocarbons, sulphur and nitrogen compounds, may have occurred since 1860 as a consequence of OH perturbations. Figure 1*a* (models 1 and 2), for which no change in surface CH_4 emissions is assumed, shows that CO increases and OH decreases could have caused background-level CH_4 to increase by 24–37% from 1860 to 1985. Figure 1*b*, however, implies that CH_4 doubling since 1860 requires a change in CH_4 fluxes as well as altered background OH in response to CO changes.

Changes in CO–CH_4–OH chemistry affect climate because O_3, CH_4 and CO_2 (to which CO converts by OH oxidation) are 'greenhouse' gases. Increases in CH_4 and CO cause tropospheric ozone to increase because CH_4 and CO contribute to photochemical O_3 production[23–25]. The temporal changes shown in Fig. 1 imply an 8–18% tropospheric O_3 increase from 1860 to the present (Table 1); observations point to a recent temporal increase in tropospheric O_3 (refs 26, 27). O_3 perturbations instantaneously alter the Earth's infrared radiative forcing. If there has been sufficient time for a temperature response, this could have caused a small rise in global temperature, depending on the altitude profile of the O_3 increase[28,29]. Atmospheric CO increases affect radiation by supplying CO_2 (provided that OH remains at adequate levels), and by suppressing OH and allowing O_3 and CH_4 to accumulate, even if CH_4 emissions do not increase. For example, atmospheric CO_2 formed from the reaction OH+CO in 1860 ($8–16\times10^{10}$ molecules cm^{-2} s^{-1}, integrated through the troposphere) exceeded the direct fossil-fuel source of CO_2, that is, 2.6×10^{10} molecules cm^{-2} s^{-1} (ref. 18). Approximately 75% of this CO was natural in origin (Table 1).

Recent work[1,2] indicates that the South China Sea is an 'Atlantic-type' marginal basin of late Tertiary age. Magnetic anomalies in the eastern part of the sea are consistent with seafloor spreading directed approximately north–south[1,2]. We present here a new morphostructural study based on coupled seabeam mapping and single-channel seismic reflection profiling, which reveals dominant normal fault scarps, striking N50° E between 113 and 119° E longitude near the axis of this basin. Such a structural fabric implies a NW–SE spreading direction, at least in the 150–200-km-wide axial region of the South China Sea, and places new constraints on geodynamic models for the formation of this basin in the tectonic and palaeogeographic framework of South-East Asia and the South-West Pacific.

The South China Sea (Nanhai), largest of the marginal basins of the western Pacific, is bounded by the continental margins

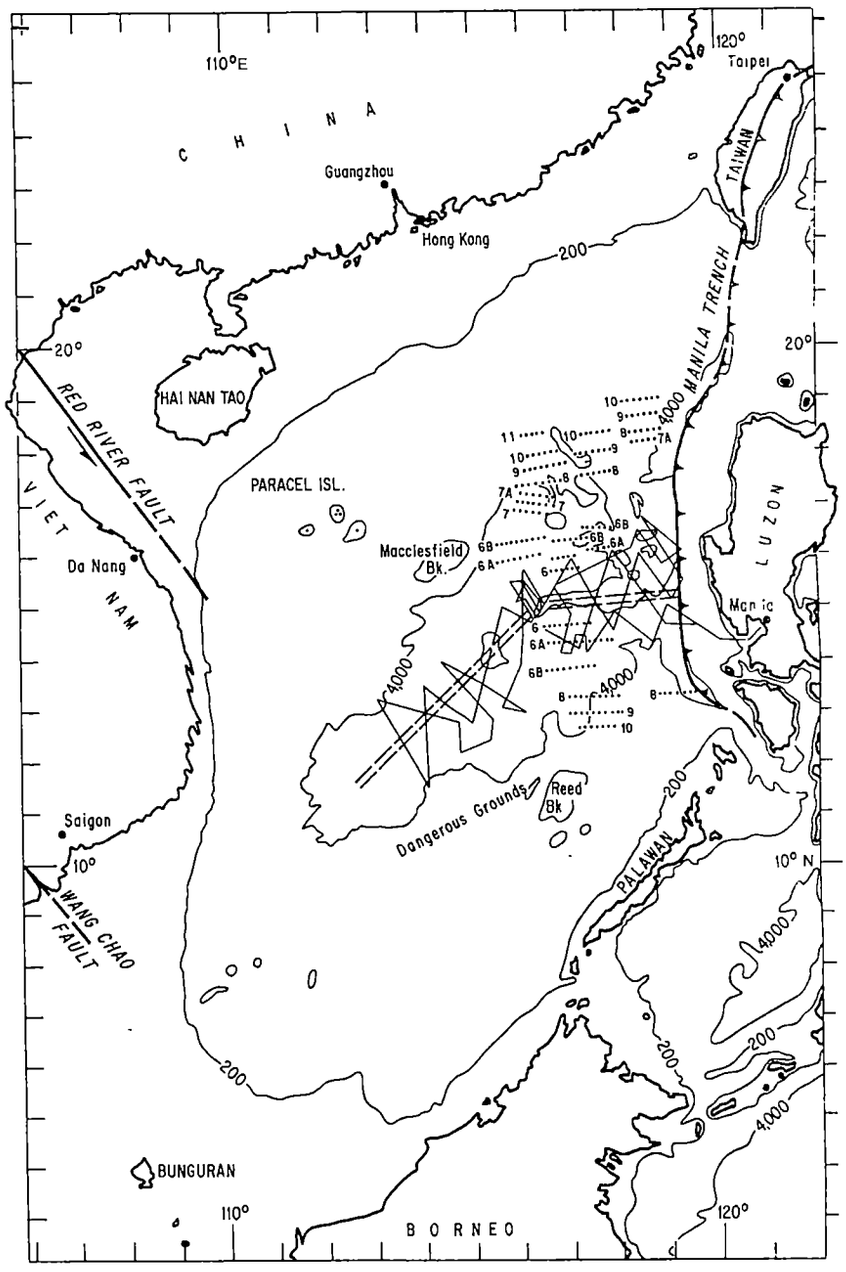

Fig. 1 Bathymetry of the South China Sea. Tracks of RV *Jean Charcot* during the Nanhai survey are reported. Also shown are major structures such as the Red River Fault and Manila Trench. Dashed parallel lines indicate inferred position of ridge axis[1,2]. Magnetic anomalies are from ref. 2.

of South China, Vietnam and Borneo, and by the Manila Trench, where its crust is now being consumed by eastward-dipping subduction (Fig. 1). East of 115° E, its ~700-km-wide oceanic floor, where east-west-trending magnetic anomalies 11 to 5e have been identified[1-3], appears to have formed mostly between 32 and 17 Myr (refs 1, 2). The east-west-trending Scarborough Seamounts probably mark the location of the spreading axis in this part of the basin[1,2]. West of 115° E, the abyssal plain divides into two wedge-shaped basins which narrow westwards, respectively north and south of the Macclesfield-Paracels high[1]. Magnetic anomalies have not yet been identified in these basins, although the deeper crust appears to be of oceanic nature[1], and the axis of the larger, southern basin, trending N50° E, is marked by a −30-mgal gravity low[1,2] (Fig. 1). The difference between the latter NE-SW structural trend and the more nearly east-west orientation of magnetic anomalies east of 115° E has been the source of conflicting interpretations. While Bowin *et al.*[3] inferred a roughly NE-SW fabric extending into the entire eastern basin, other reconstructions[1,2,4,5] imply oblique, north-south spreading in the southwestern sub-basin. Alternatively, the complexity of the South China basin could result from two (or more) distinct phases of spreading[4].

In order to obtain a clearer view of the morphology and structure of the axial floor of the South China Sea, RV *Jean Charcot* performed, between 113 and 119° E, a survey comprising 74 profiles in which seabeam mapping was coupled with single-channel seismic, magnetic and gravity recording (Figs 1, 3). The combination of seabeam with seismic reflection allowed the correlation of faults identified on the seismic sections with morphological scarps outlined by steep gradients or rectilinear bathymetric contours on the sea floor (Fig. 4). The width of the seabeam swaths (2-3 km in most of the survey area) allowed the direct determination of fault orientations, so that the kinematics of spreading could be constrained more tightly than in previous studies[1-3].

Major normal faults observed on seismic profiles (Figs 3, 4) are shown in Fig. 2, with the corresponding seabeam-derived scarp orientations. The rather thin sedimentary cover near the spreading axis does not hide the morphological expression of the faults (Figs 3, 4). Along most of the length of the ridge, we

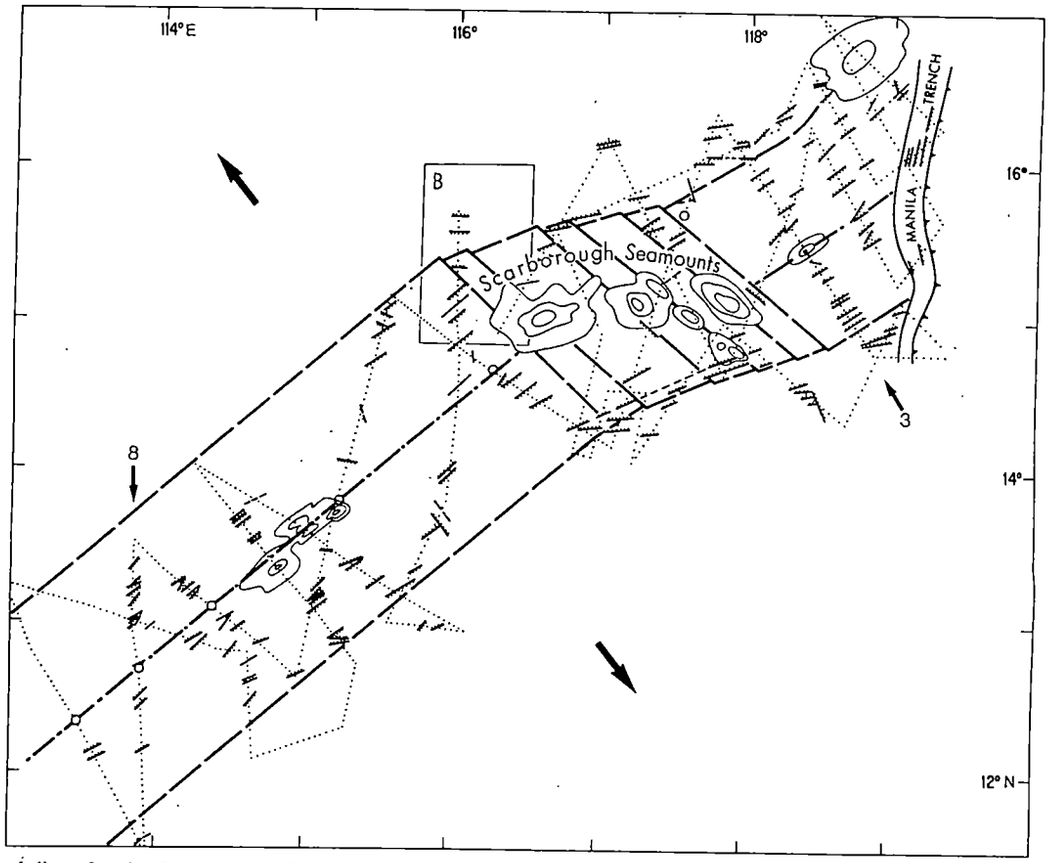

Fig. 2 Strikes and dips of major faults derived from combined analysis of seabeam and seismic reflection records. Dotted lines represent RV *Jean Charcot* profiles. Profiles 3 and 8 (Fig. 3) are indicated. Box B marks an area with denser seabeam coverage. Thin contours represent major seamounts (Scarborough chain). Thick dashed lines indicate outer limit of zone with predominant N50° E-trending scarps, and inferred transverse fault zones between 116 and 118° E. Dash-dot line outlines probable location of spreading axis.

can identify the spreading axis itself by the inwards-facing of the fault scarps and the outwards-tilting of blocks. As shown in Fig. 2, most of the normal faults strike N50 ± 10° throughout the axial region of the South China Sea, implying that the most recent spreading direction was roughly orthogonal (N140° E). Outside the central 150 km, scarps oriented N70–80° E are found, particularly between 116 and 119° E, north and south of the Scarborough Seamounts (Fig. 2).

At a more detailed level, it is possible to subdivide the axial region of the South China Sea into three distinct segments:

(1) A southwestern segment, which extends linearly from about 116° E towards the south-west, with a width of at least 150 km. The rather smooth oceanic acoustic basement, with outward-tilted blocks, is here covered by 1–2 s (seismic two-way travel time) of sediments. To the south, it appears to be bounded by structural highs trending N50–70° E, characterized by deeper reflectors, which may correspond to faulted blocks of attenuated continental crust (Fig. 3, profile 8).

(2) A northeastern segment, between about 118° E and the Manila Trench, with a NE–SW trend comparable to that of the southwestern segment. Inward-facing fault scarps striking N50° E are particularly clear up to ~75 km from the axis (Fig. 2), which is here marked by a gravity low. Farther away from the axis, major fault scarps still face mostly inwards but have more varied orientations, predominantly N70–80 E. To the north, near the Manila Trench, a large seamount masks the area in which fault scarp orientations may change.

(3) A central segment, between about 116 and 118° E, with a more complex structure and morphology. Many of the seamounts of the Scarborough chain have formed along the axis of this segment. These large submarine volcanoes dominate the fabric of the sea floor in the axial region. In addition, the sediment cover in this area is thicker than in the adjacent segments. Despite the coating of the sea floor by sediments and late volcanic products, however, scarps trending N50–60 °E are observed close to the inferred axis. They appear to be dissected by scarps trending N125–140 °E which are more numerous in this segment of the ridge than elsewhere. Moreover, the Scarborough Seamounts and minor volcanic constructions near them are elongated in these two nearly orthogonal directions (particularly the NW–SE one), which thus appear to have controlled the ascent of late basaltic volcanism. This N50° E, N135° E seafloor structural fabric is especially clear in the area near 15°30′ N, 116° E in which a dense seabeam coverage was obtained (box B in Fig. 2). At distances on the order of 80 km from the axis, scarps trending N70–80 °E are observed.

The *Jean Charcot* survey provides new insights into the latest stages of spreading in the South China Sea. Between 113 and 119° E, the 150–200-km wide axial region of the ridge appears to be composed of two rather linear, continuous, north-east-trending segments, separated by a central, east–west-trending segment where the predominant fabric of normal faults striking N50° E and bounding outward-tilted blocks is disrupted by transverse faults striking N135° E, and where the axis has been the site of late intrusions along these dominant fault trends.

Both the small- and large-scale geometries suggest that seafloor spreading took place throughout the axial region in a NW–SE direction. The offset of the northeastern and southwestern segments of the ridge, and the presence of NW–SE-striking fault scarps and elongated volcanic highs in the central segment is easily reconciled with the above spreading direction if such scarps and highs are interpreted to mark left-lateral transform fault zones. Progressive left-lateral displacement of the spreading axis across such transform zones would thus

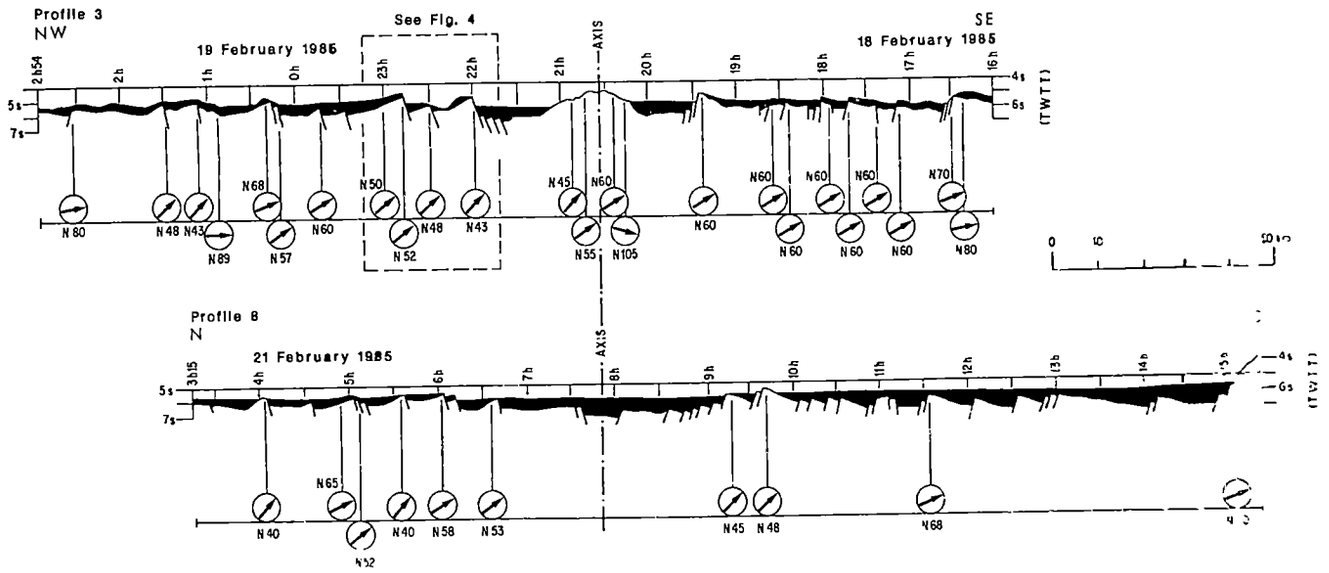

Fig. 3 Schematic sections drawn from single-channel seismic profiles 3 and 8 (sediment cover in black), and orientation of fault scarps (arrows) seen on corresponding seabeam records. TWTT, two-way travel time.

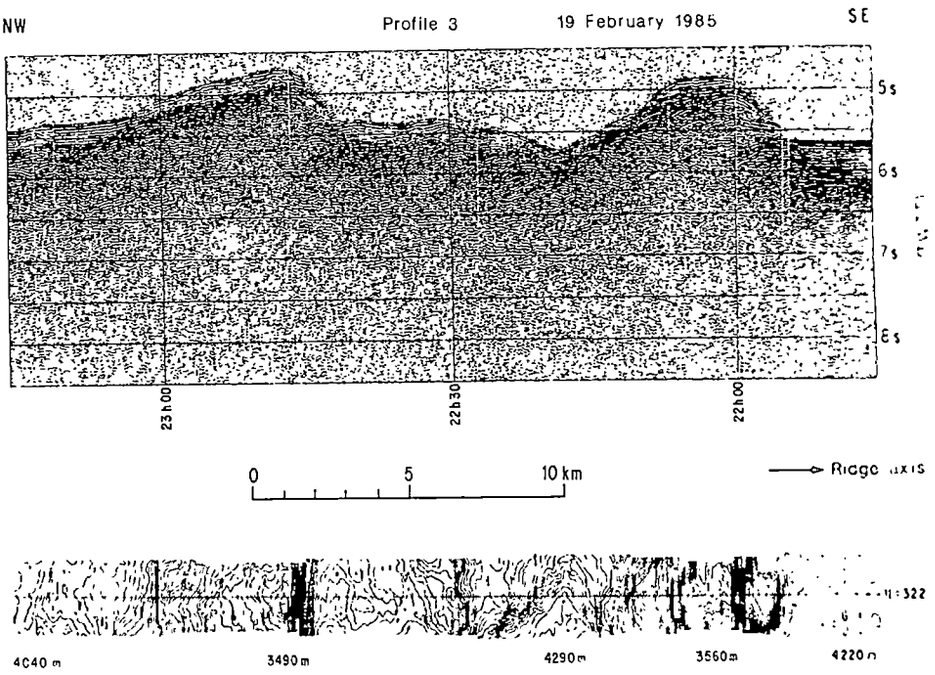

Fig. 4 Coupled single-channel seismic reflection profile (vertical exaggeration = 3) and seabeam record along part of profile 3 (box in Fig. 3). Horizontal scale is the same. Note clear northwestward-tilted blocks and southeastward-dipping normal faults. Steep gradients in bathymetric contours outline fault scarps striking N43–52° E (Fig. 3).

account for the roughly east-west average trend of the central ridge segment. This more densely fractured, and hence particularly weak crustal zone would have been a favoured injection site for basaltic magmas, allowing the formation of the Scarborough seamount chain which now outlines the ridge axis between 116 and 118° E at 15° N (Fig. 2).

The *Jean Charcot* 'Nanhai' survey discussed here was mostly confined within the area bounded by magnetic anomaly 6a[1,2] (Fig. 1), which, along with anomaly 6, was clearly identifiable on profiles made near 116° E, 16° N during a second survey to the north of the axial zone (A.B. and P.T., in preparation). Therefore, in a strict sense, the geometry and kinematics outlined above concern only the sea floor generated after about 20 Myr (that is in the most recent 3–4 Myr of spreading[1,2,4]), at a rate comparable to that estimated by Taylor and Hayes[2] (~5 cm yr^{-1}). Although the NW–SE spreading direction inferred here appears to remain approximately constant along strike, the youngest oceanic floor may have formed in two distinct, crustal environments, east and west of 115° E. West of 115° E this floor was perhaps emplaced within stretched continental crust[1,2,4], the average orientation of fault scarps and faulted blocks north of the southwestern inner basin being apparently compatible with a similar NW–SE extensional regime (A.B. and P.T., in preparation). East of 115° E, on the other hand, the inner oceanic floor formed in the centre of a 500-km-wide area already floored by oceanic crust, perhaps with a different structural fabric[1,3].

The difference between the interpretation presented here and those of previous workers[1–4] follows mostly from the first use of the seabeam imaging technique in exploring the floor of the South China Sea. In establishing the identity of a NW–SE spreading regime in the entire axial region of the sea, this interpretation is in keeping with that of Bowin *et al.*[1], and appears to contradict the north–south direction of spreading inferred by Taylor and Hayes[1,2] from nearly east–west-trending magnetic anomalies, all the way into the axis of the eastern basin. Since such anomalies are clearest outside the area of our

seabeam survey, however, it is now important to determine whether the pattern of faulting observed near the axis extends outside the 150–200-km inner part of the eastern basin. The presence of N60–80° E scarps in the outermost sections of the seabeam profiles between 116 and 119° E (Fig. 2) suggests that it may not. On the other hand, seabeam profiles made well north of the 200-km-wide axial zone, albeit west of 116°30′ E during a shorter survey following 'Nanhai' (A.B. and P.T., in preparation) also reveal N50° E-striking normal fault scarps.

A change from N50° E to N80° E in the strikes of normal faults ~100 km away from the axis could indicate a major anti-clockwise rotation of the spreading direction ~20 Myr ago. Such a major kinematic change appears to be noticeable on land in Taiwan and in the Philippines, where incipient subduction along the Manila Trench is apparently marked by new (late Oligocene–Lower Miocene) volcanism and intrusion in the western cordillera of Luzon[6,7], immediately followed by obduction of middle Oligocene ophiolites in Mindoro[8]. That change could represent the response of the spreading centre to new kinematic constraints along the nearest plate boundary and resembles that documented at about the same time within the Shikoku Basin (N. Chamot-Rooke, V. Renard and X. Le Pichon, in preparation).

Conversely, as suggested by close comparison of Figs 1 and 2, the orientation of the magnetic isochrons (N80° E) could be distinct from that of normal faulting (N50° E) in the inner as well as the outer part of the eastern South China Sea. One way to reconcile magnetic anomalies trending N80° E with normal fault scarps striking N50° E and a NW–SE spreading direction is implicit in the geometry of the disrupted central ridge segment in Fig. 2: magnetic isochrons may smooth out left-lateral offsets on closely spaced NW–SE transform faults (A.B. and P.T., in preparation). In this event, the near-parallelism between the NW–SE spreading direction, the left-lateral transform faults in the central South China Sea, and the large, left-lateral, Tertiary strike-slip faults of South China and Sundaland (Red River, Wang Chao, Three Pagodas)[9,10] could imply, in keeping with the tenets of 'rigid' plate tectonics, that the opening of that sea was driven by the southeastwards extrusion, forced by the India–Asia collision, of different parts of Sundaland along those faults[9–12].

This survey was carried out within a Cooperative Program (Nanhai project) between the National Bureau of the Sea (Beijing) and IFREMER (Paris). We thank all particpants, particularly Commandant Hubert Guidal and the crew, for collaboration on board RV *Jean Charcot*. This is IFREMER contribution 65 and IPGP contribution 902.

Propagation of internal tides from the upper slopes of the Bay of Biscay

R. D. Pingree, G. T. Mardell & A. L. New

Institute of Oceanographic Sciences, Brook Road, Wormley, Godalming, Surrey GU8 5UB, UK

The shelf-break region of the Celtic Sea (north of the Bay of Biscay) is characterized by a reduced sea-surface temperature (~1 °C) throughout the summer months[1]. The cool region stretches for ~300 km along the slopes and exhibits enhanced levels of surface phytoplankton abundance. It has been postulated[2] that physical mixing creates this favourable environment for phytoplankton growth by mixing inorganic nutrients from below the seasonal thermocline, allowing the plant cells to grow more favourably in the well-illuminated surface waters. One possibility is that the mixing is due to the production and propagation of internal tides[3–6]. The present study was undertaken to detect and observe the nature of the internal tide at the Celtic Sea shelf break. We show here that internal tides, generated at spring tides close to the 200-m contour[7–9], propagate simultaneously both on shelf and into the ocean as distorted progressive waves, and when this happens, nutrients are mixed towards the sea surface.

In 1982 and 1983, the RV *Frederick Russell* studied internal waves and tides propagating on-shelf across the Celtic Sea[9,10], whereas in 1984 and 1985 more attention was focused on the off-shelf propagating waves. The September 1985 results were obtained during the participation of the RV *Frederick Russell* in the French *ONDINE* exercise, which examined internal motions and mixing in the stratified surface waters of the Bay of Biscay (to the west of France) and neighbouring shelf regions. The characteristic shelf-break cooling and associated increases in surface levels of chlorophyll *a* (with respect to neighbouring shelf and oceanic waters) were evident (Fig. 1) and at spring tides repeated runs, in a narrow section covering a 300-km extent normal to the shelf break, were made using the SeaSoar to identify the structure of the internal tide. The SeaSoar is a towed undulating conductivity–temperature–depth/fluorometer system[11,12] which allows vertical profiles of temperature, salinity and chlorophyll *a* to be obtained while steaming at 8 knots. Some typical examples of on-shelf and off-shelf waves measured with the SeaSoar are shown in Figs 2 and 3. The internal tide (period 12.4 h) is often characterized by structures of higher frequency (period ~20 min relative to a fixed observer) and higher wavenumber (wavelength ~1 km)[10] which appear mainly in the troughs of the internal tide. Some increase in amplitude of the shorter-period waves in this position would be expected due to compressional straining of the higher-wavenumber structures by the internal tide. In addition, the shorter-period internal waves may be generated locally near this position because the leading slope of the internal tidal trough steepens initially as it propagates from the shelf-break region. The more slowly propagating shorter waves may be partially trapped in the internal tidal trough, where a favourable current structure effectively advects them along. The sea-surface signatures of the higher-wavenumber structures could be observed visually, and ship radar observations[13,14] showed that these waves propagated in a direction (020–200°) normal to the shelf break. The internal tide has an asymmetric structure, where dispersion due to nonlinearity is balanced by that due to Earth's rotation[9], and the characteristic of deeply penetrating troughs together with the associated higher-wavenumber structure has been used to identify all the longer waves encountered on the SeaSoar run. A travel-time graph can be obtained by plotting the position (distance from the 200-m contour) and time (with respect to high water at Plymouth) of each wave. The results are shown in Fig. 4*a*, where the slope of the line represents the speed of travel of the internal tides from the shelf break. The variable speed across the shelf is caused by the barotropic tidal currents alternately

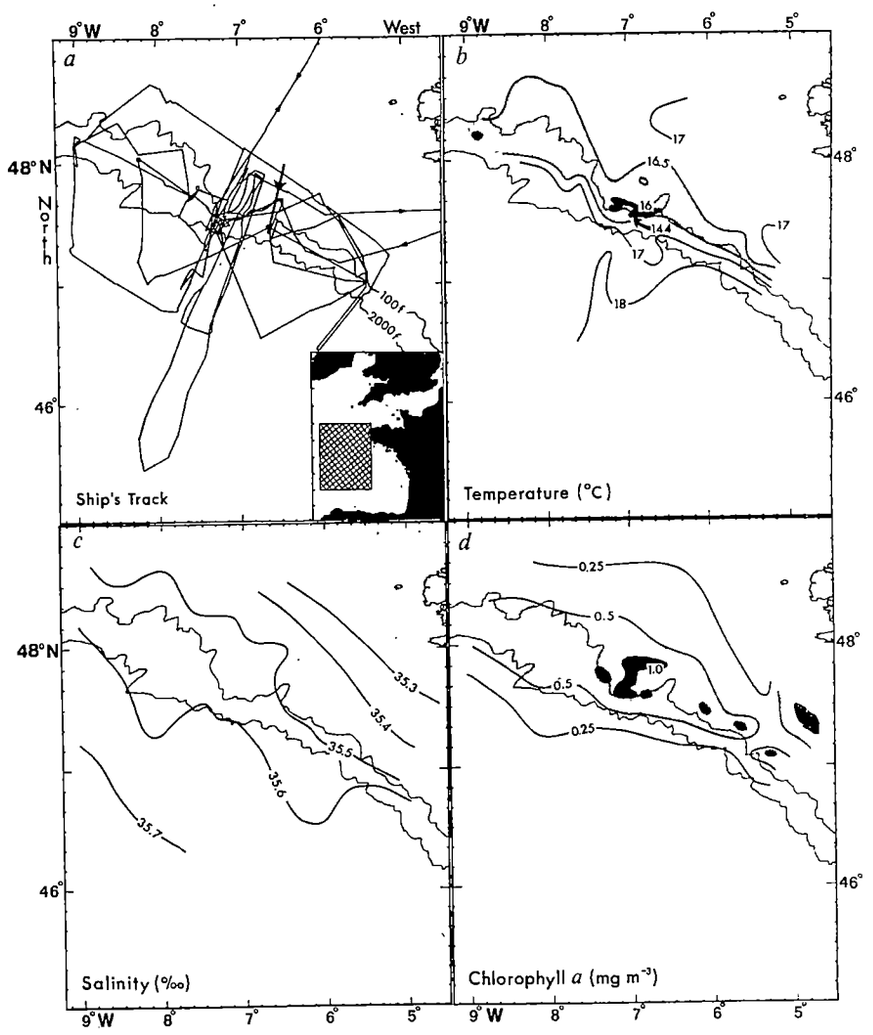

Fig. 1 *a*, Map of the region showing the cruise track of the RV *Frederick Russell* for the period 7–25 September 1985. Also shown (bold line) is the track and direction for the SeaSoar run (30 August 1984) illustrated in Fig. 2. Dots indicate positions of current-meter moorings. *b*, Mean sea-surface temperature contours for the period 13–25 September 1985. *c*, Mean sea-surface salinity contours (‰) obtained while steaming along the track shown in *a*. *d*, Mean surface levels of chlorophyll *a* (mg m^{-3}) obtained while steaming along the track shown in *a*.

assisting and opposing the on-shelf progress. Apart from an initial assistance by the barotropic tidal currents, the off-shelf propagating tide has a steadier oceanward progress since the barotropic tidal currents are only a few cm s^{-1} in the deeper (4,500 m) water regions. Scatter of the points about an idealized line is to be expected as the waves may be refracted by varying density structure[15], propagate through oceanic eddies[16–18], and originate from irregular topography in the upper slope region where there are also variations in the timing of maximum off-shelf tidal streaming in an along-slope direction.

Two interesting points that emerge from the travel graphs concern the generation times of the internal tidal troughs and the differences in mean phase speed for the on- and off-shelf waves. Both the on- and off-shelf travelling troughs seem to be generated near the 200-m contour at about the same tidal state, that is, ~2–4 h after high water at Plymouth, which corresponds to the off-shelf streaming phase for the barotropic tide (maximum off-shelf tidal streaming in a direction normal to the slope occurs ~2 h after high water at Plymouth in this region), ruling out the possibility that they propagate alternately on-shelf and off-shelf due to some form of simple lee-wave mechanism[19]. Although the actual physical mechanism has not been estab-

Table 1 Estimates of phase speeds for internal tides

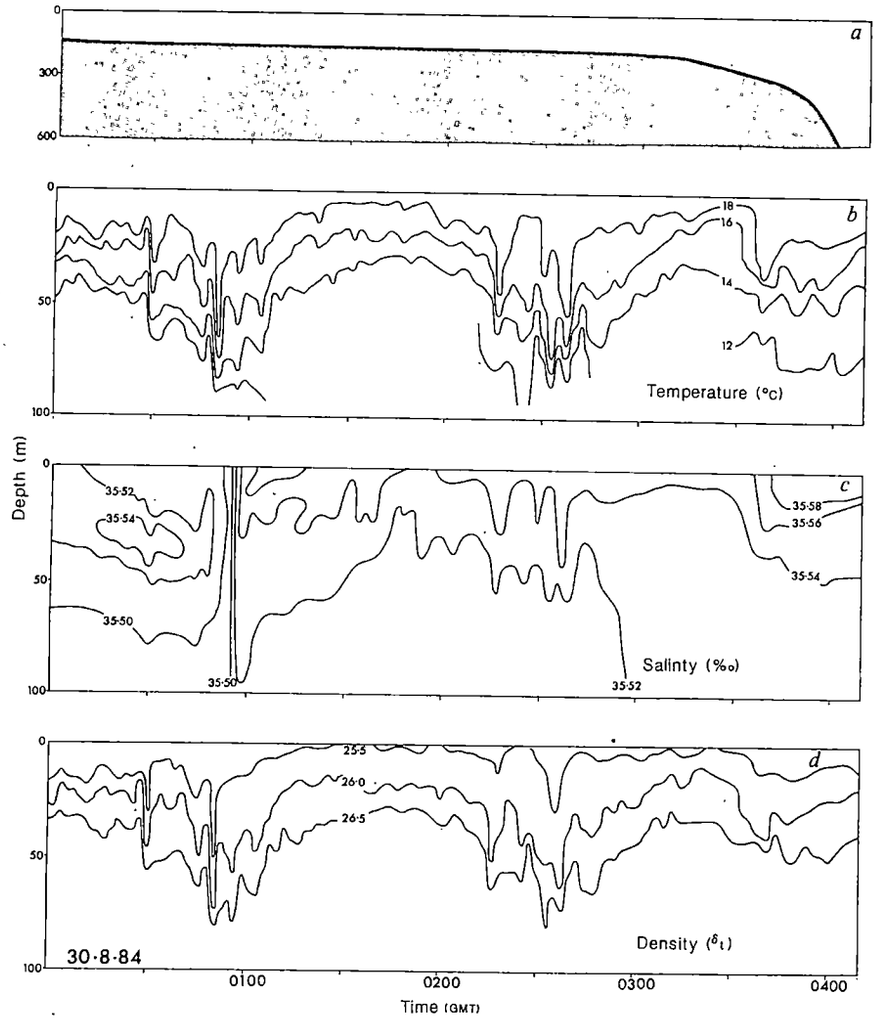

Fig. 2 Simultaneous vertical profiles of water depth (*a*), temperature (*b*), salinity (*c*) and density (*d*) obtained along the SeaSoar run shown in Fig. 1*a*. The temperature, salinity and density profiles were contoured from 100 individual profiles and show two deeply penetrating internal tidal troughs travelling on-shelf. Note the asymmetric structure of the long waves and the higher-wavenumber structures in troughs of the internal tide.

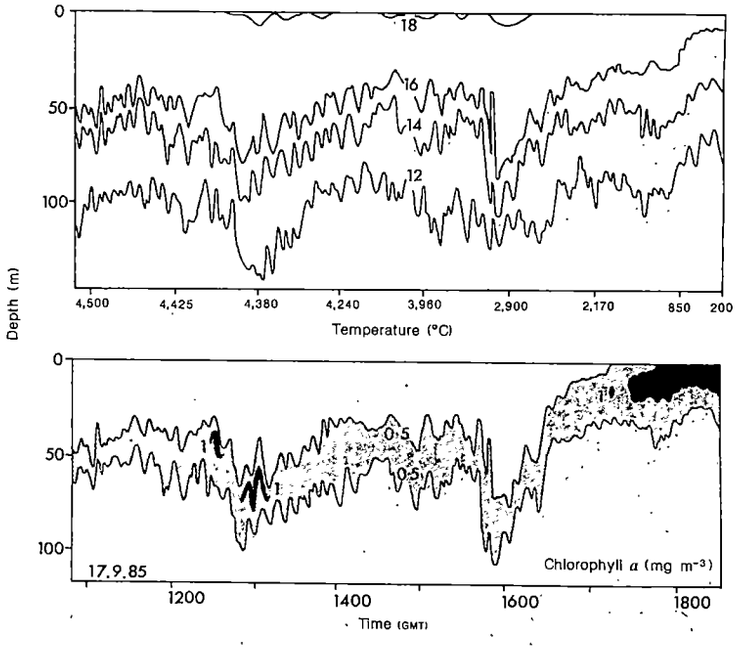

Fig. 3 Simultaneous SeaSoar profiles of temperature and chlorophyll *a*, showing two ocean propagating internal tidal troughs. The section was contoured from 180 vertical profiles and the run was made while the ship was heading towards the shelf. The two troughs at ~1300 and 1600 GMT can be identified in Fig. 4*a* and *b* as numbers 10 and 11. The total water depth (m) is indicated below the temperature section. The surface chlorophyll *a* increases at the shelf break (200 m), as depicted in Fig. 1*d*.

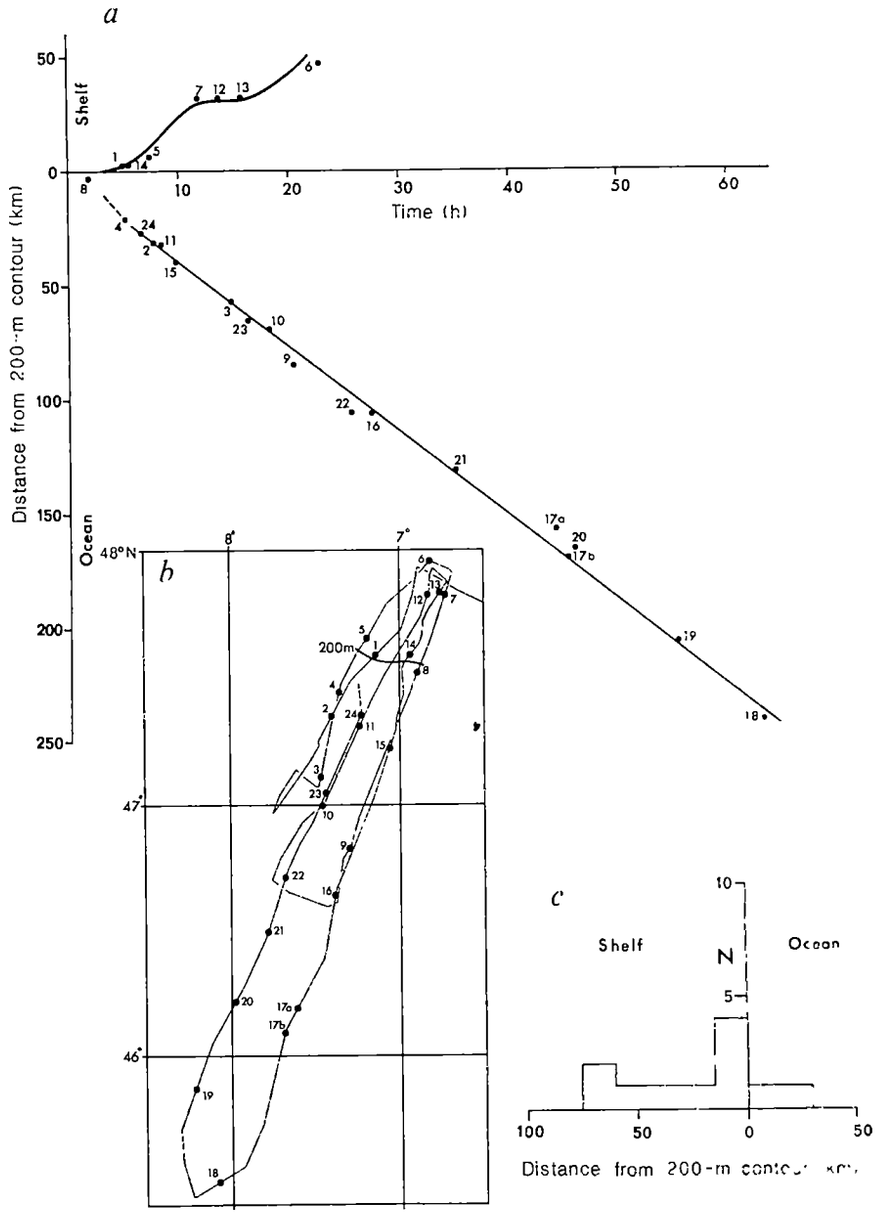

Fig. 4 *a*, Travel-time graphs for all the on-shelf and off-shelf internal tidal troughs identified in the SeaSoar records as the ship progressed along the track shown in *b*. The arbitrary time origin corresponds to high water at Plymouth and distances are measured normally from the shelf break (200-m contour) in kilometres. Individual internal tidal troughs were not followed and so at increasing distance from the shelf break the travel time, t, was determined from $t = T + n\tau$ where T is the time (in h) after the most recent high water (Plymouth) at which a trough was encountered, τ is the semidiurnal tidal period (in h) and n is an integer. Each trough has been numbered in the order in which it was observed and some individual waves were measured subsequently at increasing distances from the shelf break. For example, numbers 11, 16 and 20 represent different encounters with the same tidal trough. Note that the waves are Doppler-shifted, that is, the frequency of encounter is greater when the ship is steaming towards the generating region near the shelf break (compare the observed relative positions of waves 19, 20, 21, 22, 23 and 24 measured when the ship is heading in the direction from which the waves are coming, with the relative positions found for waves 15, 16, 17 and 18 measured as the ship is catching up and overtaking successively older internal tides). Wave 17 appeared to have two troughs and is plotted as 17a and 17b. The on-shelf travel-graph (thick line) represents a steady phase speed of 0.70 m s^{-1} travelling in a medium which is itself oscillating at ~0.70 m s^{-1} due to the barotropic tidal currents. The off-shelf travel graph is more steady at ~1.03 m s^{-1} except near the shelf break where the straight line is assumed to have an increased slope (dashed line) to take account of the increased barotropic tidal current measured on the slopes and an assumed approximate mode-1 oscillation. Errors in positioning the internal tidal troughs in space and time are generally <3 km and <10 min respectively so large deviations from the idealized line represent real variability. *c*, Frequency distribution of the number (N) of surface nutrient pulses observed within 15-km intervals from the 200-m contour. The distribution is biased towards the shelf, showing that surface nutrient levels increase at the shelf break faster than over the slopes and oceanic regions as the thermocline is eroded by internal tidal mixing.

lished, and clearly the real situation is more complex, these preliminary results suggest that during the off-shelf streaming phase of the barotropic tide the isotherms in the upper slope region descend and that this depression separates as the on-shelf and oceanward internal tidal troughs propagate from the generating zone[9,20]. At large spring tides the crest-to-trough height of the internal tide is ~50–60m in the generating region and the decay scale (the travel distance over which the amplitude falls to e^{-1} of its initial amplitude) is ~200 km for the faster ocean-going waves[8] and ~70 km for the more slowly propagating shelf internal tide. The more rapid decay rate (double) of the on-shelf tide can be partially attributed to increased dissipation due to the addition of the internal tidal currents to the barotropic tidal currents in the presence of quadratic friction[21].

Linear theory[22] indicates that in a two-layer fluid the phase speed, c, for internal tides with crests that are parallel and horizontal (Sverdrup waves), and whose wavelengths are long compared with the depth of the ocean and whose periods are long enough to be influenced by Earth's rotation, is given by

$$c = (gh_e)^{1/2} \tag{1}$$

where g is the acceleration due to gravity and h_e, the effective depth for the baroclinic mode, is defined as

$$h_e = \frac{\delta\rho}{\rho}\frac{h_1 h_2}{H(1-f^2/\sigma^2)} \quad \text{with } H = h_1 + h_2 \tag{2}$$

where $\delta\rho$ is the density difference between the upper layer of thickness h_1, and the lower layer of thickness h_2, with density ρ. The ratio of the Corolis parameter, f, at the latitude $\phi = 47°$ N, to the tidal frequency σ, is $f/\sigma = 0.76$.

The energy contained in these waves propagates at the group velocity, c_g, defined as

$$c_g = \frac{\partial\sigma}{\partial k} = c\left(1 - \frac{f^2}{\sigma^2}\right) = 0.43c \tag{3}$$

where $k = 2\pi/\lambda$ is the wavenumber, indicating that maximum internal tides (spring tides for the internal tide) will tend to occur at a distance l from the shelf break at a time $t \sim 2.3l/c$ after spring tides for the barotropic tides.

Mean values of h_1 and h_2 are estimated in Table 1, where $\Delta\rho$ now refers to the density difference that occurs over an arbitrary

50-m interval centred across the seasonal thermocline. Numerical studies showed that nonlinearity had only a small effect on the phase speed and that if the full density structure was taken into account[23-26] then the shelf situation was well represented by the first baroclinic mode, as indicated in Table 1. For the oceanic situation, the density below the thermocline increases slowly with increasing depth, and a two-layer approximation with $\Delta\rho$ estimated as above is not valid. The third and fourth modes give the most realistic phase speeds for the oceanic region. On the upper slopes, in water depths of ~1,500–500 m, the peak-to-trough amplitude of the internal tide increases to ~200–400 m (respectively) at mid-depth and towards the bottom during spring tides. There are some differences of phasing between the upper and lower layers in the deeper regions, and near the bottom in ~500 m depth the currents are intensified at some locations[19], reaching 80–90 cm s^{-1} at times. Thus, the oceanic situation differs from the shelf situation in that the full density structure results in a generation and conversion of internal tidal energy into higher internal modes and allows rays to penetrate the ocean at an angle given by the internal wave characteristic[8,19]. The theoretical estimates of the phase speeds for the internal tides are in reasonable agreement with observed values (Fig. 4) of 1.03 m s^{-1} for the ocean propagating internal tide and 0.7 m s^{-1} for the on-shelf tide, giving corresponding wavelengths of 46 and 31 km respectively, which supports the interpretation of the data obtained from the sea programme.

During the neap tide period immediately before the observations illustrated in Figs 3 and 4 there was little evidence of any internal tidal activity and the sea-surface levels of inorganic nitrate were uniformly low (<0.1 μM). During the spring tide period, nutrient pulses (where the surface values increased by >0.1 μM above background) were detected at the sea surface and their frequency distribution with respect to the 200-m contour is indicated in Fig. 4*c*. The distribution suggests that most mixing events occur near the 200-m contour but spread well on-shelf (~50 km). Although two nutrient pulses were observed on the slopes the indications are that surface nutrient pulses due to internal waves and tides are rare events in the open ocean at this time of year[6]. The distribution bias towards the shelf, the reduced vertical density structure on the shelf (Table 1) and the more rapid decay of the on-shelf propagating internal tide are consistent with increased mixing on the shelf. Some nutrient pulses are completely mixed to the surface and are detectable on successive passes, others do not persist at the surface and collapse back as the crest of the internal tide (or the crest of a structure of higher wavenumber) passes by. No new nutrient pulses were observed in the region during the next period of neap tides from 20 September to the end of the cruise (26 September).

In the present study, we have established that the thermocline is forced near the shelf break of the Celtic Sea during spring tides. In this process, mixing takes place as the internal tides and higher-wavenumber structures are generated and propagate away from the forcing region. Although a causal relationship between internal tides, nutrient renewal and increases in phytoplankton abundance in the vicinity of the shelf break has been indicated, further studies are required to quantify the nutrient flux and phytoplankton response arising from the internal tidal activity.

We thank EPSHOM and especially Yves Camus for coordinating our participation in *ONDINE*, also John Smithers, Ian Waddington, Bob Longmore and the Research Vessel Services Computing Group for assistance at sea. A.L.N. is supported by an ARE contract with NERC.

Carbonate recrystallization in basal sediments: evidence for convective fluid flow on a ridge flank

Miriam Kastner, Joris M. Gieskes & Jine-Yu Hu

Scripps Institution of Oceanography, La Jolla, California 92-93, USA

In many Deep Sea Drilling Project (DSDP) drill holes, chalks and/or limestones and even dolomites overlie oceanic basement rocks. These occurrences have often been interpreted as the result of increased calcium carbonate dissolution and reprecipitation as cement and overgrowths (recrystallization) at higher prevailing temperatures, either near an oceanic ridge system or at greater burial depths (burial diagnesis). We report here detailed chemical and isotopic analyses of carbonate sediments recovered from a drill hole on the western flank of the East Pacific Rise during Leg 92 of DSDP. This hole was drilled on 4.6-Myr old oceanic crust and recovered chalks directly overlying oceanic basement at a depth as shallow as 8 m below the sediment/water interface. Oceanic basement was not reached in this hole because of the hardness of deeper chalks, or, more likely, limestones. The chemical and isotopical evidence, detailed below, shows that considerable calcite recrystallization did occur in an aqueous medium similar to normal seawater and at relatively low temperature. This suggests that the observed recrystallization of calcareous ooze to chalk and limestone took place not as a result of burial diagenesis at higher temperatures, but as a result of extensive advective pore water flow through the sediments, which would allow recrystallization of calcium carbonate to take place. This process was, and apparently still is, widespread in the south-east Pacific Ocean.

The sediments of Hole 600C (18°55.70′ S, 116°50·45′ W) at a water depth of 3,398 m, are at least 11.8-m thick, and consist of mixtures of two components: calcite ($CaCO_3$) and red to yellow-brown semi-opaque oxyhydroxides[1], typically observed in this area of the East Pacific Rise[2-4]. The calcite appears in two forms: as biogenic components and as secondary inorganic precipitates. The relative content of $CaCO_3$ decreases with depth (Fig. 1). Some basaltic glass and altered basaltic fragments and traces of terriginous material are also present. At a subbottom depth of 10.25 m a basaltic glass layer occurs which is strongly altered to palagonite and poorly crystalline smectite.

The heat flow at this site is 580 mW m^{-2} (almost 14 heat flow units)[5], with the theoretically expected value being significantly lower[6] (~245 mW m^{-2}). The full spreading rate is ~17 cm yr^{-1}. Interstitial water analyses[7] indicated only small changes in Ca^{2+} and Mg^{2+} with depth as well as increases in dissolved NO_3^-. This suggests little influence of recent upward advection in this hole, although in the vicinity of this hole advective flow has been inferred to occur in certain zones of high heat flow[8].

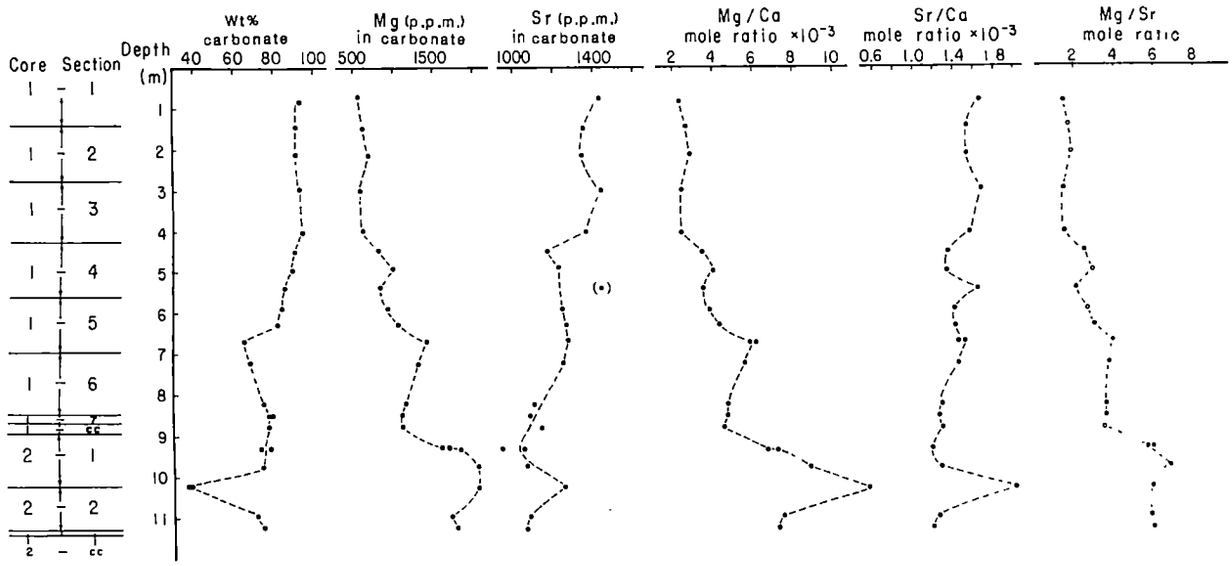

Fig. 1 Weight per cent $CaCO_3$, Mg, and Sr concentrations, and Mg/Ca, Sr/Ca, and Mg/Sr mole ratios in carbonate fraction of sediments of DSDP Hole 600C. Age boundaries: 600C-1-1 (145–150), Pleistocene; 600C-1-2 (145–150), early Pleistocene; 600C-1-4 (145–150), early Pliocene (N 20); 600C-2CC, early Pliocene (N 19).

The boundary between Pleistocene and Pliocene is located close to the top of Core 1, Section 4 (Fig. 1), at about 4.5 m sub-bottom depth[9]. A rather abrupt change in sediment colour is observed below this boundary from brownish yellow to dark brown, associated with a decrease with depth in carbonate contents. About 3 m above the base of the Hole calcareous ooze gives way to chalk.

At present, and throughout its history, the sediments of Hole 600C were deposited above the carbonate compensation depth (CCD)[4,10–13] Preservation of planktonic foraminifera, however, is only moderate to good in the younger samples and moderate to poor in the Pliocene section[14]. The presence of a basal Pliocene chalk layer of at least 3 m thickness in such a thin and young calcareous section cannot be explained by the well documented rates and processes of diagenetic reactions in pelagic calcareous oozes. In this section scanning electron microscopy (SEM) observations revealed extensive calcite dissolution, overgrowth and cement (Fig. 2)[1].

To understand the unexpectedly low degree of preservation of biogenic calcite in the lower two-thirds of Hole 600C, the calcareous fraction was analysed chemically in great detail (Fig. 1). Submarine biogenic calcite recrystallization is generally reflected in chemical, isotopical, and often also in mineralogical changes[15–17].

No important changes in chemical composition are observed in the upper 4–4.5 m, but below this systematic changes do occur, not only in the Sr contents (decreases from ~1,400 to ~1,000 p.p.m. (parts per 10^6)), but particularly in the Mg contents (increases from ~570 to ~2,000 p.p.m.). Sample 2-2 (4–6 cm) at 10.25 m, that is, volcanic glass layer, is unusual. $CaCO_3$ content is only ~37%, and both Sr and Mg increase in the recrystallized carbonate, presumably as a result of special conditions associated with reactions involving volcanic glass alteration. In this thin layer, a small fraction of the calcite cement may have originated in conjunction with low-temperature alteration of the volcanic glass[18].

Below 4–4.5 m burial depth changes in Sr/Ca and Mg/Ca ratios appear systematic, as is also demonstrated in Fig. 3, which, in addition, contains information on a sample of a basal limestone recovered from a Lower Miocene sample of DSDP Site 598 of Leg 92. The Sr/Ca ratio in the latter sample (Sr/Ca $\sim 0.63 \times 10^{-3}$) is close to the equilibrium value at ~2 °C in conditions of normal seawater Sr^{2+}/Ca^{2+} ratios[16,19]. We suggest

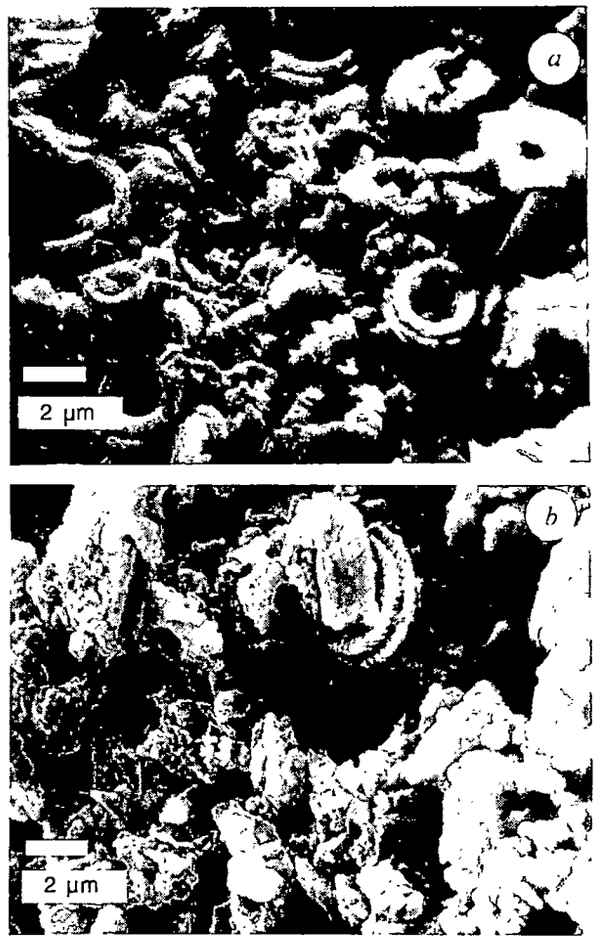

Fig. 2 Scanning electron microscopy photographs of Hole 600C carbonates: *a*, calcareous ooze at 0.8 m depth, and *b*, chalk at 11.2 m depth. Note considerable overgrowth and cementation in chalk but not in the calcareous ooze.

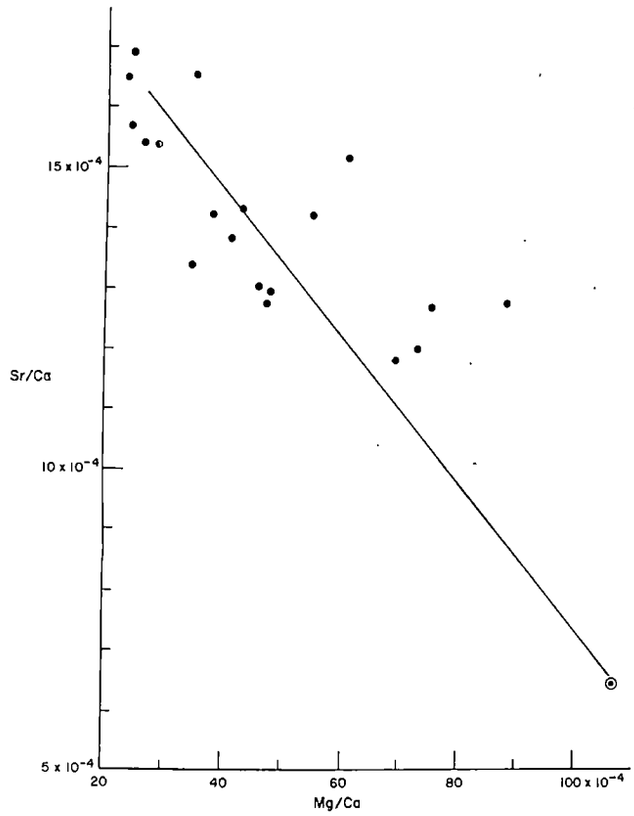

Fig. 3 Correlation between Sr/Ca and Mg/Ca mole ratios in carbonate fraction, DSDP Hole 600C. The circled point is from a basal limestone of nearby DSDP Site 598.

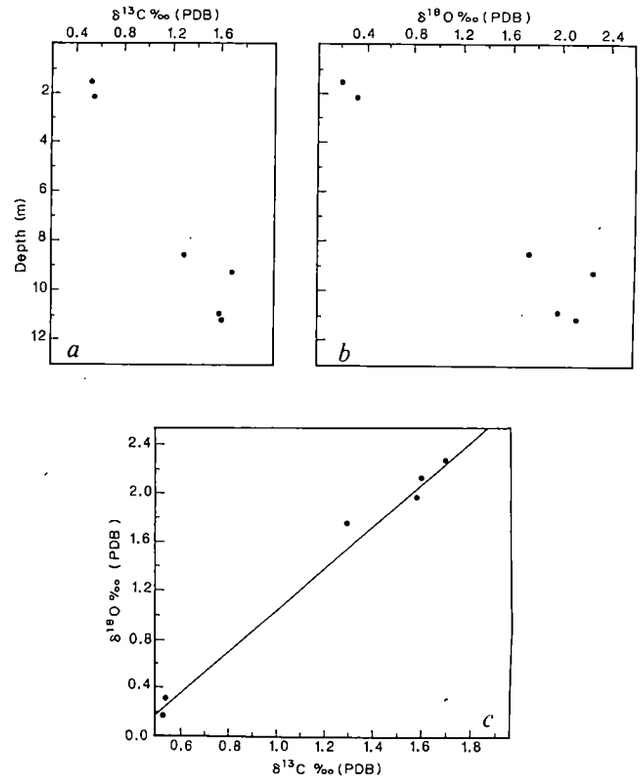

Fig. 4 DSDP Hole 600C: *a*, $\delta^{13}C$ (PDB) in carbonates versus depth; *b*, $\delta^{18}O$ (PDB) in carbonates versus depth; *c*, correlation between $\delta^{13}C$ and $\delta^{18}O$ in carbonate fraction.

that the negative slope in Sr/Ca versus Mg/Ca ratios in Fig. 3 indicates a trend of progressive calcite recrystallization.

Values of $\delta^{18}O$ and $\delta^{13}C$ of the bulk carbonate fraction and of the fraction of coccoliths increase significantly with depth (Fig. 4*a*,*b*). These trends are not expected from the known Pliocene–Quaternary palaeotemperatures[20–23]. Instead, dissolution of planktonic foraminifera and coccoliths and calcite reprecipitation as overgrowth and cements (recrystallization) at lower than surface water temperatures must be responsible for the observed increases in the $\delta^{18}O$ values. The $\delta^{18}O$ value of calcite precipitated from sea water at 2 °C and $\delta^{18}O_w = -1‰$ (SMOW), is 1.9‰ (PDB) and at 2 °C and $\delta^{18}O_w = 0‰$ is 2.9‰ (ref. 24). As for the carbon isotopes, the $\delta^{13}C$ of dissolved CO_2 in surface waters is higher than in the deep and bottom waters[25]. Because of the relatively low ΣCO_2 concentration in seawater (~2,300 μmoles kg^{-1} in Pacific Deep Water), in a sea water–$CaCO_3$ system in which $CaCO_3$ is being dissolved and reprecipitated, the $\delta^{13}C$ of the ΣCO_2 will be controlled by the solid carbonate phase. At 25 °C and in conditions of slow rates of precipitation, the carbon of the solid $CaCO_3$ will be between 1.8 and 2.3‰ heavier than that of dissolved HCO_3^- (refs 26, 27). Up to 60 °C the temperature effect is small, for example, at 20 °C + (0.035 ± 0.013)‰ $°C^{-1}$ (ref. 26). Thus, during recrystallization at low to moderate temperatures, the $\delta^{13}C$ value of reprecipitated $CaCO_3$ will increase. There is a strong positive correlation between the changes in $\delta^{18}O$ and $\delta^{13}C$ (Fig. 4*c*) which again suggests that recrystallization of carbonate is the underlying factor.

On the basis of palaeo-oceanographical and the above documented textural, chemical, and isotopical evidence, we conclude that the processes responsible for the observed extensive calcite dissolution and secondary inorganic reprecipitation and chalk formation in the sediments of Hole 600C, occurred at low temperatures, presumably close to bottom water temperatures, and in solutions similar in composition to bottom sea water. Indeed, Ca^{2+} and Mg^{2+} concentrations in fluids suggesting upward advective flow in this area are similar to sea water[8]. There is little doubt that the recrystallization occurred at an early age. We propose that observed occurrences of chalks and limestones directly overlying oceanic basement generally form at an early age and that special circumstances are needed to explain their early recrystallization. Furthermore we suggest that the most important cause of this process is advective fluid flow through the sediments on the flanks of midocean ridges. In such conditions, recrystallization reactions are greatly enhanced when compared with diffusion controlled systems in which fluid flow is essentially absent. Thus, our observations in Hole 600C suggest that, at least during the first 1–1.5 Myr of the existence of this sediment section, substantial advective flow must have occurred through the sediments. Increasing degrees of recrystallization with depth presumably imply upward flow from underlying basalts, involving low temperature, relatively unaltered sea water. This cementation will lead to eventual sealing of the basement limiting further advective flow. Much of the oceanic basement in the southeastern Pacific Ocean may be covered by similar limestone or chalk layers, which locally restrict convective fluid flow between sea water and oceanic basement.

We thank all cruise participants of Leg 92 for lively discussions. This research was supported by NSF grants OCE-8300692 (M.K.) and OCE-8218539 (J.M.G.).

Mutual diffusion in a miscible polymer blend

R. A. L. Jones, J. Klein* & A. M. Donald

Cavendish Laboratory, University of Cambridge, Madingley Rd, Cambridge CB3 0HE, UK

Self-diffusion in polymer melts has been extensively studied and is reasonably well understood in terms of the reptation model[1–4]; the related phenomenon of mutual diffusion in miscible blends of chemically different polymers has received little attention, despite its practical relevance and implications for physical processes, such as phase separation kinetics. In such blends, attractive interactions between the monomers, when summed over a polymer chain, may lead to large enthalpic driving forces favouring the mixing; this in turn results in a mutual diffusion rate which is rapid compared with the entropically driven self-diffusion[5], and which is strongly composition-dependent[6]. We have measured mutual diffusion as a function of composition in one such binary blend, polyvinyl chloride (PVC)/polycaprolactone (PCL), and report here that the mutual diffusion coefficient is strongly enhanced in the middle of the composition range. This result is qualitatively, though not quantitatively, in accord with the results of some recent theoretical treatments[5–8].

The molecular characteristics of the polymers used are given in Table 1. Diffusion coefficients were determined by measuring the broadening with time of an initially step-like concentration profile. A sharp interface was set up between blends of PVC and PCL differing in concentration by 10%; the sample was then held at a temperature of 91.5 ± 0.5 °C in a vacuum oven for known times (8 h to 7 days). The final distribution of the two polymer species after diffusion-broadening across the interface was then determined using X-ray microanalysis in a scanning electron microscope, in which X rays from inner-shell transitions excited by the electron beam, and characteristic of the element producing them, are counted by a detector. In this case we measured the concentration of chlorine atoms in the PVC across the sample; the spatial resolution of this technique is 3 μm, and with careful sample preparation a concentration resolution of 1% is possible. The resulting broadened profile was analysed using the standard Fick's law solutions to the diffusion equation, to yield directly the value of $D(c)$, the mutual diffusion coefficient at the average concentration c of the diffusion couple. Examples of concentration profiles before and after broadening are given in Fig. 1. Previous workers have used a similar technique[9,10], but in these earlier studies pure materials were allowed to interdiffuse; this does not give satisfactory information about the concentration dependence of the diffusion coefficient for the polydisperse polymers used in experimental

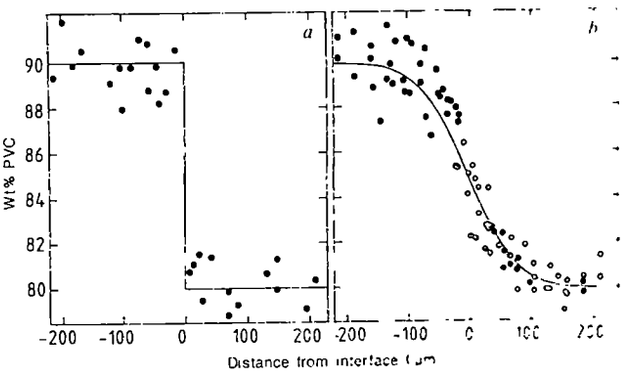

Fig. 1 *a*, Initial concentration profile between two blends (80% PVC/20% PCL, 90% PVC/10% PCL) as revealed by X-ray microanalysis immediately after joining. *b*, Concentration profile after annealing under vacuum for 114.2 h at 91.5 °C. The solid curve is an error-function fit corresponding to $D = 7.42 \times 10^{-11}$ cm^2 s^{-1}, obtained by least-squares analysis. The figure is a composite of five individual profiles measured from different sections of the same diffusion couple. The scatter of each point is ~2–3 times that expected due to counting statistics.

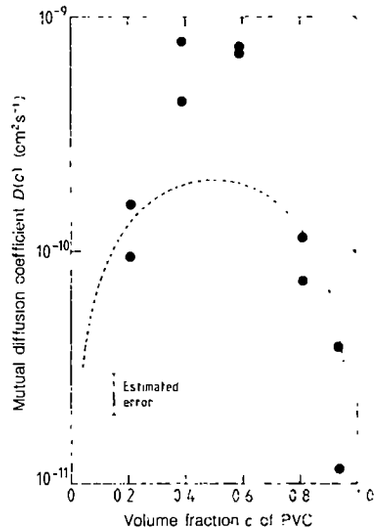

Fig. 2 The measured variation of $D(c)$ with blend composition for the miscible polymer blend PVC/PCL at 91.5 °C. The concentration plotted is the mean volume fraction of PVC in the diffusion couple. Each point corresponds to a value of $D(c)$ taken from a composite concentration profile such as that in Fig. 1, made up of several different profiles for the same diffusion time. Points for a given c correspond to runs carried out over times differing by a factor of ~3. The broken line shows the concentration dependence predicted by equation (1), assuming D_0 to be constant and neglecting the difference in degree of polymerization of the polymers. The actual value chosen for D_0 is arbitrary.

Table 1 Relative molecular masses (M_rs) of polymer samples

Polymer	M_w	M_n	M_w/M_n
PVC	83,500	37,400	2.2
PCL	33,000	10,700	3.1

The polymers used in this study were purchased from Aldrich Chemical Co., and were used as supplied. The M_r characterizations, supplied by Aldrich, were obtained by light scattering and gel-permeation chromatography. M_w, weight-averaged M_r: M_n, number-averaged M_r.

work, as the standard methods for obtaining this information from diffusion profiles apply only to strictly binary systems[11].

Figure 2 shows the measured variation of $D(c)$ with concentration, based on profiles such as that in Fig. 1. A marked maximum in $D(c)$ towards the centre of the concentration range is apparent.

A prediction for the concentration dependence of $D(c)$ is provided by some recent analyses. As in the case of small molecules, the mutual diffusion coefficient may be written as the product of a mobility term and a thermodynamic term expressing the departure from ideality of mixing[12]. The thermodynamic term may be evaluated using the Flory–Huggins theory for the free energy of mixing of a polymer blend; for polymers of identical chain lengths this gives[6–8]

$$D(c) = D_0[1 - 2\chi Nc(1-c)] \quad (1)$$

where c is the volume fraction of one polymer, D_0 is a coefficient expressing the mobility of the components (if the two materials have identical mobilities this would correspond to their self-diffusion coefficient), and χ is an interaction parameter (for polymers to be miscible χ must be $<1/2\ N$). For this sytem χ has been estimated by melting-point depression, and is expressed per monomer unit of PCL ($\chi = -0.38$)[13]. The presence of the polymerization index N ensures that the second term in equation (1) dominates for all but the smallest concentrations; that is, the diffusion is driven by enthalpy rather than by entropy. It is this that leads to the characteristic observed concentration dependence. For polymers with differing molecular masses the thermodynamic term is slightly different[8]; this introduces a skewing of the curve towards the region rich in the longer polymer.

The measured concentration dependence in the system we have studied is rather stronger than the simple quadratic relation given in equation (1) (compare with broken line in Fig. 2). Quantitative agreement with this result is not to be expected, because of the simplifications in the model used. In particular, no microscopic theory exists for the average mobility term D_0 when the polymers have different mobilities. In this system it is clear that there are large differences between the mobilities of the pure components; this is reflected in the large variation of glass transition temperature with composition[14]. Nonetheless, the present study shows directly for the first time that in a miscible polymer blend the mutual diffusion coefficient does indeed vary strongly with blend composition; a maximum is indicated near the middle of the blend composition range, in qualitative agreement with recent theoretical treatments.

We thank Dr F. Brochard, Professor E. J. Kramer and Dr R. C. Ball for useful discussions. R.A.L.J. holds an SERC CASE studentship with ICI PLC.

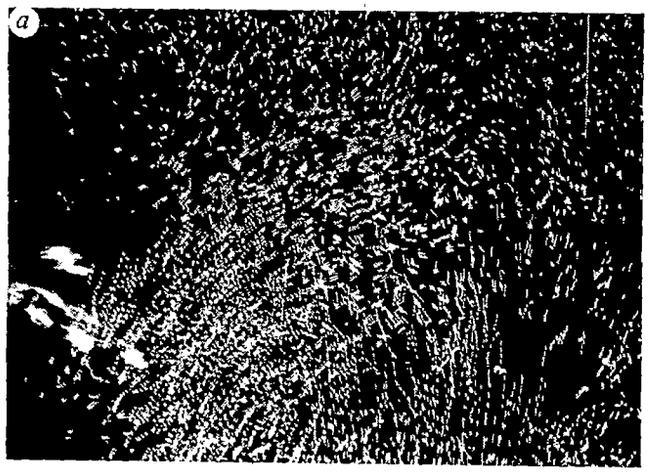
Vortex flow visualizations reveal change in upstroke function with flight speed in bats

Jeremy M. V. Rayner, Gareth Jones & Adrian Thomas



Department of Zoology, University of Bristol, Woodland Road, Bristol BS8 1UG, UK

The flapping wings of flying birds and bats generate complex, unsteady air movements. These consist of well-defined vortex structures which are a necessary result of the aerofoil action of the wings, and which transport momentum below and behind the animal in reaction to the lift force which both balances weight and provides thrust[1]. Visualization of the vortex patterns enables the aerodynamic function of the flapping wings to be determined[2–6]. Here we present the results of experiments with small vespertilionids which allow the first description of the vortex wake of bats. The aerodynamics of flapping flight is similar between birds and bats: thrust is always generated during the downstroke, but wingbeat gait (the cyclic pattern of wing movements) and the mechanical function of the upstroke are determined by wing morphology. We present the first evidence from aerodynamic experiments that in an individual bat or bat species, upstroke function and wingbeat gait also vary with flight speed, with aerodynamic lift being generated during the upstroke at high speeds but not during slow flight. This result confirms that flapping gaits are not species-specific, but are selected according to the mechanical conditions experienced by the animal.

We trained long-eared bats (*Plecotus auritus* L.) and noctules (*Nyctalus noctula* L.) to fly through a cloud of neutrally buoyant helium-filled soap bubbles, and recorded wake airflows by photographing the movements of the bubbles in stereo; illumination by four electronic flash guns fired successively at short intervals (8–12 ms) enabled vortex-induced air speeds to be determined, since speed is proportional to the distance between bubble images. Discrete vortices are identified by localized high flow velocities and pronounced rotational flows. This method has been applied to various species of birds[3,4,6], but has not been used previously with bats. Figures 1–3 show typical photographs from a total of about 250 of the two species, together with sketches, drawn from stereo pairs, of the associated discrete vortex patterns.

Wake photographs should be interpreted in relation to the balance of forces on the flying animal. The lift on the flapping wings acts horizontally as a thrust as well as vertically supporting the weight. If weight support alone were required the wings would not need to be flapped (a fixed gliding wing can generate sufficient lift to equal weight), but flapping of the wings must serve also to balance frictional and vortex drag forces: in gliding flight drag is uncompensated, and the animal has no alternative but to descend or decelerate relative to the air. The wake vortices transport momentum, the mean reaction of which in flapping flight is experienced as a lift force acting on the wings and providing *both* thrust and weight support. In the downstroke the wings move forwards and downwards relative to the air, and lift has the required forwards and upwards action[1,5,7,8]. In the upstroke, however, the wings move primarily upwards; at high flight speeds they also travel forwards, the air flow meets the ventral side of the wing as in the downstroke, and if lift is to contribute to weight support it cannot also give thrust, but must retard the animal[5–7]. In slow flight the wings may move slightly backwards relative to the air; lift forces are likely to be small or absent[1,7], but it has been suggested that if in bats the air flow strikes the dorsal surface of the wing, the resulting weak lift may act as both thrust and weight support[5,7,8].

Thus, upstroke function is the main mechanism of differentiation between flapping flight gaits in flying vertebrates, and the upstroke may be expected to act in different ways at different flight speeds. Experiments with birds have confirmed that gaits are constrained by wing morphology[2–6]: an active, lifting

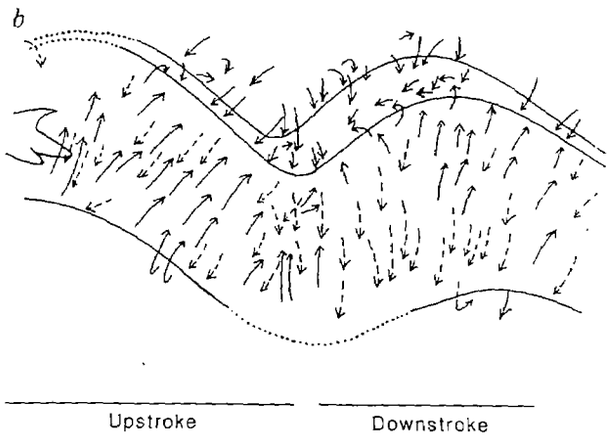


Fig. 1 Flow visualization for the noctule *N. noctula* in steady forward flight at ~7.5 m s^{-1}. *a*, Flow visualization photograph (one half of a stereo pair). *b*, The wake vortices and induced air movements as drawn from stereo pairs. (Bubble direction can be inferred from the photographs as the light intensity is not constant during each flash[3,4]; broken arrows indicate air movements between the vortex cores.) The wake is formed from a pair of continuous vortex tubes which follow the path of the wings; the spacing of the core centres is ~75% of the distance between the wingtips. The cross-sectional diameter of the cores is greater than that commonly seen in birds[2-4] owing to the relatively small size of the bat. The bat is climbing slightly, but this does not substantially distort wingbeat action compared with level flight. Flash interval 10 ms.

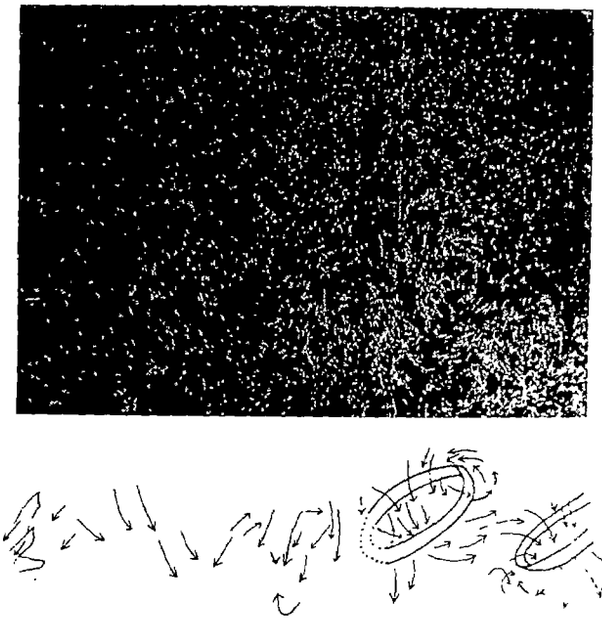

Fig. 2 Flow visualization for noctule in slow flight (3 m s^{-1}), together with the transition to faster flight as the bat accelerates. Two vortex rings are visible to the right; no trailing vorticity is shed during the upstroke, and there is a strong momentum-transporting flux of air through the centres of the rings. These are followed by a weak, continuous tube vortex closer to the bat. Flash interval 10 ms; only three flash guns were used in taking this photograph.

upstroke is more common in long-winged species (typically in fast flight at ~8 m s^{-1} in the kestrel *Falco tinnunculus*[3,6], with above-average aspect ratio and pointed wings), but is absent in small finches[2], which have shorter, rounded wings. During an active upstroke (that is, with aerofoil action generating a lift force) the effective wingspan must be reduced by flexing or sweeping back the wing to reduce retardation from lift and so ensure a mean positive thrust. Theoretical models predict that in an individual animal the upstroke should be active at higher flight speeds, while in slow flight it should be inactive and the wingtips should be brought close to the body to minimize friction drag and inertial forces[1,5,7]. The experiments reported here provide the first direct aerodynamic evidence for such changes in upstroke function.

The wakes of flying microbats have much in common with those of birds. When the wings are actively generating lift, the vortex sheets shed from the trailing edges roll rapidly into a pair of discrete vortex lines or tubes behind the wingtips. In fast flight (7–9 m s^{-1}—normal cruising speeds) the noctule's wake is a continuous, undulating vortex pair (Fig. 1); this indicates that the upstroke is active in the way described above, and confirms an earlier prediction[5] based on wingbeat kinematics. The vortex structure is similar to that seen for the kestrel[3,6]. The marked absence of transverse vorticity leads to the remarkable conclusion that in both animals the strength (circulation) of the bound wing vortex does not vary during the wingstroke; this conveys certain mechanical advantages[5,7]. Both noctule and kestrel have wings of above-average aspect ratio, and use similar wingbeat kinematics which are fully consistent with this form of wake[5]. The wingtip is swept back in the bird, while the arm wing is flexed in the bat; but, in both, the wingtip moves towards the body during the upstroke.

At lower speeds (3 m s^{-1}) the noctule wake is rather different (Fig. 2): prominent transverse vortices are shed at the top and bottom of the downstroke, and the upstroke is flexed and inactive. Circulation can no longer remain constant, although it may be nearly so during the downstroke. This 'vortex ring' wake is similar to that of small finches[2] and slow-flying pigeons[3,4,6]. Noctules are fast-flying bats which rarely fly sufficiently slowly to show an inactive upstroke, but together our results (as illustrated by Figs 1 and 2) provide the first evidence that upstroke function is variable and is not in general species-specific; moreover, an individual animal changes its gait optimally as flight speed increases. In slow flight (1–2 m s^{-1}) in the long-eared bat (which has rather large wings of low aspect ratio) the wake is similar to that of the slow-flying noctule (Fig. 3), with a clear vortex ring corresponding to aerodynamic lift during the downstroke. Our flow visualizations provide no evidence that the upstroke is active in *P. auritus* at any speed, although Norberg concluded from wingbeat photography that in this species at low speeds a weak lift acts as thrust[8]. In slow flight the wingbeat kinematics of both species show considerable flexure and twisting of the wings during the upstroke[5,7-10], and any lift generated then is weak. It has been suggested[5,8,9] that the rapid 'flick' phase at the top of the upstroke in this and similar bats[8-10] may

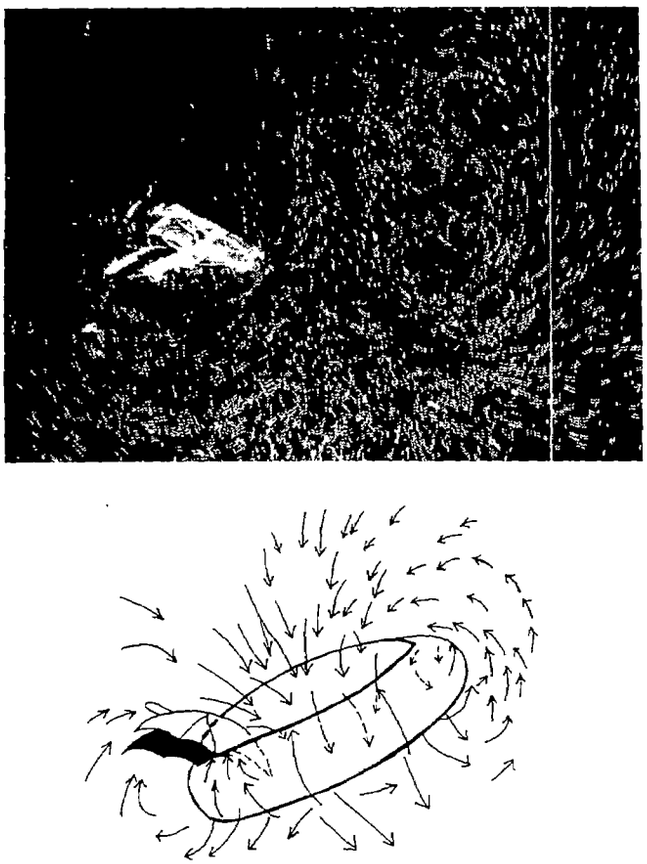

Fig. 3 Flow visualization for long-eared bat *P. auritus* in slow flight (1.5 m s^{-1}). Intense rotational flows induced by a vortex ring generated during the downstroke are visible; at the time of the photograph the wings were at the bottom of the downstroke, and ring generation was still in progress. No vorticity had been shed during the predeeding upstroke, but a similar ring was generated by the preceeding downstroke. The wake in this species is similar to that recorded previously in finches[2] and pigeons[3,4]. Flash interval 8 ms. The matching stereo pair of this photograph is shown on the front cover.

generate thrust; this would entail generation of a concentratated transverse vortex at the start of the flick, approximately midway through the upstroke. We found no trace of such vortices in any of our photographs, although as any lift would necessarily be small, they might have been obscured by the more dominant forces and vortices associated with the downstroke. Although unsupported by the present experimental evidence, we cannot exclude the possibility of weak upstroke lift in at least some bat species.

Despite obvious morphological differences, the flapping-wing aerodynamics of birds and bats show considerable similarities. In both groups gaits are defined by upstroke function, which has been shown to vary with wing morphology. Gait changes with flight speed similar to those reported here in bats have been inferred in birds from analysis of wingbeat kinematics[1,5]; similarly, in bats these changes are likely to be reflected in generation of upstroke lift and the structure of the wake vortices.

Genetics and evolution of female choice

M. E. N. Majerus, P. O'Donald, P. W. E. Kearns & H. Ireland

Department of Genetics, University of Cambridge, Downing Street, Cambridge CB2 3EH, UK

Fisher's theory of the evolution of sexual selection by female choice depends crucially on the premise that the preference of females to mate with males of a specific genotype is itself genetic[1]. In the polymorphic ladybird *Adalia bipunctata*, a genetically determined, non-assortative female preference for melanic males has been demonstrated[2]. Models of the evolution of female choice show that the rate of evolution and the final outcome of this selection depend critically on the exact mode of inheritance of both the preferred character and the preference[3]. Here we describe experiments in which the level of preference has been raised by artificial selection over 14 generations. Resultant estimates of heritability are consistent with models in which one or a small number of genes control the preference. Analysis of the levels of preference in isofemale lines derived from the high preference stock shows a quadrimodal distribution in preference. These results are entirely consistent with the deduction that a single dominant gene controls female choice. We conclude that this complex behavioural strategy is based on simple genetics. Furthermore, the demonstration of a simple genetic basis to female mating preferences in *A. bipunctata* implies that sexual selection by female choice is not only important in the evolution of male sexual adornments in sexually dimorphic species, but may also maintain polymorphisms that are not sex-limited.

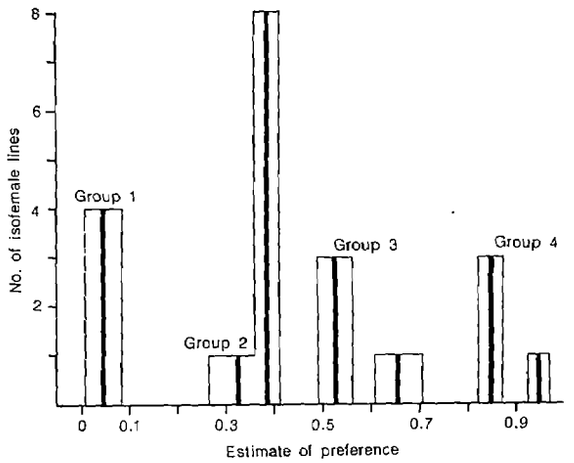

Fig. 1 Isofemale lines shown divided into four distinct groups. The solid black bar shows the position of the estimated preference in the given number of lines, open bars, the standard error. In groups 2, 3 and 4, the preference is also shown for the line most divergent from the others in the group. When groups are considered separately, each of groups 1, 2 and 3 is found to be statistically homogeneous. Group 4 is heterogeneous, with line Z35 having a significantly higher preference. In later population cage experiments, however, Z35 did not show a higher preference. The total χ^2 for heterogeneity within all groups is not significant (Table 2).

Q represents the four-spot melanic *A. b. quadrimaculata* and T the two-spot non-melanic *A b. typica*. The numbers of matings are the combined numbers in two replicate lines. $\hat{\gamma}$, is the estimated proportion of preferential matings for Q males, shown with the standard error[15]. At generations 5 and 10, the replicates were allowed to mate together without artificial selection. Two new lines were then formed from the unselected generations 5 and 10 to give selected generations 5 and 10 for each of the new replicates. The data shown are those for the selected generations 5 and 10 only. The drop in preference at generations 5 and 10 suggests that there may have been some natural selection against the high preference. The latter drop is the main source of the heterogeneity that gives rise to the significant residual χ^2.

In ladybirds, sexual selection takes place because females exercise a genetically determined preference for melanic males. In a natural population of the two-spot ladybird, *A. bipunctata*, at Keele, UK, melanic males gain a mating advantage over non-melanic males. About 20% of matings take place preferentially with melanic males[4]. Majerus, O'Donald and Weir[2] selected increased female preference, raising the proportion of preferential matings from 20% to more than 50% in four generations. Reciprocal matings between males and females from the selected, high preference line and the unselected, original Keele stock showed that female preference, and not male competitiveness, had indeed been selected. The preference was genetic, in accordance with the premise of Fisher's theory.

We have now repeated this experiment, but have selected for both increased and reduced preference, producing high and low preference lines. The experimental protocol follows that of our previous selection experiment[2]. The results of selecting for increased preference are shown in Table 1. At generation 10, single pairs were selected at random from the high line. Each batch of eggs was laid by each female in a separate Petri dish and the larvae thus reared separately to avoid larval cannibalism. In this way, large numbers of progeny, up to 600 from some females, have been produced for measurement of the female preference within each 'isofemale line'. In initial, formal mating tests, 10 males and 10 females each consisting of 5 *A. bipunctata quadrimaculata* melanics (Q) or 5 *A. bipunctata sexpustulata* melanics (S) and 5 *A. bipunctata typica* non-melanics (T) were placed in containers and allowed to mate. At 30-min intervals, mating pairs were removed and replaced with individuals of similar phenotypes. In each 30-min interval, therefore, matings took place without replacement. The results are shown in Table 2. Since as many as five or six matings might take place in each interval, the sampling without replacement creates a very difficult problem for the statistical estimation of the preferences Nevertheless, a general test of significance based on the null hypothesis of no preference shows wide variation between the isofemale lines. Female progeny from some lines mate almost solely with melanics, while those from others mate at random or show intermediate levels of preference (between lines $\chi^2_{39} = 387.08$; $P \sim 0$). No significant differences were found when Keele males or males from other lines were used instead of males from the same line as the females ($\chi^2_4 = 6.01$; $P = 0.198$). The variation in preference is thus produced entirely by genetic differences contributing to the female choice. Lines showing high, intermediate and low levels of preference were chosen for further genetic analysis. We have now tested the preference in some of these lines using large numbers in population cages, with replacement of males as in our original experiments[2]. Table 3

Analysis of χ^2

Component of variation	χ^2	Degrees of freedom	P
Between groups	362.39	3	—
Within groups	24.69	17	0.102
Within replicates of lines	20.35	19	0.374
Total	407.43	39	—

In this analysis of χ^2, the data for replicates of tests on individual lines have not been included. Totals over replicates within lines are shown. The analysis of χ^2 is based on the null hypothesis of random mating of male phenotypes: it is an analysis of the values of χ^2 for interaction in the $2 \times 2 \times N$ table of numbers of mated and unmated phenotypes of males in tests on the isofemale lines. Note that the same males and females may be used several times in successive series of tests.

gives the results obtained so far.

The distribution of levels of preference in the isofemale lines suggests that female preference for melanic males may be largely under the control of one or a very few major genetic loci. The isofemale lines can be divided into four groups according to their preference (see Table 2, Fig. 1). Group 1 females show no significant preference, group 2 females have levels of preference between 0.32 and 0.43, group 3 females have levels of preference of 0.50–0.65, and group 4 females have the highest levels of preferences, between 0.80 and 0.94. There is overall homogeneity within the groups ($\chi^2_{17} = 24.69$; $P = 0.102$), and highly significant differences between groups ($\chi^2_3 = 362.39$; $P = 1.8 \times 10^{-9}$).

The population cage experiments on progeny from the isofemale lines corroborate this apparent discontinuity in the preference distribution (Table 3). Matings were observed in cages in which melanic males and non-melanic males were maintained at the ratio 3Q:7T as in previous experiments[2,4]. If matings take place with males at this ratio, no preference has been exercised and mating has been random. An excess of Q males in mating indicates preference. A simple model yields an estimate of the proportion of females mating preferentially

$$\hat{\gamma} = \frac{n_Q(1-v) - n_T v}{(1-v)(n_Q + n_T)}$$

where v is the frequency of Q males ($v = 0.3$ in these experiments), and n_Q and n_T are respectively the numbers of Q and T males observed to mate. Again, some lines show high levels of preference (lines Y19, Z28, Z35, Z37 and Z40), while others show no preference at all (lines Y12, Z4, Z33) or intermediate levels of preference (lines Y9, Y14, Z13, Z34).

The pattern of preference levels can be easily explained by a single dominant gene. In the population at Keele, females would either carry the preference gene and hence show the high level of preference at about $\gamma = 0.85$ or lack the gene and show no preference at all. If about one-quarter of the females have the preference, this would give the observed level of 20% preferential mating in the unselected Keele population. After selection has raised the preference to around 50% as in our high line, the preference gene would then have a frequency of $P = 0.36$. At this gene frequency, 24% of matings should only produce females with the preference ($\gamma = 0.85$), 21% should produce females of which three-quarters have the preference ($\gamma = 0.64$) and 38% of matings should produce females of which half have the preference ($\gamma = 0.43$). Females from the rest of the matings should all mate without preference, for none of them would carry the preference gene. The isofemale lines follow this pattern closely, as Fig. 1 shows, with groups 1–4 represented by 4, 9, 4 and 4 isofemale lines respectively ($\chi^2_3 = 0.453$, $P = 0.93$ for test of goodness-of-fit).

We have thus shown that female ladybirds are highly polymorphic in their preference for melanic males. This polymorphism is genetic. Single-gene models, such as those of O'Donald[3] and Kirkpatrick[5], may therefore be sufficient to explain the evolution of female choice as a mating strategy.

In the ladybirds, natural and sexual selection apparently act to maintain a stable polymorphism of melanic and non-melanic phenotypes[6]. However, unlike the most obvious and widely quoted examples of evolution by sexual selection—such as the breeding plumage of male peacocks, pheasants, ruffs and birds of paradise—the sexes of the ladybirds are alike: they both show the same polymorphism of melanic and non-melanic phenotypes.

The theory of sexual selection may thus apply more widely than has generally been supposed. It may explain not only the evolution of highly developed display characters in males but also the evolutionary stability of simple genetic polymorphisms in which no sexual dimorphism is present. Sexual selection has been implicated in the maintenance of other non-sex-limited polymorphisms, in scarlet tiger moths[7], snow geese[8,9], arctic skuas[10], and even in the polymorphism of electrophoretic allozymes in the milkweed beetle *Tetraopes tetraophthalamus*[11]. However, the genetic basis of the mating preference has not been demonstrated in any of these cases. That female mating preference can be controlled by a simple genetic system could allow for the appearance and rapid evolution of a frequency-dependent mechanism that would maintain such polymorphisms.

In the wider context of the sociobiological interpretation of animal behaviour, we have shown that a single gene may determine behaviour as complex as the alternative mating choices that an animal might make. This has been a point of great controversy. Models in sociobiology have been based on the assumption that alternative strategies—for example whether to be a 'hawk' or 'dove' in conflicts—are genetic polymorphisms[12,13]. This simple genetic model of complex behaviour has been challenged by opponents of sociobiology[14], but female choice behaviour in *A. bipunctata* is certainly both genetic and polymorphic.

This work was funded by a SERC research grant to P.O'D. and was carried out in a laboratory built in 1984 with a grant from the Wolfson Foundation for research in population genetics.

A benzodiazepine used in the treatment of insomnia phase-shifts the mammalian circadian clock

Fred W. Turek & Susan Losee-Olson

Department of Neurobiology and Physiology, Northwestern University, Evanston, Illinois 60201, USA

Between 5 and 20% of the adult population in Western countries suffer from insufficient and/or unsatisfying sleep[1,2], often associated with certain psychiatric disorders or with certain types of professional activities (for example, shift workers) and travel schedules (for example, jet lag)[1,3,4]. The benzodiazepines are at present the drug treatment of choice for the management of anxiety and stress-related conditions as well as insomnia[5]. Benzodiazepines are thought to act by potentiating the action of the neurotransmitter γ-aminobutyric acid (GABA), a widely distributed transmitter in the central nervous system[6]. The circadian system has a key role in the regulation of the sleep–wake cycle[7–12], and at least some forms of insomnia may be the result of a disorder of the circadian sleep–wake rhythm[8,9]. Similarly, at least some forms of depression may also involve disruption of normal circadian rhythmicity[13,14]. A central pacemaker for the generation of many circadian rhythms in mammals, including the sleep–wake cycle, appears to be located in the suprachiasmatic nucleus[15], and recent research indicates that both cell bodies and axons containing GABA are present within the bilaterally paired suprachiasmatic nuclei[16,17]. These findings raise the possibility that the benzodiazepines, commonly prescribed for sleep and mental disorders, may have an effect on the central circadian pacemaker. Here we report that the acute administration of triazolam, a short-acting benzodiazepine[18] commonly prescribed for the treatment of insomnia, induces a phase-shift in the circadian rhythm of locomotor activity in golden hamsters. This suggests a role for GABA-containing neurones in the mammalian circadian system.

A useful approach in determining whether a specific pharmacological agent can influence a circadian clock is to follow an easily measured pacemaker property, such as the phase of a rhythm driven by the clock, during acute administration of the drug[19]. We have examined the potential phase-shifting effects of triazolam on the circadian rhythm of wheel-running behaviour in golden (Syrian) hamsters. Nine-week-old outbred adult male golden hamsters (*Mesocricetus auratus*, Lakeview Hamster Colony, Newfield, New Jersey) were initially housed in groups and placed under a light/dark (LD) regime of 14:10 (14 h of light per 24-h day) for 1–3 weeks. The animals were then moved to individual cages equipped with a running wheel to allow for the continuous recording of locomotor activity[20]. The animals were transferred 2 to 3 weeks later to either constant light (LL; $N = 40$) or constant darkness (DD; $N = 40$) and were kept under these constant environmental conditions for at least 2 weeks before receiving an intraperitoneal injection of vehicle or 2.5 mg of triazolam dissolved in 0.5 ml of dimethyl sulphoxide at various circadian times. All injections were timed to occur 0, 3, 6, 9, 12, 15, 18 or 21 h after the onset of activity, with onset of activity being designated as circadian time (CT) 12. Thus CT 6 and 21 represent phase points occurring respectively 6 h before and 9 h after the onset of locomotor activity. The hamsters were injected with vehicle or triazolam at least once, and up to four times, with an interval of at least 2 weeks between consecutive injections. The phase-shifting effects of triazolam on the circadian rhythm of locomotor activity were assessed by comparing the onsets of activity before and after drug treatment. The precise nature of the onset of wheel-running activity in the golden hamster makes it easy to detect phase-shifts as small as 15 min (Fig. 1).

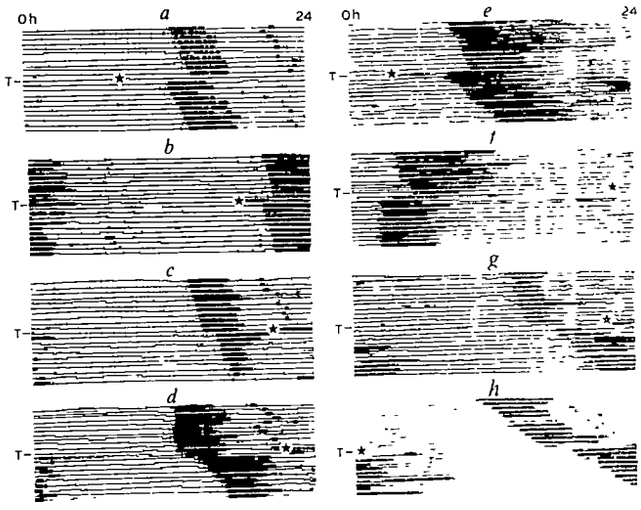

Fig. 1 Representative sections from the activity records of eight hamsters for a 10–12-day period before and after they were injected with 2.5 mg of triazolam at various circadian times. Each line represents a single 24-h period and successive days are plotted from top to bottom in each record. The four animals depicted on the left (*a–d*) were exposed to constant darkness while the four animals shown on the right (*e–h*) were exposed to constant light throughout the study. The day of the triazolam injection is noted by the letter 'T' to the left of each record, and the exact time of the injection on that day is indicated by the star. Using the daily onsets of activity for the 5 days preceding the injection as phase reference points for the pre-injection rhythm, a time of activity onset on the succeeding day was graphically projected. In addition, the daily onsets of activity for 2–7 days after the injection (once a new steady state was achieved) were used as phase reference points for the post-injection rhythm, and a time of activity onset for the first circadian day following the injection was projected backwards. The subtraction of the estimated phase of the rhythm after the treatment from the projected phase of the rhythm before treatment yields the magnitude of the phase-shift induced by the injection of vehicle alone or triazolam. Thus, a negative value indicates a delay in the onset of activity; a positive value indicates a phase advance. Using the onset of activity as representing circadian time (CT) 12, the CT of each injection and the resulting phase shift ($\Delta\phi$) in minutes were calculated to be: *a*, CT = 6, $\Delta\phi = +150$; *b*, CT = 9, $\Delta\phi = +90$; *c*, CT = 18, $\Delta\phi = -60$; *d*, CT = 21, $\Delta\phi = -85$; *e*, CT = 6, $\Delta\phi = +110$; *f*, CT = 6, $\Delta\phi = +180$; *g*, CT = 18, $\Delta\phi = -120$; *h*, CT = 21, $\Delta\phi = -100$. On 32 different occasions, vehicle alone was injected at various circadian times. No clear phase-shift (>10 min) was observed in the activity rhythm following any of these injections.

While injections of vehicle alone had no effect on the rhythm of locomotor activity, injections of 2.5 mg of triazolam induced phase-shifts in the activity rhythm that were dependent on the circadian time of administration in animals exposed to either

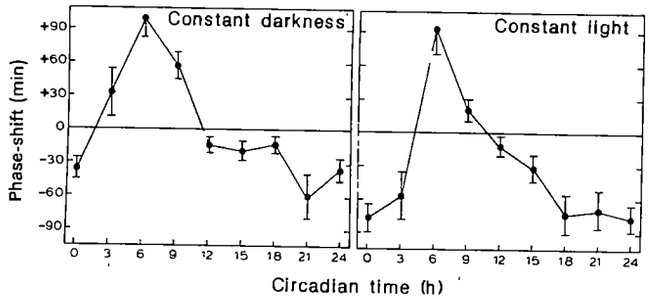

Fig. 2 Mean (±s.e.m.) phase-shifting effect of a systemic injection of triazolam at various circadian times on the free-running rhythm of locomotor activity in hamsters exposed to constant darkness (left, 9 animals per time point) or constant light (right, 7–9 animals per time point). A point above the solid line indicates an advance in the onset of activity, a point below the line indicates a delay in activity onset. The onset of locomotor activity represents CT 12. The values presented for circadian times 0 and 24 represent the same data.

DD or LL (Fig. 1). Phase-shifts induced by triazolam were usually completed within one or two cycles. Injection of as little as 0.1 mg of triazolam has also been found to phase-shift the circadian rhythm of activity (F.W.T., unpublished results). A plot of the phase-shifts induced by triazolam as a function of the circadian time of administration revealed that the general shapes of the 'phase response curves' in DD and LL were similar, with triazolam injections at CT 6 and 9 inducing phase advances while injections between CT 12 and 24 induced phase delays (Fig. 2). The major difference between the phase response curves is that while the mean response to an injection of triazolam at CT 3 was an advance of the activity rhythm for animals exposed to DD, a delay in the activity rhythm was observed in the animals exposed to LL that were injected with triazolam at this circadian time.

The phase response curves generated by injections of triazolam are radically different from those generated by light pulses (on a background of constant darkness) in hamsters and in other mammalian species[20,21]. Light pulses, as well as carbachol, a cholinergic agonist that mimics the phase-shifting and entraining effects of light pulses, induce phase delays early in the subjective night (for example CT 12–14) and phase advances late in the subjective night (for example CT 18–22)[19]. The region CT 3–12 is referred to as a 'dead zone' because light does not induce any phase-shift at these circadian times[21]. In contrast, triazolam induces clear phase advances during the dead zone for light and induces phase delays at a time when light induces phase advances. These results, together with the fact that the phase response curves for triazolam are similar under either LL or DD conditions, indicate that the phase-shifting effects of triazolam do not involve an activation of light input pathways to the biological clock.

Because the effects of triazolam are probably mediated by the GABAergic system[6], the present results suggest a role for GABA-containing neurones in an input pathway to a central biological clock regulating the circadian rhythm of locomotor activity (and presumably many other circadian rhythms) and/or in the clock system itself. The finding that GABA neurones are located within a central circadian pacemaker in rodents—the suprachiasmatic nucleus[16,17]—raises the possibility that the phase-shifting effects of triazolam occur at the level of the suprachiasmatic nucleus itself. Further support for a role of GABA in the circadian organization of mammals is the observation that bicuculline, a selective antagonist of GABA, can block the phase-delaying, but not the phase-advancing effects of light pulses on the circadian rhythm of locomotor activity in hamsters[22].

While triazolam treatment (0.5 m.g) of patients suffering sleep disturbances is effective in improving sleep following a shift in the sleep–wake schedule[23,24], triazolam did not appear to facilitate the re-entrainment of the sleep–wake cycle to the new schedule[24]. However, as the results of the present study demonstrate, the phase-shifting effects of triazolam on the biological clock are dependent on the circadian time of administration. Therefore, any attempt to design an appropriate drug regime that will enhance sleep, as well as shorten the time needed for re-entrainment of the circadian system following a shift in the sleep–wake cycle, must take into account both the direction of the phase shift and the circadian time of drug administration. Drugs which can induce phase-shifts in the circadian system may be useful in the treatment of various physical and mental illnesses that have been associated with a disorder in circadian time-keeping[25].

This work was supported by NIH research grant HD-09885, the Whitehall Foundation and the Upjohn Company, which also provided the triazolam for this study. We thank Dr Eve Van Cauter for critical comments and Dr Kenneth Starz for assistance in the preparation of this paper.

Replication of the neurochemical characteristics of Huntington's disease by quinolinic acid

M. Flint Beal, Neil W. Kowall, David W. Ellison, Michael F. Mazurek, Kenton J. Swartz & Joseph B. Martin

Department of Neurology, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts 02114, USA

Huntington's disease (HD) is an autosomal dominant neurological disorder characterized by progressive chorea, cognitive impairment and emotional disturbance[1]. The disease usually occurs in midlife and symptoms progress inexorably to mental and physical incapacitation. It has been postulated that an excitotoxin is involved in the pathogenesis of HD[2,3]. Schwarcz and colleagues have shown that quinolinic acid (QA) can produce axon-sparing lesions similar to those observed in HD[4–7]. The lesions result in a depletion of neurotransmitters contained within striatal spiny neurones, for example γ-aminobutyric acid (GABA), while dopamine is unaffected. Recently, we and others have demonstrated that in HD striatum there is a paradoxical 3–5-fold increase in both somatostatin and neuropeptide Y which is attributable to selective preservation of a subclass of striatal aspiny neurones in which these peptides are co-localized[8–12]. In the present study we demonstrate

that lesions due to quinolinic acid closely resemble those of HD as they result in marked depletions of both GABA and substance P, with selective sparing of somatostatin/neuropeptide Y neurones. Lesions produced by kainic acid (KA), ibotenic acid (IA) and *N*-methyl-D-aspartate (MeAsp) were unlike those produced by QA, as they affected all cell types without sparing somatostatin/neuropeptide Y neurones. These results suggest that QA or a similar compound could be responsible for neuronal degeneration in HD.

Although the HD gene has been localized to the short arm of chromosome 4, the pathogenesis of the disease remains unknown[13]. The excitotoxin hypothesis was advanced following the demonstration that KA lesions reproduce many of the neurochemical and neuropathological features of HD[2,3]. These lesions, however, proved to be an imperfect model of HD as they did not spare somatostatin/neuropeptide Y neurones[14-16]. Furthermore, KA is not known to exist in mammalian tissues. It was subsequently shown by Schwarcz and colleagues that QA, an endogenous metabolite of tryptophan present in human brain, could produce excitotoxin lesions in striatum[4-7]. We therefore examined the ability of this compound to reproduce both the neurochemical and histological features of HD in rat striatum.

Male Sprague–Dawley rats (175 g) were anaesthetized with Nembutal (50 mg per kg intraperitoneal, i.p.) and positioned in a David Kopf small-animal stereotaxic apparatus. A 30-gauge blunt-tipped Hamilton syringe needle was inserted into the left striatum at the coordinates 8.4 mm anterior, 2.6 mm lateral and 4.5 mm ventral to the dura[17]. Drugs dissolved in 1 μl of phosphate-buffered saline (PBS) were infused over a period of 2 min; the needle was left in place for an additional 2 min and then slowly withdrawn. Two weeks after the injection the animals were killed and their brains were removed and sectioned at 2-mm intervals as described previously[10]. Both striata, the frontal cortex dorsal to the lesion and hippocampus caudal to the lesion were dissected and placed in a solution of chilled 0.1 M HCl containing 1 mM EDTA and 4 mM sodium metabisulphite. The tubes containing the tissues were frozen and thawed three times, then an aliquot of supernatant was taken for analysis of catecholamines and amino acids using HPLC with electrochemical detection[18,19]. The remaining tissue was boiled for 10 min to inactive peptidases, and the supernatant lyophilized before reconstitution in radioimmunoassay buffer. Radioimmunoassays for somatostatin-like immunoreactivity (SLI), neuropeptide Y-like immunoreactivity (NPYLI), substance P-like immunoreactivity (SPLI) and vasopressin-like immunoreactivity (VLI) were done as described previously[20-23]. Proteins were measured by fluorimetric assay[24].

In an initial experiment control animals were injected with PBS alone, while experimental animals received increasing doses of QA (8 animals per dose). The right (unlesioned) striatal values did not differ from control values by one-way analysis of variance (ANOVAR); these values were therefore averaged with control values to provide a 100% control mean. The left (lesioned) striatal values were expressed as a per cent of the control mean. Control striatal concentrations of neuropeptide (per mg protein) were: SLI, 2.63 ± 0.37 pM; NPYLI, 3.47 ± 0.51 pM; SPLI, 357 ± 54 fM; GABA, 31.2 ± 5.3 nM. Increasing doses of quinolinic acid resulted in significant dose-dependent reductions in both SPLI and GABA (Fig. 1). Not until the highest dose of QA had been reached was SLI or NPYLI affected. (The highest dose was hyperosmolar and might therefore have caused nonspecific damage.) Nevertheless, even at this dose, SLI and NPYLI were preserved relative to SPLI and GABA. In contrast, increasing doses of kainate induce a graded loss of both SLI and SPLI[11]. Dopamine concentrations were unaffected, as expected for a transmitter contained within afferent terminals. There was no significant alteration in SLI, NPYLI or SPLI in frontal cortex or hippocampus with any of the lesions.

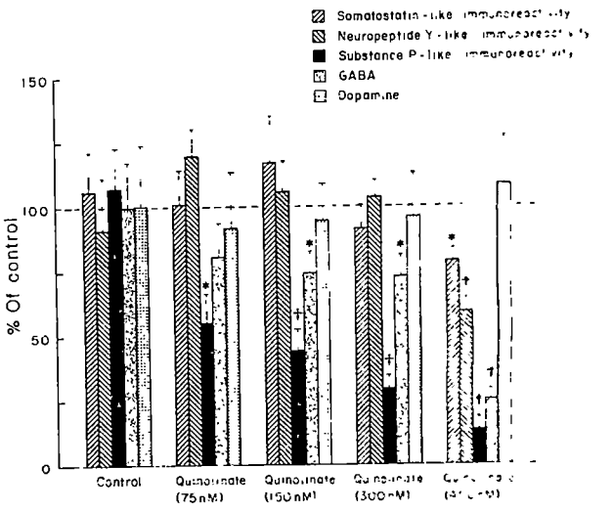

Fig. 1 Increasing doses of quinolinic acid injected into rat striatum resulted in a dose-dependent reduction in both GABA and substance P-like immunoreactivity, but somatostatin and neuropeptide Y were unaffected until the highest dose was applied. $*P < 0.05$, † $P < 0.01$ compared with controls (by ANOVAR).

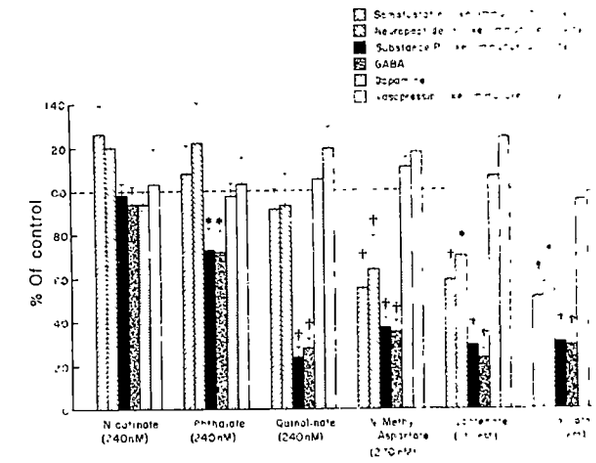

Fig. 2 Quinolinic acid (QA)-induced striatal lesions produced reductions in GABA and substance P comparable to those seen with *N*-methyl-D-aspartate, ibotenic acid and kainic acid, but only QA spared somatostatin and neuropeptide Y. Phthalic acid, which is structurally related to QA, produced similar but less potent changes than QA. $*P < 0.05$, † $P < 0.01$ compared with controls (by ANOVAR).

In a second experiment control animals received nicotinic acid (NA), while experimental animals received phthalic acid (PA), QA, MeAsp, IA or KA (Fig. 2). Nicotinic acid is structurally identical to QA except for the absence of a carboxylate group at position 2 on the pyridine ring. Eight animals in each group were killed 3 weeks after the injection and analysed as in the initial experiment. There was no significant alteration of SLI, NPYLI or SPLI in frontal cortex or hippocampus. Quinolinic acid, MeAsp, IA and KA produced comparable reductions in both SPLI and GABA but only QA lesions spared SLI and NPYLI. Dopamine and VLI (markers of striatal afferents) were unaffected by any of the lesions. Phthalic acid, which is structurally identical to QA except for a substitution of carbon for the nitrogen in the pyridine ring, was less potent than, but qualitatively similar to, QA in its toxicity. Somatostatin and neuropeptide Y were not depleted to the same extent as substance P or GABA by any of the lesions, but this probably reflects

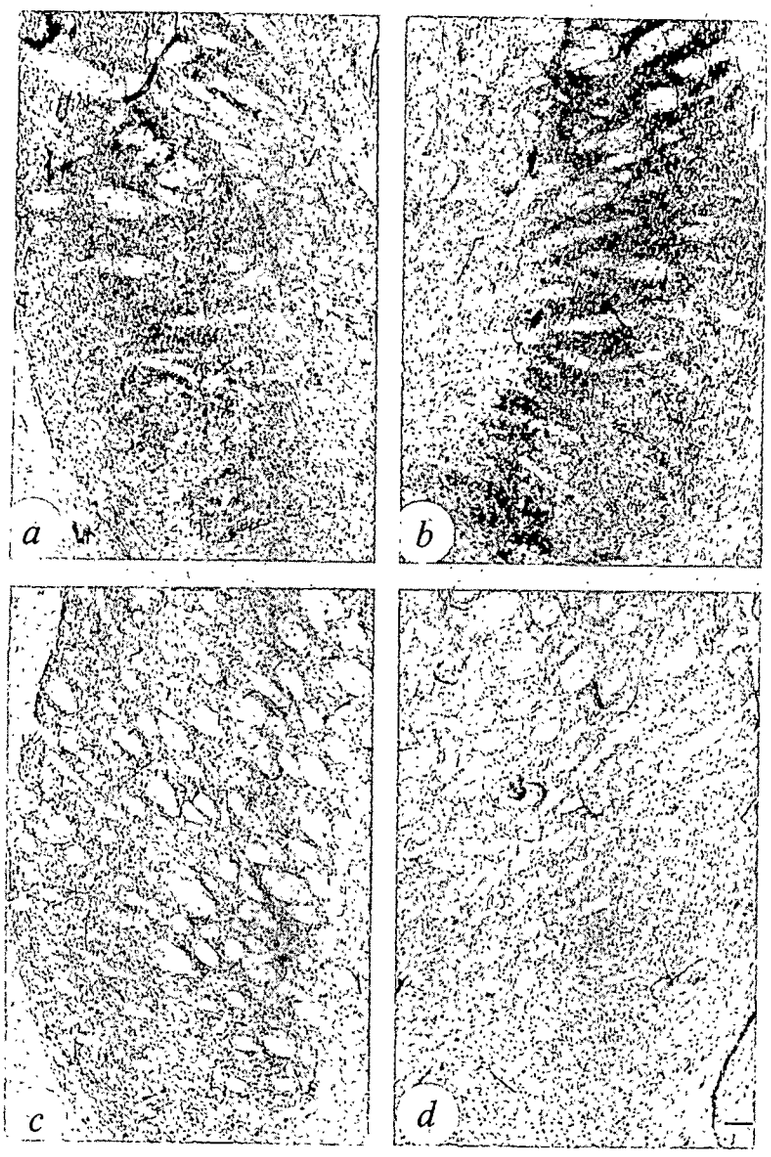

Fig. 3 *a*, *b*: Control (*a*; non-injected) and quinolinate-lesioned (*b*) striatum from the same section stained for NADPH-diaphorase and counterstained with cresyl violet. *c*, *d*: Control (*c*) and kainate-lesioned (*d*) striatum stained as for *a*, *b*. Both sections are equidistant from the injection sites and the lesioned sides show decreased (cresyl violet-stained) neuronal density, but this is difficult to discern because of gliosis. The diaphorase-containing neuronal population (darkly stained neurones) is resistant to the effects of quinolinate (*b*) but is depleted in concert with total neuronal loss in kainate-induced lesions (*d*).

the presence of these neuropeptides in striatal afferents as well as in intrinsic striatal neurones[25,26]. Previous work has suggested that 25–40% of striatal somatostatin may be contained in striatal afferents[10,25–27].

Lesions intended for histological analysis were made identically to those in experiment 2, except that the dosage was halved by administering the drug in 0.5 μl of saline. Five animals were studied per group. Three weeks after the lesions, the rats were pretreated with diisopropyl fluorophosphate (2 mg per kg intramuscular, i.m.) and atropine (5 mg per kg i.p.) 18 h before they were killed. Brains were immersion-fixed in 4% paraformaldehyde in 0.1 M phosphate buffer (*p*H 7.4) at 4 °C. Sections 50 μm thick were cut and processed for diaphorase and cholinesterase histochemistry as described previously[28,29]. Striatal neurones that stain for diaphorase also contain both SLI and NPYLI[30,31].

Nicotinate injections produced no histologically identifiable striatal lesions. In contrast, quinolinate, kainate, ibotenate and phthalate all produced a zone of necrosis surrounded by an area of total neuronal loss at the injection site; neuronal counts made in adjacent sections showed neurotoxic effects, as demonstrated by decreased neuronal density. Diaphorase neurones were resistant to the neurotoxic effects of quinolinate but were more sensitive than cholinesterase neurones to the neurotoxic effects of both kainate and ibotenate (Fig. 3, Table 1). The latter finding is consistent with a previous report[32]. Cholinesterase neurones were equally vulnerable to all neurotoxins examined. The histological observations indicate that preserved concentrations of both SLI and NPYLI are attributable to selective preservation of somatostatin/neuropeptide Y neurones in the face of QA neurotoxicity. Phthalic acid showed qualitatively similar effects but to a lesser degree.

As QA-induced striatal lesions spare somatostatin/neuropeptide Y neurones, they are a better model of the neurochemical and histological features of HD than lesions produced with other excitotoxins. Several other features make QA an attractive candidate for an aetiological agent of HD. It has been shown that neonatal animals are resistant to QA toxicity while mature animals are susceptible[5]; this agrees well with the typical onset of HD in middle age. In addition, it has been shown that striatum, globus pallidus and hippocampus are particularly vulnerable to quinolinic acid neurotoxicity while cerebellum, substantia nigra, amygdala, septum and hypothalamus are less susceptible[5]; many of these regions are affected in HD although the most marked pathology is seen in striatum, which suggests that other factors, such as glutamate input, may influence the topography of the pathology.

Selective sparing of somatostatin/neuropeptide Y neurones could conceivably be related to an ability of these neurones to metabolize quinolinic acid. All striatal somatostatin/neuropep-

Table 1 Quantitative analysis of diaphorase and cholinesterase neuronal populations in double-stained sections

Neurotoxin	Ratio of diaphorase cell counts (control/lesion)	Ratio of cholinesterase cell counts (control/lesion)	Fractional diaphorase/ cholinesterase counts (control/lesion)
Quinolinate	0.97±0.07*	2.04±0.26	0.53±0.03†
Kainate	1.52±0.15	1.59±0.25	1.26±0.10
Ibotenate	1.39±0.14	1.82±0.27	1.30±0.17
Phthalate	1.15±0.06	1.86±0.27	0.71±0.08

Sections at several striatal levels were counted and the cell counts on control and lesioned sides are expressed as a ratio (control striatum cell counts/lesioned striatum cell counts). A ratio of >1 indicates fewer neurones in the lesioned striatum than in the control; this is true in all cases except for diaphorase neurones in the quinolinate-injected cases, where diaphorase cell count ratios are ~1 (that is, unchanged). This proportional sparing of diaphorase neurones is shown further by comparing the numbers of diaphorase and cholinesterase neurones (expressed as the fractional diaphorase counts, calculated by dividing the diaphorase count by the cholinesterase count) (final column). The greater number of diaphorase neurones compared with cholinesterase neurones (which are depleted) in the quinolinate-lesioned striatum results in a ratio of <1. Ratios of >1 suggest that diaphorase neurones are more sensitive than cholinesterase neurones to kainate and ibotenate.

* The value obtained with quinolinate is significantly less than that for kainate ($P<0.01$) or ibotenate ($P<0.05$) by the Kruskal-Wallis multiple-comparison test.

† The quinolinate value is significantly less than that for kainate ($P<0.004$) or ibotenate ($P<0.001$) by the Kruskal-Wallis multiple-comparison test.

tide Y neurones also contain the enzyme NADPH-diaphorase[30,31], and it has been shown that QA can act as a precursor of NADH or NADPH in mammalian liver[33–35]. It is possible, therefore, that these neurones are able to take up and metabolize quinolinic acid; this might explain the relative sparing of the nucleus accumbens in HD[36,37], as concentrations of both somatostatin and neuropeptide Y as well as the density of NADPH-diaphorase neurones and terminals are 2–3-fold higher in nucleus accumbens than in the remainder of the striatum[9,10,31]. It would also explain the paradoxical susceptibility of these neurones to MeAsp yet their resistance to QA, as both compounds are thought to act at the same receptor[5]. Some evidence, however, suggests differential effects which might implicate separate receptors[38,39]. It has been suggested that NADPH-diaphorase neurones are resistant to a variety of neurotoxins[39]; however, the present data suggest that this is not the case with excitotoxins, except for quinolinic acid.

Various therapeutic strategies are suggested if QA proves to be of aetiological significance in HD. Quinolinic acid neurotoxicity is dependent on cortical (presumably glutamatergic) input and can be blocked with kynurenic acid, 2-amino-5-phosphonovaleric acid and 2-amino-7-phosphonoheptanoic acid[5,38,40,41]. It is therefore possible that early diagnosis using molecular genetics could be followed by therapeutic intervention in an attempt to retard the neurodegenerative process.

Channel properties of an insect neuronal acetylcholine receptor protein reconstituted in planar lipid bilayers

W. Hanke & H. Breer

Universität Osnabrück, Fachbereich Biologie/Chemie, D-4500 Osnabrück, FRG

A pentameric membrane protein composed of four types of polypeptide has been identified as the minimal structural unit responsible for the electrogenic action of acetylcholine on electrocytes and muscle cells[1–3]. Because many populations of central and peripheral neurones also have nicotinic acetylcholine receptors (AChRs), considerable effort has recently gone into identifying the neuronal receptor[4,5]. The central nervous tissue of insects contains very high concentrations of nicotinic AChRs[6,7], and we have recently purified an α-toxin binding protein, a putative AChR, from neuronal membranes of locusts[8,9]. It is a component of high relative molecular mass, clearly composed of identical subunits, a structure predicted for an ancestral AChR protein[10,11]. To verify that the purified polypeptides not only represent ligand binding sites but that they are indeed functional receptors, we have now reconstituted the isolated protein in a planar lipid bilayer. We show that in this system cholinergic agonists activate functional ion channels, that have properties comparable to those exhibited by the peripheral AChRs in vertebrates; thus, for the first time a functional acetylcholine receptor channel has been indentified in nerve cells.

The purified receptor protein was first reconstituted into lipid vesicles produced from asolectin and cholesterol by dialysis[12]. These proteoliposomes were then fused with the intact bilayer[13] to incorporate the purified receptor polypeptides. Both sides of the membrane were bathed in solution containing 100 mM NaCl, 1 mM $CaCl_2$ and 10 mM HEPES *p*H 7.2. Receptor-containing vesicles and agonists were added to the *cis* side, and membrane potentials are given with respect to virtual ground on the *trans* side.

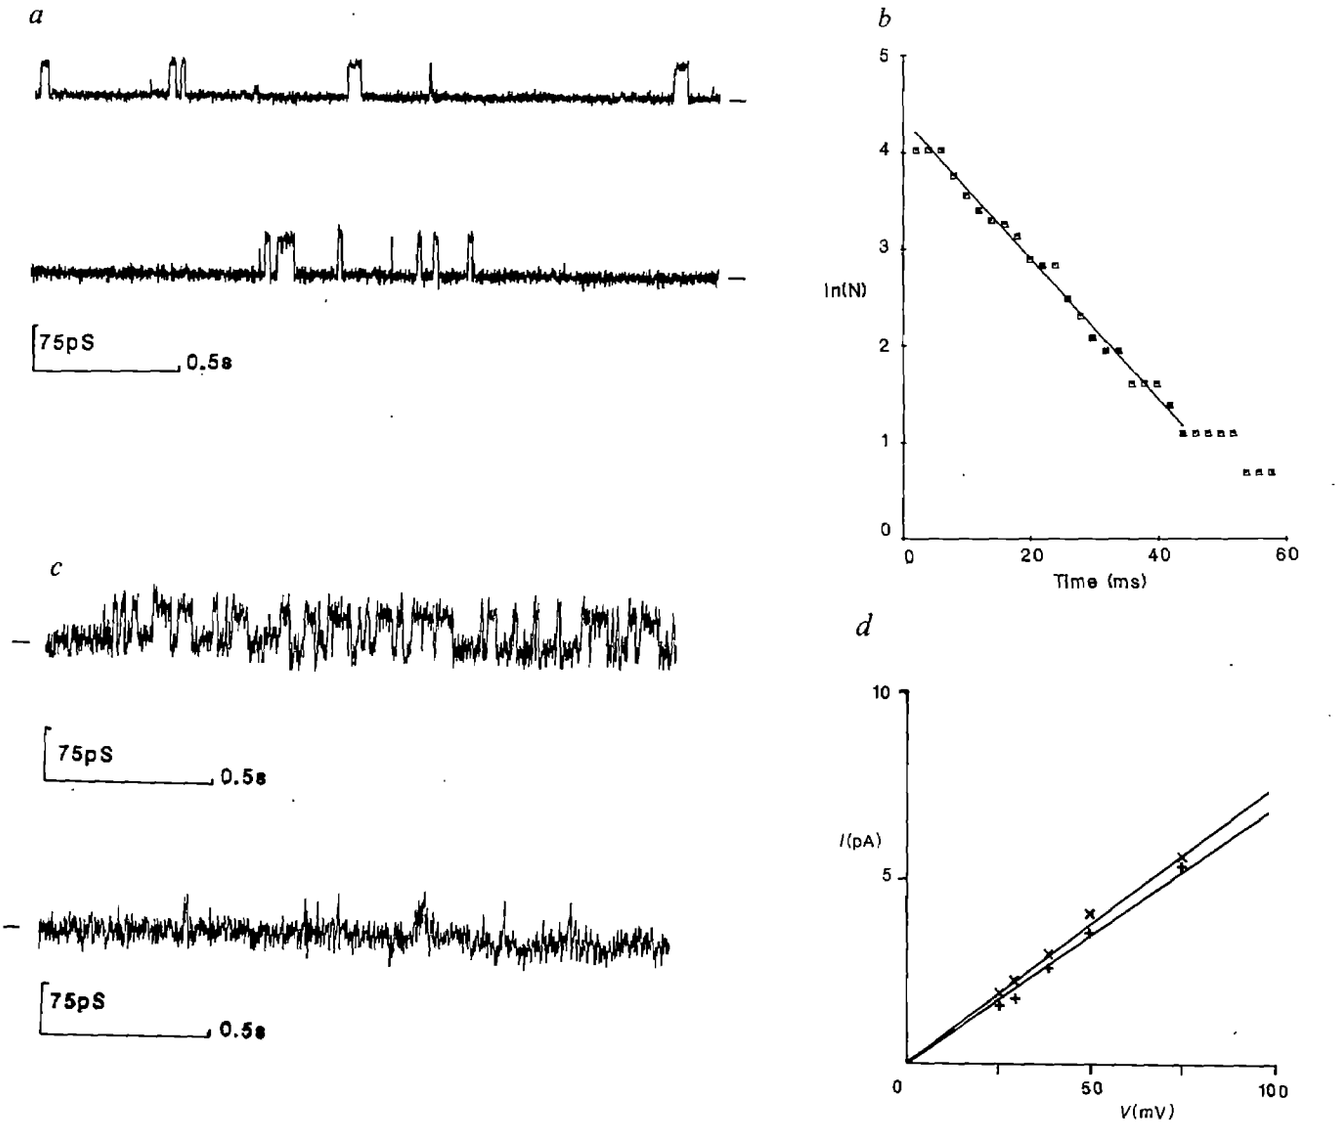

Fig. 1 Cholinergic agonist-induced fluctuations of cationic channels in planar lipid bilayers containing reconstituted α-toxin binding proteins isolated from the nervous tissue of locust. *a*, Current fluctuations of the AChR channel in the presence of 0.5 μM suberyl dicholine at an applied potential of 50 mV. *b*, Evaluation of the lifetime of current events ($n = 78$). Experimental conditions as in *a*. Mean lifetime, 14 ms. *c*, Current fluctuations of the AChR, channel in the presence of two different concentrations of carbamyl choline in aqueous solution: upper trace, 50 μM; lower trace, 0.5 μM. Both traces were obtained from the same bilayer, starting with the lower concentration. $P(o) = 0.75$ and 0.05 in the presence of 50 μM and 0.5 μM carbamyl choline, respectively. The closed state of the channel is indicated at each trace separately (bars on left-hand side). *d*, Current-voltage (I–V) relation for a single channel under conditions given in *a*. ×, Current in the presence of 100 NaCl (75 pS); +, current in the presence of 100 KCl (70 pS). In these and subsequent traces, an upward deflection of the current trace corresponds to opening of a membrane channel.

Methods. Bilayers were made from 1-palmitoyl-2-oleoyl-glycero-3-phosphatidylcholine (Avanti), phosphatidylethanolamine purified from egg yolk by column chromatography in our laboratory, and dioleoyl phosphatidylglycerol (Avanti) in a 40:60:20 molar ratio. 10 mg of lipid mixture was dissolved in 1 ml hexane and 50 μl of this solution was spread on each side of a hexadecane-pretreated hole of about 150 μm diameter. Bilayers were folded onto this hole after the solvent had been allowed to evaporate quantitatively. The lipid bilayer used was virtually solvent-free[18] and generated as described previously[12]; it was shown to be electrically stable and did not respond to cholinergic agonists. Aqueous solutions on both sides of the bilayer contained 100 mM NaCl, 1 mM $CaCl_2$, 10 mM HEPES at *p*H 7.2. The aqueous solutions of the vesicle preparations added were identical except that each contained additionally 200 mM sucrose. The lipid composition of the vesicles was asolectin/cholesterol in a 15:2 molar ratio. The vesicles contained the purified native AChR protein isolated from neuronal membranes of locusts[9]. The vesicle preparation was stored on water/ice and kept there for a maximum of 3 days. 50 μl of the vesicle preparation was added to the *cis* side of the bilayer. The *trans* side was defined to be at virtual ground potential. The receptor-containing lipid bilayer was stable and no resolvable ion channel fluctuation was detected in the absence of any agonist. Agonists were added as indicated and the *cis* side was stirred until first channel fluctuations occurred. Current fluctuation traces were filtered at 300 Hz (−3 dB point, low pass) for better amplitude resolution and stored on an FM-tape recorder for later analysis. Several ($n > 5$) independent experiments were performed for each condition.

Figure 1*a* shows the current flowing through individual agonist-activated channels after addition of 0.5 μM suberyl dicholine to the *cis* side; the size of the current indicates a channel conductance of 75 pS (Fig. 1*a*, *d*). Evaluation of the current duration under these conditions (Fig. 1*b*) showed a distribution with a single exponential indicating a mean lifetime (τ_0) of 14 ms. Figure 1*c* shows the effect of various concentrations of carbamyl choline on the same receptor channel. Again, fluctuations of a channel showing a conductance of 75 pS were observed. With 50 μM carbamyl choline, the current fluctuations

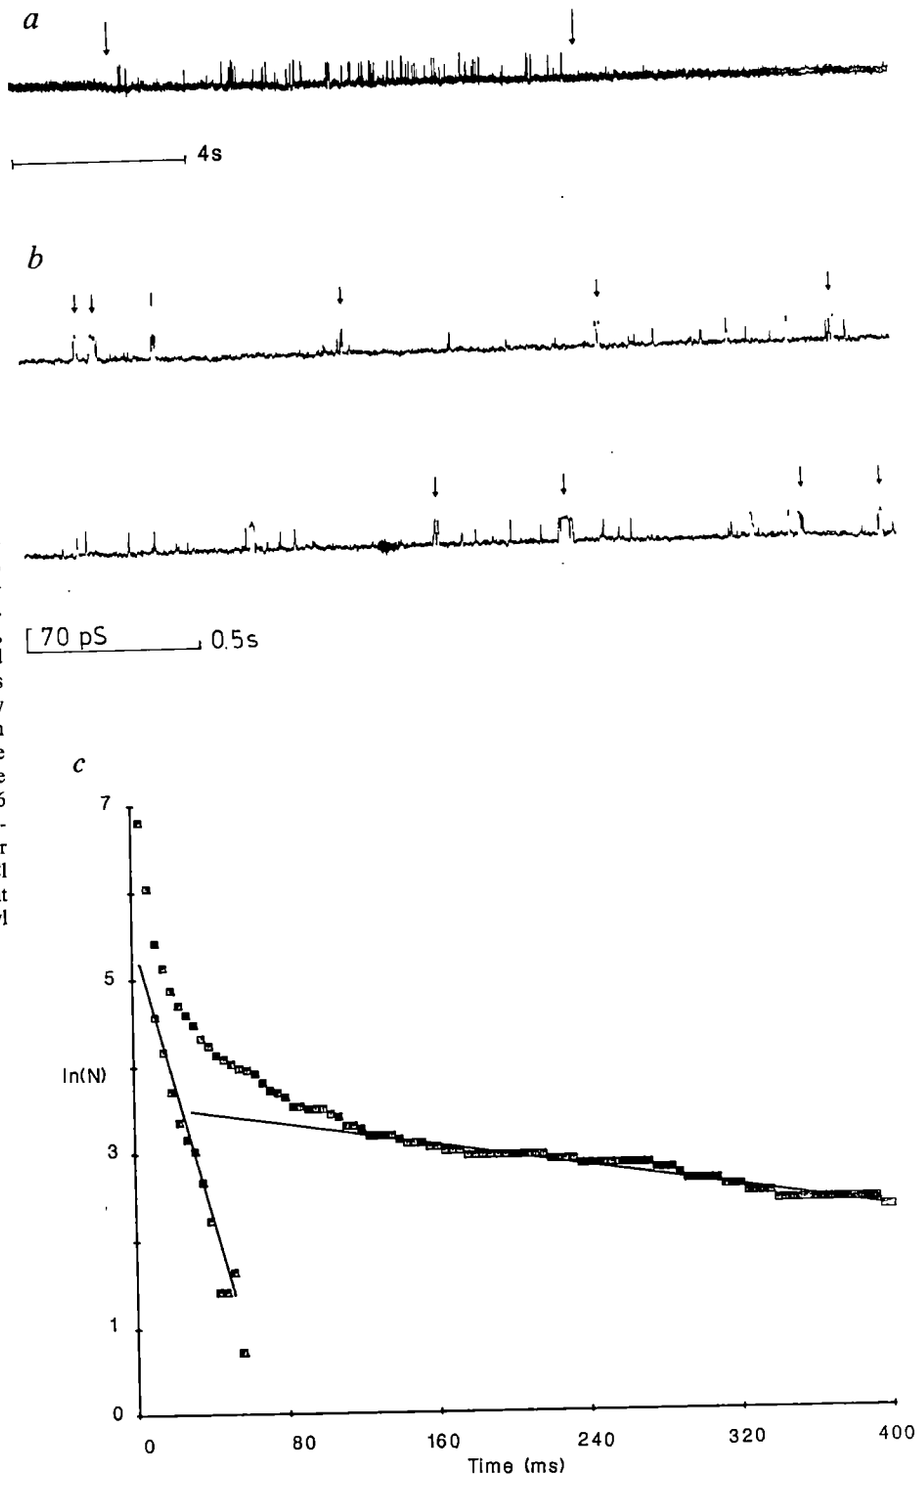

Fig. 2 Structural details of the kinetics and conductance of the neuronal AChR channel. *a*, Bursting of the channel at 25 mV. Arrows indicate the beginning and end of the burst shown. *b*, Occurrence of the multiple gating events, indicated by arrows as in *a*, on an expanded timescale. *c*, Distribution of closed time events plotted at half log scale. The graph clearly demonstrates two different components, with decay constants of $\tau_s = 315$ ms (closing time between bursts) and $\tau_f = 25$ ms (closing time within bursts). Of the 904 events evaluated, 36 were classified as belonging to the slow component. Experimental conditions were similar to those of Fig. 1, except that 100 mM NaCl was replaced by 100 mM KCl. All current fluctuations were induced by 1 μM suberyl dicholine.

had a mean duration of about 15 ms and a high probability of being in the open state ($P(o) = 0.75$), while with 0.5 μM carbamyl choline the channel lifetime was only 3–5 ms and the probability of the channel being in the open state was close to zero ($P(o) \leq 0.05$). These results suggest that the α-toxin binding protein, purified from the nervous tissue of insects, behaves like a functional AChR; although quite different in its molecular organization, its response to agonist application was comparable to that of AChRs from electrocytes in lipid bilayers[13,14].

Comparison of agonist action at the same concentration (compare Fig. 1*a* and *c*, lower traces) shows clearly that suberyl dicholine induced significantly greater current durations (14 ms) than did carbamyl choline (3–5 ms). A similar agonist dependency has been observed on muscle receptors[15] and electrocyte receptors in lipid bilayers[13,14]. A current–voltage curve of single channels obtained with 0.1 M NaCl on both sides of the bilayer showed that the channel behaved ohmically over the voltage range studied (±100 mV). The conductance decreased only slightly if potassium (70 pS) was substituted for sodium (75 pS), indicating that the channel is not significantly selective for sodium over potassium (Fig. 1*d*), and conductance was unchanged when chloride was replaced by sulphate, indicating that the channel is impermeable to chloride.

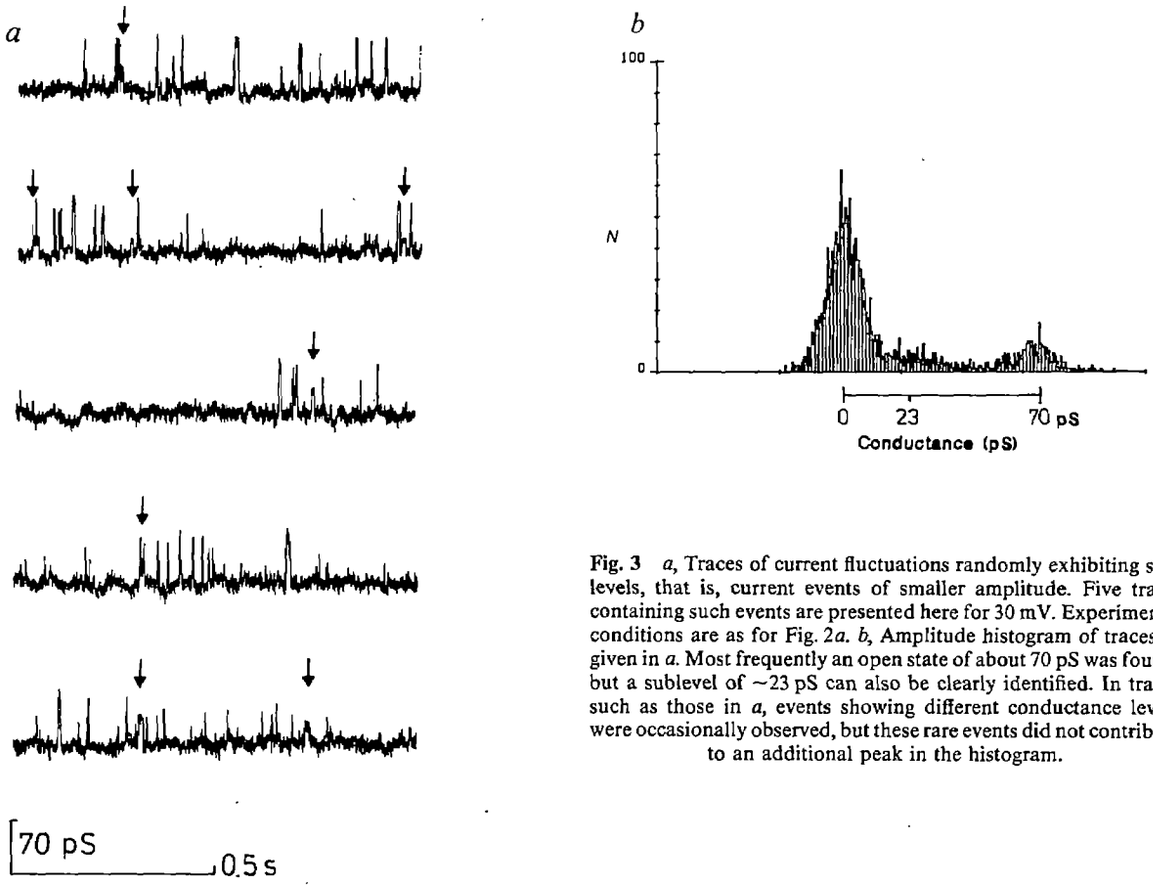

Fig. 3 *a*, Traces of current fluctuations randomly exhibiting sublevels, that is, current events of smaller amplitude. Five traces containing such events are presented here for 30 mV. Experimental conditions are as for Fig. 2*a*. *b*, Amplitude histogram of traces as given in *a*. Most frequently an open state of about 70 pS was found, but a sublevel of ~23 pS can also be clearly identified. In traces such as those in *a*, events showing different conductance levels were occasionally observed, but these rare events did not contribute to an additional peak in the histogram.

Figure 2 shows details of the neuronal receptor channel fluctuations. All current traces in this figure were obtained in the presence of 1 μM suberyl dicholine and an aqueous solution containing symmetrical 100 mM KCl. In Fig. 2*a* the occurrence of bursts of channel activity is shown on a compressed timescale. Within these bursts channels did not open randomly, but rather, multiple gating events occurred, as shown in Fig. 2*b* on an expanded timescale. In addition to isolated single-channel openings, we found blocks of two to five or even more openings. Figure 2*c* evaluates the distribution of channel closed times under the conditions of Fig. 2*a*. The distribution is fitted by two exponentials, indicating a mean closed time between bursts (τ_s) of 300 ms and a mean closed time within bursts (τ_f) of 25 ms.

We also resolved conductance details of the ion channels created by the neuronal AChR protein (Fig. 3) and found currents indicating openings of channels with a conductance lower than the predominant channel type. These channels usually had a conductance of about 23 pS. Selected stretches of recordings show a few of these events (Fig. 3*a*), while Fig. 3*b* shows an amplitude histogram of current fluctuations to quantify this phenomenon. The agonist-induced increase in the bilayer conductance could be completely inhibited by low concentrations of (+)tubocurarine; thus, single-channel currents induced by 1 μM suberyl choline were blocked after the addition of 5 μM (+)tubocurarine. The antagonist did not affect the conductance of the channel, but rather reduced the frequency of occurrence of current events.

These features of the neuronal receptor—the occurrence of bursting multiple gating events and the (+)tubocurarine-induced reduction of the probability that the channel will be in the open state—have also been described for the muscle AChR of vertebrates[16,17]. Our study shows that the purified α-bungarotoxin binding protein isolated from insect central nervous tissue displays the properties of a chemically gated ion channel, thus representing a functional receptor. Experiments are in progress to determine the primary structure of the insect neuronal receptor protein using gas-phase microsequencing and recombinant DNA techniques; such information will allow us to estimate the structural and functional relatedness of insect and vertebrate receptors; this aspect is of particular interest in view of the fact that the complete sequence of a possible neural AChR polypeptide from rat has recently been reported[5].

Potentiation of synaptic transmission in the hippocampus by phorbol esters

Robert C. Malenka, Daniel V. Madison & Roger A. Nicoll

Departments of Pharmacology and Physiology, University of California, San Francisco, California 94143, USA

Protein kinase C (PKC), a calcium-dependent phospholipid-sensitive kinase which is selectively activated by phorbol esters, is thought to play an important role in several cellular processes[1,2]. In mammalian brain PKC is present in high concentrations[1] and has been shown to phosphorylate several substrate phosphoproteins[3–6], one of which may be involved in the generation of long-term potentiation (LTP)[7,8], a long-lasting increase in synaptic efficacy evoked by brief, high-frequency stimulation. Since the hippocampus contains one of the brain's highest levels of binding sites for phorbol esters[9] and is the site where LTP has been most thoroughly characterized, we examined the effects of phorbol esters on hippocampal synaptic transmission and LTP. We found that phorbol esters profoundly potentiate excitatory synaptic transmission in the hippocampus in a manner that appears indistinguishable from LTP. Furthermore, after maximal synaptic enhancement by phorbol esters, LTP can no longer be elicited. Although the site of synaptic enhancement during LTP is not clearly established, phorbol esters appear to potentiate synaptic transmission by acting primarily at a presynaptic locus since changes in the postsynaptic responses to the putative transmitter, glutamate, cannot account for the increased synaptic responses induced by phorbol esters. These findings, in conjunction with previous biochemical studies, raise the possibility that, in mammalian brain, PKC plays a role in controlling the release of neurotransmitter and may be involved in the generation of LTP.

The details of the rat hippocampal slice preparation have been described elsewhere[10]. For all experiments, orthodromic stimulation of fibres in stratum radiatum was adjusted to evoke a 1–2-mV population spike recorded in the CA1 region of stratum pyramidale while another recording electrode placed in stratum radiatum recorded a population excitatory postsynaptic potential (e.p.s.p.) field. A variety of phorbol analogues known to activate PKC were used including 4β-phorbol-12,13-dibutyrate (PDBu), 4β-phorbol-12,13-diacetate (PDAc), and 12-deoxyphorbol-13-isobutyrate[11], all of which elicited similar responses. We also applied 4β-phorbol and 4α-phorbol-12,-13-didecanoate, analogues which do not activate PKC[11]. These drugs were applied by superfusion to over 50 slices. Standard techniques were used for intracellular recording.

Application of phorbol esters caused a pronounced and long-lasting increase in the amplitude of the population spike and decreased its latency (Fig. 1*a*,*b*). Concomitantly the initial slope and amplitude of the population e.p.s.p. increased (Fig. 1*a*,*b*), even at low stimulus strengths when the reflection of the population spike did not appear in the late phase of the population e.p.s.p. Washing the slice with control solution for up to 2 h did not reverse the effects of the phorbol esters. This may be due to the difficulty in completely washing out of the slice the highly lipid soluble phorbol esters. Concentrations of phorbol ester as low as 100 nM (the lowest tested) were effective although higher doses had more rapid and larger effects. Intracellular recordings corroborated these findings ($n = 9$; Fig. 2*b*). The increase in the e.p.s.p. often occurred in the absence of any change in membrane potential or input resistance. Application of phorbol analogues which have been shown not to activate PKC in other systems did not enhance synaptic responses (Fig. 1*c*). This suggests that the potentiation of synaptic transmission by phorbol esters may be due to the activation of PKC, although these physiological experiments cannot entirely rule out an action of phorbol esters independent of PKC.

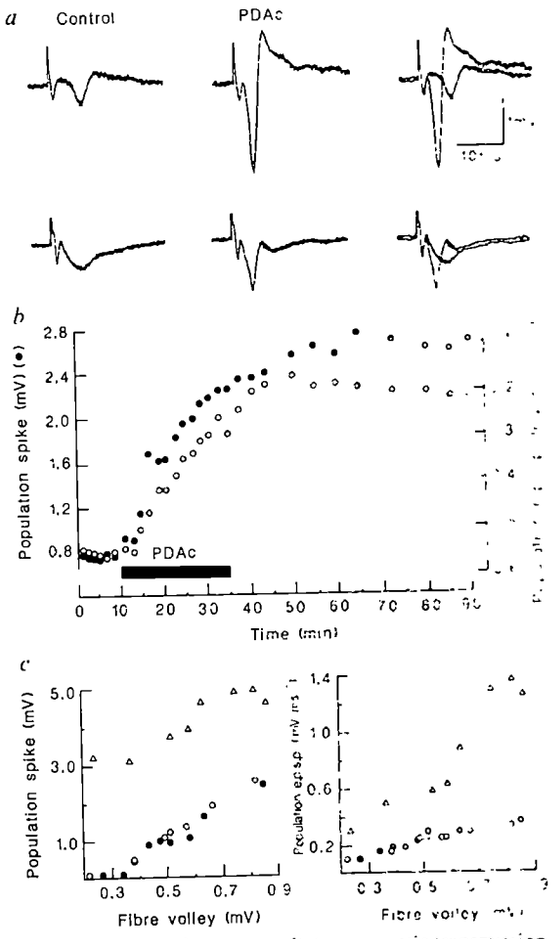

Fig. 1 Phorbol esters increase excitatory synaptic transmission in the hippocampus. *a*, The population spike (top row) and population e.p.s.p. (bottom row) are shown from an experiment in which 2 μM phorbol-12-13-diacetate (PDAc) was applied to the hippocampus for 25 min. The responses in the PDAc column were taken 20 min after returning to drug-free solution. The responses are shown superimposed in the right-hand column. *b*, The changes in the population spike amplitude and population e.p.s.p. initial slope during this experiment; each point is the average of four responses. *c*, The population spike amplitude and population e.p.s.p. initial slope are plotted as a function of presynaptic fibre volley amplitude. Responses were obtained by varying stimulation strength in control media (●), following a 30-min exposure to a solution containing 10 μM 4β-phorbol (○) and also following a 20-min exposure to 5 μM phorbol-12,13-dibutyrate (△), all in the same slice. Sample traces in this and all subsequent figures are averages of four responses.

Methods. The population spike corresponds to the synchronous activation of pyramidal cells. Its amplitude was determined by the method of Alger and Teyler[35]. The initial slope of the population e.p.s.p. was measured as an indication of dendritic synaptic responses because the peak amplitude is often contaminated by the reflection of the population spike. All responses were digitized for later data analysis using a Nicolet 4094 digital oscilloscope

One mechanism which could account for the increased size of the e.p.s.p. is that more presynaptic fibres are activated in the presence of phorbol esters than in control. To control for this variable we compared the population e.p.s.p. with the presynaptic fibre volley by constructing input-output curves (Fig. 1*c*). Application of inactive phorbol analogues had no effect on this input-output function while application of active phorbol ester to the same slice shifted this curve so that a presynaptic fibre volley of the same size elicited a much larger postsynaptic response. These results indicate that changes in presynaptic axonal excitability cannot account for the actions of phorbol esters on synaptic transmission.

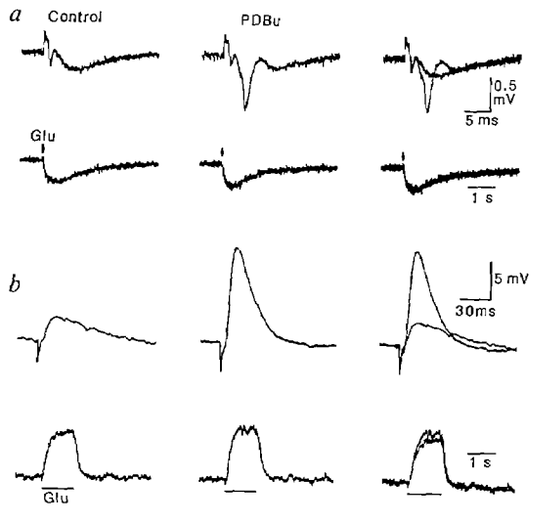

Fig. 2 Phorbol esters have minimal effects on the responses to glutamate at a time when synaptic responses are greatly increased. *a*, The population e.p.s.p. (top row) and response to pressure application of glutamate (5 mM, 40 ms, 50 p.s.i.) (bottom row) recorded with the same extracellular microelectrode are shown before and following application of 5 μM phorbol-12,13-dibutyrate (PDBu). The responses are superimposed in the right-hand column. *b*, The intracellularly recorded e.p.s.p. (top row) and responses to iontophoretically applied glutamate (0.5 M, 20 nA) (bottom row) recorded from the same cell before and following application of 5 μM PDBu. Responses are superimposed in the right-hand column.

Methods. For the field potential experiment, an electrode (tip diameter 2–5 μm) attached to a Picospritzer (General Valve Corp) and filled with 5 mM glutamate in Ringer solution was positioned close to the recording microelectrode in stratum radiatum. Short pulses of glutamate (10–50 ms; 50 p.s.i.) were applied to the slice to elicit small field responses of approximately the same amplitude as the population e.p.s.p. For the intracellular experiments, standard iontophoretic techniques were used. The iontophoretic pipette was filled with 0.5 M glutamate and placed in the mid-apical dendritic zone.

Recently, phorbol esters have been shown to have significant direct postsynaptic effects on hippocampal pyramidal cells[12,13]. To examine the possible locus of phorbol ester's actions on synaptic transmission, we compared the effect of PDBu on the population e.p.s.p. and the field potential elicited by extracellular pressure application of glutamate[14], the putative neurotransmitter at the synapse under study[15]. PDBu caused the usual increase in the population e.p.s.p. but failed to alter the glutamate field response (Fig. 2*a*, $n = 4$). This strongly suggests that any phorbol ester-induced change in postsynaptic parameters (for example, membrane potential) cannot account for the increase in the population e.p.s.p. While intracellularly recorded glutamate responses were often increased, this increase could account for only a small fraction of the increase in the monosynaptic e.p.s.p. recorded from the same cell (Fig. 2*b*) (mean per cent increase in the e.p.s.p. = 135 ± 30 ($n = 4$); per cent increase for the glutamate response = 18 ± 8 ($n = 4$)). Thus it appears likely that the enhancement of synaptic transmission caused by phorbol esters is due primarily to a presynaptic action.

Comparison of synaptic enhancement during phorbol ester application and following a presynaptic tetanus which evokes LTP reveals a precise mimicry. During both conditions, the size of the population spike and e.p.s.p. increase, the population spike latency decreases, and the relationship between the fibre

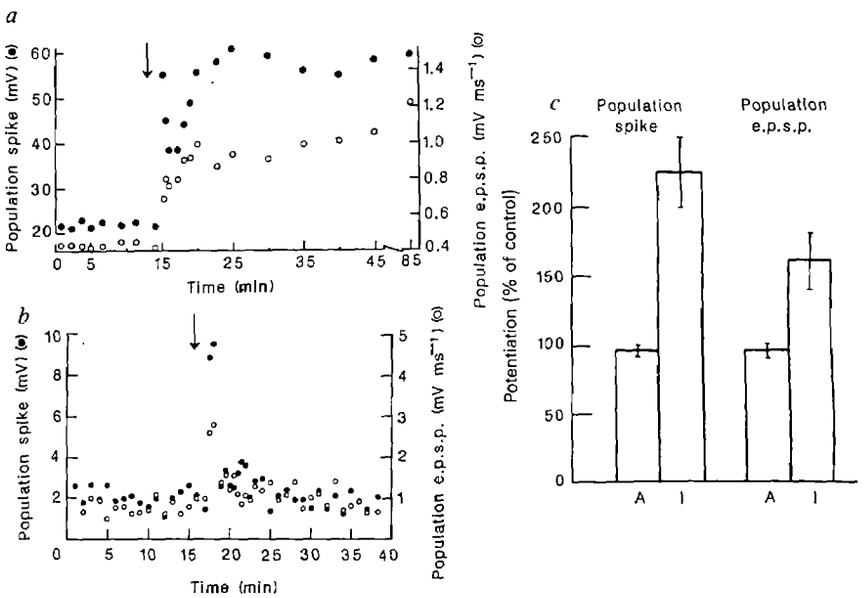

Fig. 3 Increase in synaptic transmission during LTP and its blockage by phorbol esters. *a*, Changes in synaptic responses after high-frequency stimulation (arrow; two 100-Hz/1-s stimulation trains separated by 30 s) from a slice bathed for 20 min with 10 μM of the inactive phorbol ester, 4α-phorbol-12,13-didecanoate. Note that responses are still potentiated more than 80 min after the stimulation. *b*, The changes in synaptic responses from a slice washed for 20 min with 10 μM PDBu are plotted following an identical stimulation as given in *a* (arrow). The responses exhibit post-tetanic potentiation but not long-term potentiation. *c*, Application of phorbol esters which activate PKC prevents LTP. Active or inactive phorbol esters were applied in a blind study. The mean (±s.e.m.) potentiation of the population spike and e.p.s.p. from two groups of slices, one (A; $n = 10$) exposed for 20 min to 10 μM PDBu, an activator of protein kinase C, and the other (I; $n = 10$) exposed for 20 min to 10 μM 4α-phorbol-12,13-didecanoate, an inert phorbol analogue. Highly significant differences between the two groups of slices (A and I) were found (population spike, $P < 0.001$; population e.p.s.ps, $P < 0.01$; Mann–Whitney *U*-test).

Methods. For the blind study, slices were placed in the recording chamber and bathed for 20 min either with 10 μM PDBu or with 10 μM 4α-phorbol-12,13-didecanoate. The experimenter did not know which randomly chosen solution had been applied until after all data analysis was completed. Only those slices meeting the minimum criterion of being able to generate a population spike of at least 5 mV were kept. Following exposure to phorbol esters, a 1–2-mV population spike was elicited every 15 s and responses recorded until a stable 20-min baseline was obtained. A tetanus was then given consisting of two, 100-Hz/1-s stimulus trains separated by 30 s using a voltage twice that used for control responses. Following the tetanus, stimulus voltage was returned to the control value and responses were recorded every 15 s for an additional 30 min. All responses taken during the 5 min prior to the tetanus were averaged and compared with the average of all responses recorded between 25 and 30 min following the tetanus. LTP was considered to have occurred if 30 min after the tetanus the population spike amplitude and/or the population e.p.s.p. initial slope were greater than 125% of control. Since the protocol for this study involved obtaining a control population spike of a fixed amplitude, lower-stimulus voltages would be used in slices exposed to PDBu. To control for this, in four additional slices we first obtained control responses before applying PDBu and for the tetanus used a stimulus voltage two times this pre-phorbol control value. Again we never observed LTP. This demonstrates that possible differences in the stimulus parameters during the tetanus cannot account for the blockade of LTP by phorbol esters.

volley and postsynaptic responses shifts in an identical manner[16]. If activation of PKC is involved in the generation of LTP it should be possible to occlude its generation by maximally activating this enzyme. In a pilot study we found that in seven out of seven slices treated with active phorbol esters we were unable to generate LTP while in seven out of eight control slices LTP was elicited. Based on these findings, we undertook a more rigorous blind study (see Fig. 3 legend) to test this hypothesis. Figure 3 compares the results of high-frequency stimulation in two slices from the blind study, one bathed in an inactive phorbol analogue (Fig. 3*a*) and the other bathed in PDBu (Fig. 3*b*). When stimulated with a tetanus, slices bathed in the inactive phorbol exhibited a brief post-tetanic potentiation (PTP) followed by LTP (Fig. 3*a*), while slices bathed in PDBu exhibited only PTP (Fig. 3*b*). Figure 3*c* summarizes the findings of the blind study. Of the 10 slices exposed to the inactive phorbol analogue, 8 exhibited LTP whereas none of the 10 slices exposed to PDBu exhibited LTP. However, since PDBu did not prevent PTP (Fig. 3*b*) the actions of phorbol esters appear to be specific to the long-lasting form of synaptic potentiation. Consistent with our results is the recently reported preliminary finding that phorbol esters prolong the decay of LTP *in vivo*[17].

The mechanisms underlying synaptic plasticity have generated a great deal of discussion. The most common site responsible for alterations in synaptic strength has been reported in a variety of systems to be the presynaptic terminal[18–21]. Based on our experiments examining glutamate responses and input–output curves, we propose that the enhancement of synaptic transmission induced by phorbol esters is also caused by an action localized to the presynaptic terminal. Consistent with this proposal are several biochemical studies performed in brain tissue which have demonstrated that PKC is present in presynaptic nerve terminals[22], is activated during depolarization of the presynaptic nerve terminal[3], and phosphorylates proteins found in presynaptic terminal membrane[3–6]. Furthermore, phorbol esters have been shown to enhance calcium-dependent neurotransmitter release from both rat brain synaptosomes[23] and cultured brain neurones[24].

The precise mechanism underlying the enhancement of neurotransmitter release induced by phorbol esters is unknown. Phorbol esters have been shown to block a calcium-activated potassium current in hippocampal pyramidal cells[12,13] and similar channels have been shown to exist in rat presynaptic nerve terminals[25]. Blockage of these channels might prolong the action potential in the terminal, thus increasing transmitter release. A similar mechanism involving a different type of potassium channel has been proposed to account for the enhanced transmitter release which underlies behavioural sensitization in the marine mollusc, *Aplysia*[26]. Phorbol esters have also been shown to directly enhance calcium currents in an invertebrate neurone[27]. Alternatively, phorbol esters may sensitize the secretory process to calcium as has been shown in other cell types[2]. A presynaptic locus may also account for the generation of LTP since increases in glutamate release have been demonstrated during LTP in the hippocampus[28,29]. However there are also several experiments consistent with significant postsynaptic modifications[30,31].

Several proteins have been shown to be phosphorylated following the generation of LTP in the hippocampus[7,8,32,33]. One of these, F1 (possibly the same as the synaptically associated B50), also appears to be a substrate for PKC[7,8] although its anatomical localization and function are as yet unknown. If PKC activation is necessary for the induction of LTP, one possible sequence of events for the induction of LTP could be that the high-frequency stimulation raises intracellular calcium concentration to a level that results in a significant activation of PKC. In fact, a recent report has demonstrated that in erythrocyte vesicles small increases in calcium concentration can cause a translocation of PKC from a soluble to a membrane-bound compartment[34]. An alternative hypothesis would be that high-frequency stimulation causes the release of some extracellular messenger capable of stimulating inositol phospholipid turnover. This would result in the generation of diacylglycerol and the subsequent activation of PKC.

This work was supported by NIH grants MH-38256, RCDA MH-00437, the Klingenstein Fund (to R.A.N.), NS-07495 (to R.C.M.) and the Scottish Rite Schizophrenia Research Program NMJ, USA.

Note added in proof: Recently a report has appeared[36] demonstrating translocation of PKC from soluble to membrane fractions following LTP in the hippocampus, thus supporting a role for PKC in LTP.

Platelet activation—a role for a 40K anti-phospholipase A_2 protein indistinguishable from lipocortin

Lhousseine Touqui, Bernard Rothhut, Angus M. Shaw, Armel Fradin, B. Boris Vargaftig & Françoise Russo-Marie

Unité associée Institut Pasteur/Inserm No. 285, Institut Pasteur, 28 rue du Dr Roux, 75015 Paris, France

Stimulus–response (S–R) coupling in platelets requires an intermediary other than an elevation in cytosolic free calcium ($[Ca^{2+}]_i$)[1,2]. While an increase in $[Ca^{2+}]_i$ is essential in S–R coupling, effecting phosphorylation of myosin of relative molecular mass (M_r) 20,000 (20 K)[3], platelet activation is also associated

with phosphorylation of a 40K protein[4], which can occur in the absence of changes in $[Ca^{2+}]_i$ (ref. 5). The 40K protein is the substrate for protein kinase C (PKC)[6,7]. Mounting evidence suggests that activation of PKC by diacyglycerol is the other signal involved in S–R coupling[6,8–10]. Although phosphorylation of the 40K protein is associated with certain platelet functional responses[4,6,8,11,12], no precise role has been accredited to it. Recently, we and others have described several proteins (collectively known as lipocortin) which inhibit phospholipase A_2 (PLA_2)[13–19]. One of the most conspicuous proteins of this group is a 40K peptide whose inhibitory activity can be suppressed by prior phosphorylation[18,20]. We hypothesized that the 40K protein described in platelets may possess anti-PLA_2 activity and that phosphorylation by PKC, suppressing its inhibitory activity, may represent the mechanism underlying mobilization of arachidonic acid, the precursor of prostaglandins. The results of the present study strongly support this hypothesis.

Agonist-induced platelet activation is closely associated with phosphorylation of a 40K protein[4,6,8,10–12] which is the substrate for PKC. Although activators of PKC such as phorbol myristate acetate (PMA) or 1-oleyl-2-acetylglycerol (OAG) can induce some platelet responses, such as aggregation and degranulation[9], no specific function has been reported for the 40K protein. Recent studies have shown that activators of PKC, such as PMA, enhance the activity of PLA_2 in calcium ionophore-stimulated platelets [21], suggesting a possible role for PKC/40K protein in the regulation of PLA_2 activity. Further support for such a role derives from studies[18] which demonstrated, in peritoneal neutrophils, the existence of an anti-phospholipase A_2 protein with a M_r of 40K whose anti-PLA_2 activity can be reduced by prior phosphorylation. The phosphorylation of this protein, originally named lipomodulin and now termed lipocortin[16], in neutrophils parallels the release of arachidonic acid during stimulation by a chemo-attractant. Subsequent investigations[20] demonstrated that in murine thymocytes this protein is phosphorylated by a PKC-dependent mechanism.

On the basis of these observations, we hypothesize that the platelet 40K protein may have anti-PLA_2 activity and that this activity may be regulated by phosphorylation, in a manner similar to that described for lipocortin in neutrophils[18]. Thus, by altering the anti-PLA_2 activity of the 40K protein, activation of PKC may have an important role in the regulation of PLA_2 activity in platelets. To substantiate this hypothesis, we extracted platelet proteins before and after activation of PKC and assayed the extracted proteins for PLA_2 inhibitory activity.

Plasma-free platelet suspensions were prepared from whole blood obtained from the central ear artery of adult New Zealand White rabbits, as described elsewhere[22]. Platelets were lysed by glycerol loading[23] and homogenized in the presence of a membrane solubilizer, Tween-20 (0.5% v/v). Proteins were separated by HPLC using a TSK G2000 SW Ultropac column. The mobile phase, adjusted to a flow rate of 0.2 ml min^{-1}, consisted of Tris-NaCl (0.1–0.15 M, *p*H 7) containing 2 mM EDTA. The activity of each HPLC fraction (0.4 ml) was assessed by monitor-

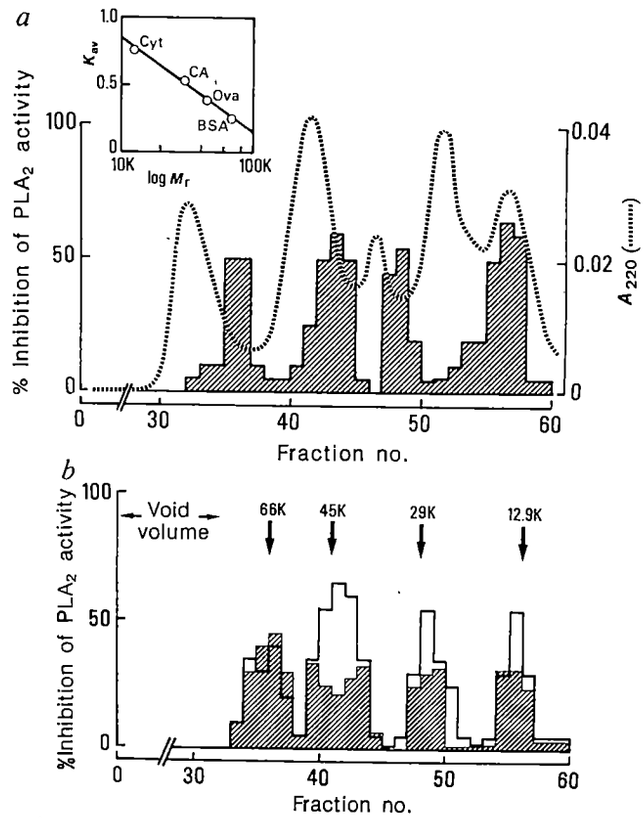

Fig. 1 Anti-phospholipase A_2 activity of HPLC fractions. *a*, Estimation of the M_rs of inhibitory fractions from untreated platelets. *b*, Anti-PLA_2 activity of fractions from thrombin-stimulated platelets. Washed platelets (2×10^9 cells ml^{-1}) were suspended in Tyrode's–gelatin (TG) buffer containing (1 mM) $MgCl_2$, 2 mM $CaCl_2$ and 0.25% (w/v) gelatin (*p*H 7.4). *a*, Aliquots (3 ml) of the platelet suspension were lysed by glycerol loading, then 1 ml of Ca^{2+}-free TG buffer was added to each aliquot to induce osmotic shock. Lysates were then homogenized in the presence of a membrane solubilizer, Tween 20 (0.5% v/v). Ca^{2+}-free TG buffer was added to the homogenates to attain a final protein concentration of 4 mg ml^{-1}. These mixtures were stored in aliquots at −60 °C until required. Aliquots of homogenates containing 0.2 mg protein were subjected to HPLC and the proteins separated on a TSK G 2000 SW Ultropac column using Tris-NaCl buffer (0.1–0.15 M, *p*H 7) as the mobile phase. The M_rs of the resolved proteins were determined by referring to a calibration curve (inset) derived using protein standards [bovine serum albumin (BSA), ovalbumin (Ova), carbonic anhydrase (CA) and cytochrome *C* (Cyt)]. The anti-PLA_2 activity of each fraction was assessed by monitoring its ability to inhibit the release of porcine pancreatic PLA_2-induced ^{3}H-oleic acid from a suspension of labelled *E. coli* membranes[31]. Briefly, 0.1-ml aliquots from each HPLC fraction were each added to 0.25 ml of Tris buffer (100 mM, *p*H 8) containing 10 mM $CaCl_2$ and preincubated with porcine pancreatic PLA_2 (50 ng) for 10 min at 4 °C. In controls, protein fractions were substituted with HPLC buffer. Reactions were initiated by adding *E. coli* substrate (25 μl, 250,000 c.p.m.) and terminated 5 min later by the addition of 50 μl 2 M HCl. The released oleic acid was trapped in the supernatant by the addition of excess BSA (100 mg ml^{-1}), and after centrifugation (10,000*g*, 5 min) to remove particulate material, an aliquot of supernatant was counted for radioactivity by liquid scintillation spectrophotometry. In the absence of any inhibitor, 50 ng PLA_2, over a period of 5 min, induced the release of 8–12% of incorporated oleic acid, a value which represented between 40 and 60% of the maximum response. The inhibition of the anti-PLA_2 activity of the various fractions from one typical experiment is expressed as a percentage of the release evoked in the absence of an inhibitor. The dotted line, representing the profile of the resolved proteins, was determined by measuring the optical absorbance of the eluate at 220 nm. *b*, Aliquots (3 ml) of the platelet suspension were challenged with thrombin (1 U ml^{-1}) (or saline in the case of controls) for 1 min at 37 °C. Reactions were stopped by adding ice-cold EDTA (5 mM final concentration). Thereafter, cells were lysed, homogenized and anti-PLA_2 activity determined (following lysis control cells received 1 U ml^{-1} thrombin). The cumulative results from five experiments are shown; error bars have been omitted for clarity. Compared with controls (open blocks), thrombin treatment (hatched blocks) decreased the inhibitory activity of the fractions containing the 40K, 30K and 15K proteins by 54.7±5.2% ($P<0.001$), 31.0±5.5% ($P<0.01$) and 10.0±2.2% (not significant), respectively (mean±s.e.m.). When thrombin was replaced by PMA (10 nM) a marked decrease in the anti-PLA_2 activity of the 40K fraction was observed (see text).

ing its ability to inhibit porcine pancreatic PLA_2-induced ^3H-oleic acid release from a suspension of labelled *Escherichia coli* membranes (see Fig. 1 legend).

Four fractions, with apparent M_rs of 15K, 30K, 40K and 60K, were found to possess anti-phospholipase activity (Fig. 1*a*), suggesting that rabbit platelets contain proteins which are similar to those now referred to as lipocortin[16]. The principle M_rs reported for the lipocortin proteins are 15K, 30K and 40K. The inhibition associated with the 60K fraction has been reported previously[17] and appears to be due to a nonspecific effect of albumin. The 30K and 15K peptides are considered to be active proteolytic fragments of the 40K protein as in the presence of protease inhibitors (which were omitted in the present study) only the 40K fraction is recovered from the cells[24].

To determine whether the 40K protein extracted from rabbit platelets was similar to lipocortin, we examined the effect of a monoclonal antibody (BF26)[25] raised against renocortin—a lipocortin from rat renomedullary interstitial cells[15,25]—on the ability of the protein fractions to inhibit PLA_2 activity in an *in vitro* assay (see Fig. 1 legend). Fractions containing the 40K protein were incubated with various dilutions of antibody for 1 h at 37 °C and for 24 h at 4 °C. The anti-PLA_2 activity following incubation with a 1:50 dilution of BF26 was reduced from 28.3±3.5% to 6.0±0.7% (mean±s.e.m. of six observations, $P<0.001$). Controls, in which antibody alone was incubated with HPLC buffer, had no effect on PLA_2 activity. This result demonstrates that the 40K protein is immunologically identical to lipocortin.

We further questioned the role of lipocortin in platelets by observing the effect of thrombin, a potent activator of PKC[4], on the anti-phospholipase activity of the extracted proteins. Following treatment of intact platelets with this agonist, the inhibitory activity of the 40K, 30K and 15K fractions was reduced (Fig. 1*b*), the predominant effect being observed with the 40K fraction; no effect on the 60K fraction was observed. In addition, when these fractions were pretreated with alkaline phosphatase, their anti-phospholipase activities were restored (Table 1), suggesting that the effect of thrombin on lipocortin

Table 1 Effect of alkaline phosphatase on HPLC fractions from thrombin-treated platelets

Fraction	% Inhibition of PLA_2 activity	
	Control	Alkaline phosphatase-treated
40K	38.9±7	64.3±4.0*
30K	22.8±6.5	42.8±2.9*
15K	21.7±5.1	51.3±5.1*

The homogenate from thrombin-treated platelets was subjected to HPLC and 0.3-ml aliquots from fractions corresponding to M_rs of 40K, 30K and 15K were each incubated with 1.2 U of insoluble alkaline phosphatase (AP) (*p*H 10) at 20 °C for 90 min. The enzyme was then recovered by centrifugation (5,000*g*, 5 min) and the anti-PLA_2 activity of these and time-matched controls, which received AP buffer alone, was assayed as already described. Values are the mean±s.e.m. of 7–8 observations.

* Significant difference compared with the control ($P<0.001$).

(that is, a reduction of its anti-PLA_2 activity) was linked to a phosphorylating event. This notion was subsequently confirmed using ^{32}P-labelled platelets treated with thrombin or PMA and subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE). There was increased incorporation of ^{32}P in two major bands, one corresponding to myosin light chain (20K) and another corresponding to 40K (Fig. 2*b*,*c*). To establish whether the 40K protein was in fact lipocortin, aliquots of homogenates from thrombin- or PMA-stimulated, ^{32}P-labelled platelets were incubated with the monoclonal antibody BF26. Immunoprecipitated proteins were pelleted and subjected to SDS-PAGE; the

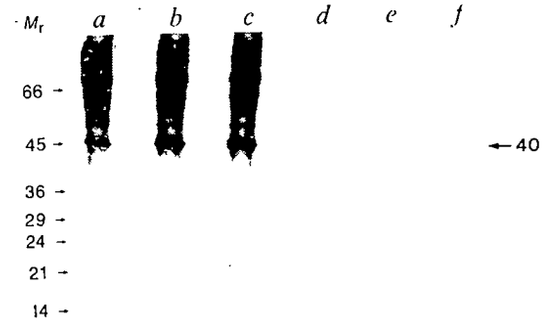

Fig. 2 Immunoprecipitation and SDS-PAGE of ^{32}P-labelled proteins from platelets. The figure shows the autoradiogram of proteins from control (*a*), thrombin-treated (*b*) and PMA-treated (*c*) platelets before immunoprecipitation. *d*, Immunoprecipitation of proteins from thrombin-treated platelets by nonspecific antibody. *e*,*f*, Immunoprecipitation with specific antibody (BF26) of proteins from thrombin(*e*)- or PMA(*f*)-treated platelets. The arrow indicates the 40K protein immunoprecipitated by the specific antibody. **Methods.** Washed platelets were incubated with ^{32}P (0.5 mCi ml^{-1}) for 1 h at 22 °C and aliquots (100 μl) were incubated with thrombin (1 U ml^{-1}), PMA (10 nM) or vehicle alone. After 1 min, reactions were stopped by adding 50 μl of RIPA buffer (*p*H 7.2) containing 140 mM NaCl, 10 mM Tris-HCl, 10 mM EDTA, 1% Nonidet P-40, 0.1% SDS, 1 mM phenylmethylsulphonyl fluoride, 200 IU ml^{-1} aprotinin, 30 mM nitrilotriacetic acid and 30 mM sodium fluoride. Aliquots (15 μl, each containing 100,000 c.p.m.) of homogenates obtained from thrombin- or PMA-treated platelets were incubated at 4 °C with protein A–Sepharose (60 mg ml^{-1}) for 30 min and nonspecific protein binding was subsequently eliminated by centrifugation (5 min at 5,000*g*). Then, 90 μl of supernatant were incubated with anti-renocortin antibody BF26 (26.7 mg protein ml^{-1}) at 37 °C. In the case of the control, aliquots (90 μl) from thrombin-treated platelets received an equivalent amount of nonspecific antibody of the same class (IgG1) as BF26. After 1 h, rabbit anti-mouse antiserum (1:10 dilution) was added to increase specific binding; 30 min later, protein A–Sepharose (60 mg ml^{-1}) was added and the mixture incubated for 18 h at 4 °C. The antibody-bound proteins were pelleted by centrifugation then subjected to SDS-PAGE as described in ref. 32 and radioactivity visualized by autoradiography. Total ^{32}P incorporated into proteins, determined by trichloroacetic acid precipitation, was increased 2–3-fold in thrombin-treated platelets. The radioactivity immunoprecipitated by BF26 (316±38 c.p.m.) in proteins from control platelets increased by 3.7-fold (to 1,168±160 c.p.m.) in proteins from thrombin-treated platelets. In contrast, no significant radioactivity was immunoprecipitated by the nonspecific antibody. Similar results were obtained with proteins from PMA-treated platelets (data not shown).

resultant autoradiograms showed a distinct band corresponding to a M_r of 40K (Fig. 2*e*,*f*), demonstrating that at least part of this protein is immunologically identical to lipocortin. The 30K and 15K fractions (proteolytic fragments of 40K) did not appear in the autoradiograms, as protease inhibitors were present in these experiments.

The present study shows that rabbit platelets contain a 40K anti-phospholipase protein which is recognized by a specific anti-lipocortin antibody (from renomedullary cells), indicating that this protein is immunologically indistinguishable from lipocortin. As shown in Fig. 2, the radioactivity associated with the immunoprecipitated band does not represent all of the phosphorylated 40K protein observed after stimulation with thrombin or PMA; one possible explanation for this is that the 40K protein is not unique but consists of various different proteins, as reported by Imaoka *et al.*[7], and that lipocortin is one of these proteins.

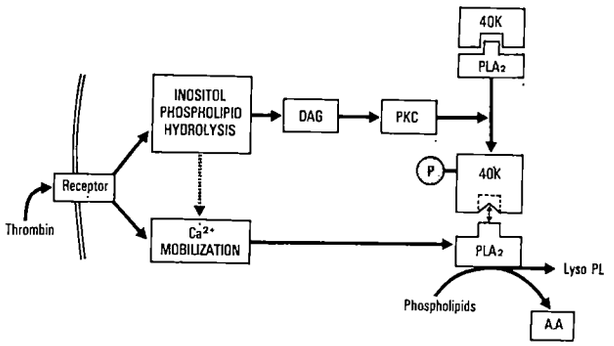

Fig. 3 Synergistic action of protein kinase C (PKC) activation and Ca^{2+} mobilization for eliciting full PLA_2 activation in thrombin-stimulated platelets.

Previous studies[20] have shown that the anti-PLA_2 activity of lipocortin from murine thymocytes can be regulated by PKC-dependent phosphorylation. Here we have shown that, in response to thrombin, the anti-PLA_2 activity of the 40K protein is decreased and that this reduction appears to be associated with phosphorylation of the 40K protein. A role for PKC in suppressing the anti-PLA_2 activity of the 40K protein is therefore suggested. Indeed, when thrombin was replaced by 10 nM PMA, a specific activator of PKC, the anti-PLA_2 activity of the 40K protein was reduced from $71.6 \pm 9.9\%$ in dimethyl sulphoxide (DMSO)-treated control platelets to $16.6 \pm 10.6\%$ after PMA treatment (mean ± s.e.m. of eight observations $P < 0.01$), further suggesting that the anti-PLA_2 activity of the 40K protein in platelets is regulated by PKC.

It has been proposed[26] that two intermediaries—diacylglycerol (DAG) and an elevation in $[Ca^{2+}]_i$—are involved in S–R coupling in various cell types. Here we propose that phospholipase A_2 is also regulated by these two intermediaries to achieve optimal activity. The regulation of PLA_2 by Ca^{2+} and DAG is summarized in Fig. 3. In this scheme, receptor activation leads to an increase in $[Ca^{2+}]_i$ and the concomitant formation of DAG, from the hydrolysis of inositol phospholipids[26]. Activation of PKC, by DAG, phosphorylates the 40K lipocortin, suppressing its anti-PLA_2 activity. In the presence of an agonist-induced elevation in cytosolic $[Ca^{2+}]_i$ (PLA_2 enzymes have an absolute dependency on ionic Ca^{2+}; ref. 27) optimal activity is evoked.

In preliminary experiments, we have observed that the PKC activator PMA, at concentrations that induce phosphorylation of the 40K protein, does not cause the release of ^{3}H-arachidonic acid (^{3}H-AA) from labelled platelets. However, the release of AA induced by the Ca^{2+} ionophore A23187 (250 nM) was enhanced from $15 \pm 4\%$ to $38 \pm 5\%$ (mean ± s.e.m. of four experiments, $P < 0.05$) by pretreating the platelets with PMA (10 nM), which further lends credence to our proposed scheme. A similar PMA-mediated potentiation of ionophore-induced AA release and of thromboxane B_2 formation in rabbit neutrophils and human platelets has been reported elsewhere[21,28]. More recently, both PMA and DAG have been shown to potentiate the release of AA from ionophore-stimulated human platelets[29].

The nature of the interaction between lipocortin and PLA_2 has not yet been elucidated. In Fig. 3 we have shown lipocortin, in its unphosphorylated state, bound to and inactivating PLA_2, rather like the non-enzymatic subunit of crotoxin in snake venom[30]. Phosphorylation of lipocortin dissociates the complex, allowing, in the presence of an elevation in cytosolic calcium, optimal activity of PLA_2.

Equivalence of intracellular *p*H of differentiating *Dictyostelium* cell types

David I. Ratner

Department of Biology, Amherst College, Amherst, Massachusetts 01002, USA

During the development of the cellular slime moulds, spore and stalk cells arise from vegetative amoebae. The intracellular *p*H (pH_i) of the developing cells has been postulated to be important in the choice of morphogenetic programmes[1]. This hypothesis stems from the observation that the addition to the culture medium of weak (membrane-permeable) acids or bases favours the differentiation of pre-stalk or pre-spore cells respectively[1–3]. Similarly, compounds that are known to inhibit a *Dictyostelium* plasma membrane proton pump induce preferential pre-stalk development[1,4,5]; and a stalk-specific *Dictyostelium* morphogen, 'DIF', has been suggested to act via intracellular acidification[6,7]. However, in these studies the pH_i values of pre-spore and pre-stalk amoebae were unknown, and the actual effects of the various agents mentioned above on pH_i were also unknown. By monitoring the intracellular fluorescence of a *p*H-sensitive dye, I have measured the relative intracellular *p*H of pre-spore compared with pre-stalk amoebae. I report here that, contrary to the above hypothesis, there is no significant difference in the pH_i of the two cell types.

The cytoplasmic *p*H of vegetative *Dictyostelium discoideum* amoebae has recently been measured as 6.5–6.7 on the basis of ^{31}P-NMR spectroscopy[8,9] (though the spectra may be open to other interpretations[10]). Unfortunately, NMR measurements require more material than can be obtained as purified precursor cell types. In contrast, *p*H measurements based on the fluorescence of intracellular probes are rapid and highly sensitive. Permeant derivatives of fluorescent dyes readily cross the plasma membrane; negatively charged dye molecules, liberated by intracellular esterases, then accumulate within the cytoplasm. Jamieson *et al.*[11] studied changes in pH_i during *Dictyostelium* development by monitoring the fluorescence of cells labelled

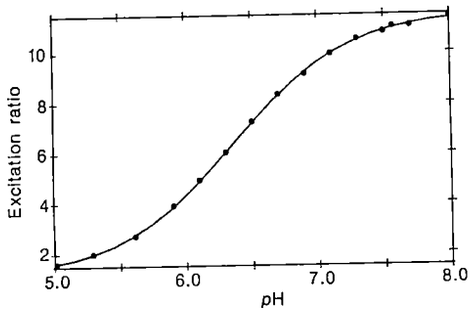

Fig. 1 *p*H-dependence of the excitation ratio of fluorescein in phosphate buffer. Values plotted are the ratio: fluorescence intensity at 489 nm illumination/fluorescence intensity at 438 nm illumination, as a function of the buffer *p*H. Experimental values represent the average of two spectral determinations, which were generally found to agree within 1%. The smooth curve is a theoretical fit derived from the observed *p*K and the fluorescence parameters at the extremes of *p*H.

Methods. Fluorescein (MCB) was dissolved at 0.2 μM in 20 mM phosphate buffers (mixtures of Na_2HPO_4 and KH_2PO_4) of varying *p*H. *p*H determinations, using an Orion 601A meter, and fluorescence spectra were obtained at 0–2 °C. Fluorescence measurements were made with a dual-beam Spex Fluorolog 2 spectrometer controlled by a Datamate, model DM1. Excitation bandwidth 0.9 nm, integration time 1 s, scanning increment 1 nm, emission monochrometer set at 510 nm. All spectra were recorded in a ratio mode to correct for the spectrum due to lamp output.

with fluorescein. The following comparison of the pH_i of prespore and pre-stalk cells was made using a modification of their method.

The fluorescence excitation spectrum of fluorescein is highly *p*H-dependent, the major effect being on the relative fluorescence intensities resulting from illumination at the excitation maximum (489 nm) compared with illumination at a shorter wavelength (438 nm)[11–13]. Figure 1 shows a standard curve, used to calibrate pH_i measurements, of the excitation ratio of fluorescein in phosphate buffer. Sensitivity is excellent over the *p*H range 5.8–7.0 (fluorescence $pK = 6.4$), a range well suited for examination of *Dictyostelium* amoebae.

When amoebae (vegetative or developing) are incubated with a relatively high concentration (100 μM) of fluorescein diacetate, intense but diffuse labelling of the cytoplasm results (ref. 11 and my unpublished results); this indicates that the major contribution to the fluorescence of intracellular dye is cytoplasmic, hence the pH_i reported is expected to be essentially that of the cytoplasm. Figure 2*a* shows the excitation spectrum of fluorescein-loaded vegetative *D. discoideum* amoebae. Despite its negative charge over the entire physiological range, fluorescein is lost from *Dictyostelium* (and mammalian[13]) cells at an appreciable rate. Therefore, measurements were performed quickly, at low temperature, and correction made for any loss of dye from the cells. Figure 2*a* includes the spectrum of the cell suspension, that of the cell-free filtrate taken immediately thereafter, and the calculated difference spectrum corresponding to intracellular fluorescein. The pH_i of the vegetative amoebae in Fig. 2*a* is 6.94. The average pH_i in 14 such measurements was 6.93 ± 0.21. These measurements were obtained in phosphate buffers spanning 2.5 *p*H units (*p*H 5.0–7.5); the intracellular *p*H was unaffected by such changes in the fluorescence buffer (see also refs 8–10).

The fluorescence procedure is also applicable to pre-spore and pre-stalk cells. The two cell types, obtained from migrating slugs, were purified by gradient centrifugation, and fluorescence

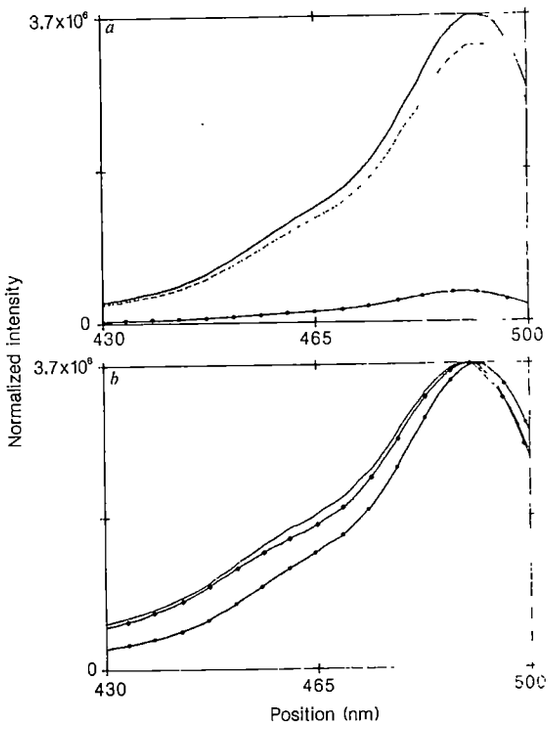

Fig. 2 Fluorescence excitation spectra of vegetative (*a*) and developing (*b*) amoebae. *a*, Spectra for a vegetative cell suspension (—), for the cell-free filtrate (●—●) dye loss 10%, and for intracellular fluorescein calculated as the difference spectrum of the first two (·····) pH_i 6.94. *b*, Normalized, filtrate-corrected spectra for three cell types: pre-spore, pH_i 6.08 (—), pre-stalk, pH_i 6.12 (◆–◆) and a concurrent vegetative cell preparation, pH_i 6.94 (●–●). The pH_i values were determined from the excitation ratio of intracellular fluorescence according to the calibration curve of Fig. 1. Cellular autofluorescence is negligible: the intensity of unlabelled cells is $<10^{-4}$ that of cells containing probe. Note that the difference in pH_i between vegetative and differentiating cells does not result from the choice of strains, as vegetative NC4 amoebae (not shown) have a pH_i equal to that of vegetative AX3 cells.

Methods. Vegetative cells of *D. discoideum* strain AX3 were harvested from axenic medium[18], washed in cold buffer and incubated at 2×10^6 ml^{-1} in 10 mM PO_4 *p*H 6.0 (prepared from Na_2HPO_4 and KH_2PO_4), 9 mM NaCl, 9 mM KCl, 2 mM $CaCl_2$ and 100 μM fluorescein diacetate (Sigma) added from a 100-mM stock solution in dimethyl sulphoxide. After incubation at 22 °C for 15 min, with shaking, cells were washed three times in cold buffer, the final wash immediately preceding the fluorescence measurement. Prespore and pre-stalk amoebae were obtained from migrating slugs of strain NC4, mechanically dissociated in the presence of EDTA, and purified by density gradient centrifugation[19]. Labelling of the precursor cells differed from that of vegetative amoebae only in that the incubation period was increased to 25 min. Vegetative amoebae were resuspended at 10^6 ml^{-1} in 20 mM PO_4 *p*H 7.0; differentiating amoebae were resuspended at 2×10^6 ml^{-1} in buffer of *p*H 6.0. Excitation spectra were obtained from 4 ml of cells as in Fig. 1, except that the integration time was reduced to 0.5 s. Immediately after scanning, each cell suspension was filtered through a 0.45-μm membrane filter (Millipore) under gentle suction. The time between the final washing of the suspended cells and the completion of filtration was <4 min. Leakage of dye during this interval was quantitated by determining the relative fluorescence intensities of the filtrate and cell suspension measured at 440 nm. Dye loss generally accounted for 10–15% of the total fluorescence. Suspension buffers were customarily chosen with a *p*H approximating that of the cells (as revealed in earlier measurements) to ensure that any imprecision in the dye loss correction would have a negligible effect (on the order of 1%) on the calculated intracellular excitation ratio. Because of the small redshift of intracellular fluorescein relative to free dye (the excitation maximum averaging 491 nm rather than 489 nm), the cellular excitation ratio was computed from intensity values at 491 and 440 nm.

measurements were performed as for vegetative amoebae. Figure 2*b* compares filtrate-corrected excitation spectra for pre-spore, pre-stalk and vegetative amoebae. Although the spectra obtained for the differentiating cells differ from that obtained for the vegetative cells, they are very similar to one another. Indeed, as summarized in Table 1, there is no significant difference in the pH_i of the two precursor populations. As is true of vegetative cells, the measured intracellular pH is independent of that of the surrounding medium (Table 1). However, differentiating

Table 1 Identity of pH_i of pre-spore and pre-stalk amoebae

		Pre-spore		Pre-stalk	
Expt	pH_0	Excitation ratio	pH_i	Excitation ratio	pH_i
1	6.85	4.78	6.07	5.52	6.20
		3.97	5.92	5.37	6.18
2	6.0	5.65	6.22	5.51	6.20
		4.80	6.08	5.06	6.12
3	6.0	5.47	6.19	5.16	6.14
		5.52	6.20	5.11	6.13
		Mean $pH_i = 6.11 \pm 0.11$		Mean $pH_i = 6.16 \pm 0.04$	
		Mean of all pH_i values $= 6.14 \pm 0.08$			

Experimental methods and data manipulation were as described in Fig. 2 legend. For each of the three experiments shown, pre-spore and pre-stalk spectra were taken alternately. There is no significant difference between the pH_i values of the pre-spore and pre-stalk groups. Similarly, the pH of the cell suspension buffer ($pH_0 = 6.85$ as opposed to 6.0) and the length of time for which cells were held at 0 °C prior to spectroscopy had no effect on pH_i. The excitation ratio is explained in Figs 1 and 2 legends.

slug cells give the somewhat acidic value for pH_i of 6.14 ± 0.08. The acidification may be the result of accumulation of metabolic acids produced during prolonged slug migration[14], given that the pH_i of amoebae developing in suspension or on pads for shorter periods of time is similar to that of vegetative cells (my unpublished observations; see also refs 8, 10). Because cells within migrating slugs continue to interconvert between pre-spore and pre-stalk (evident immediately in bisected slugs[15] and inferred for undisturbed slugs[16,17]), the acidic pH_i is, for this reason alone, unlikely to be determinative of the differentiated cell state.

Several controls argue that the fluorescence measurements are a valid indication of relative pH_i values. It is conceivable that the production and accumulation of relatively high concentrations of fluorescein within cells (reaching values in excess of 10^{-4} M; ref. 13 and my unpublished observations) might alter the normal pH_i. However, measurements of the pH_i of vegetative amoebae by the independent criterion of ^{31}P-NMR showed no difference between the pH of highly fluorescent cells and that of control cells ($pH_i = 6.7$ for both; C. Thompson and D.R., unpublished observations). The small disparity between the pH_i of vegetative cells determined by fluorescence (pH_i 6.9) and that determined by NMR spectroscopy (pH_i 6.7) may reflect the particular calibration method used here, or a possible mitochondrial contribution to the fluorescence. With slug cells, varying the degree of labelling suggested that there might be a slight acidification attributable to fluorescein, but the effect was small (<0.2 pH units) and not cell-type-specific (data not shown). Finally, the observed pH_i of total slug cells was found to be identical (pH_i 6.15) whether or not the cells were subjected to gradient centrifugation.

Despite any uncertainty in absolute pH, it is clear that the pH_i values of pre-spore and pre-stalk amoebae are, within experimental error, identical. Thus the hypothesis of a more acidic pH within pre-stalk than pre-spore cells is untenable. This hypothesis has been suggested primarily by the established effects on cell proportioning of weak acids and bases, and of known or presumed proton pump inhibitors[1-7]. However, recent measurements using both NMR and fluorescence spectroscopy (ref. 10; C. Town, personal communication; and my unpublished observations) have failed to detect the predicted effects of these compounds on pH_i. Rather, the treated amoebae maintain their pH_i; in so doing, they may perhaps perturb the concentration of some other metabolite(s) whose flux across the plasma membrane is coupled, positively or negatively, to that of protons. Such a metabolite might be the physiological regulator of precursor differentiation in *Dictyostelium*.

This research was supported by NSF grant PCM 8202833. I thank C. Thompson for performing NMR spectroscopy and Dr R. Blankenship for an introduction to fluorescence methods.

NATURE VOL. 321 22 MAY 1986

What future for nuclear power?

The outlook for civil nuclear power has blackened everywhere in the aftermath of the Chernobyl accident. Here is what governments other than the Soviet should now do.

WHATEVER went wrong at Chernobyl, that accident has not done much for the job prospects of nuclear engineers outside the Soviet Union. To be sure, there may be a little short-term employment to be had in Austria, where the government decided last week that it will now dismantle the country's only nuclear power station, which has been waiting on the brink of full operation for several years. The Swedish government, which had already decided to build no more reactors, and to close down its nuclear industry when the dozen reactors now operating reach the end of their useful lives in 2010, now says that it may bring forward that deadline. Even in France, Western Europe's most bullish nuclear operator, discontent with the nuclear policy the new government has inherited is being demonstrated in the usual way, with huge crowds gathering around the perimeter of some nuclear plants. At least until the Soviet report of the Chernobyl accident is published, the operators of nuclear plants in Western Europe and elsewhere will find themselves on tenterhooks.

In its broadest sense, the question whether communities should make electricity from uranium is political. Voters have a right to decide whether they wish their governments to sponsor the generation of electricity by means that can cause social disruption and damage on the scale on which it has been caused in the Ukraine. Electorates have a right to know, for example, whether their governments have arrangements that will allow communities to survive serious nuclear accidents without bringing civic administrations to the point of collapse. But in at least three Western European countries, nuclear safety is bound to be an issue in general elections in the coming months. In Britain and West Germany, where pro-nuclear governments must go to the polls quite soon (Britain within two years, West Germany next spring), doubts on nuclear safety will be exploited by the opposition parties. In the Netherlands, where there are elections this week, the government has thought it prudent to sidestep the issue by saying that it will not now plan to add to the two reactors now operating, as had been intended in the 1990s. In the United States, it is inevitable that Chernobyl will reinforce the opposition to plans for nuclear construction; the chance must have markedly diminished that the Long Island Lighting Company will be given a licence to operate the Shoreham plant, which is ready to operate but which has been held up for lack of a convincing plan to evacuate the locality in case of a nuclear accident. What should public utilities and their often timorous governments do now?

Decisions

The first maxim is an old one: do not panic. There is no need, for there is no evidence that nuclear accidents are catching. Probably the opposite is the truth. An accident on the scale of that in the Ukraine will, if anything, make reactor operators elsewhere even more vigilant. Quick decisions are usually costly decisions. The decision of the government of the Netherlands to scrap plans for nuclear development on the eve on this week's elections may be electorally prudent, but may cost Dutch taxpayers money in the coming decade and will not contribute one jot to the safety of the two reactors now operating. And the same is even more true elsewhere. Many communities (in France and Japan, for example) could not turn their backs on nuclear power without giving up some of their present use of electricity. Even those inclined to follow such a course must pay at least as much attention to the safe operation of existing plants during the remainder of their operating lives.

Utilities, governments and their taxpayers should also remember that nothing has happened in the past three weeks to diminish the economic prize to be won by the safe operation of nuclear energy. In very round numbers, a kilogram of uranium can now be bought on the open market for $100, but will yield thermal energy worth $1,000 if used as fuel in a thermal reactor. In a fast reactor designed for breeding fissile material, the value of the thermal energy from a kilogram of uranium may be a further 1,000 times as much. The endless argument about the economics of nuclear power turns on the question of how much of this huge economic rent must be spent on building reactors, on making them safe and on disposing of the radioactive waste materials. Even though uranium would not be as cheap if its exploitation in nuclear energy were more fashionable, the sheer size of the economic benefit cannot be ignored even now. If a country such as Britain were to replace its present annual consumption of 100 million tonnes of oil by the equivalent in uranium, the economic gain would far exceed the government's annual borrowing requirement. It would be foolhardy to ignore the size of this potential economic benefit simply because a reactor in the Ukraine went out of control last month.

Plans

Equally, however, it would be wrong for governments elsewhere to pretend that what happened at Chernobyl is irrelevant to their domestic power policies. In the litany of the hazards of civil nuclear power, the possibility of a serious reactor accident has always been the most awesome. Quite apart from the tragic loss of life in and around the Chernobyl reactor, and the social and economic disruption that the accident has caused, the consequences for the communal psychology of the region around Kiev can only be guessed at. It is natural that people elsewhere should now say that they would pay quite a high price to avoid such accidents on their doorsteps. Prudent governments will pause and reassess their plans to build reactors by some process so public that their constituents will be confident in whatever decisions emerge. Access to a full explanation of what happened at Chernobyl, promised last week by Mr Mikhail Gorbachev, will be an essential starting point for that.

In the West, the process will be complicated by the degree to which civil nuclear power has already been turned into a public and political issue by a gaggle of environmental movements whose motives are rarely as innocent or even respectable as advertised. The West German Greens, for example, likely to emerge from next year's election in a government coalition with the Social Democrats, are as fierce about the supposed evils of the corporatist state as about those of nuclear power. In countries such as Britain, the bubbling opposition to the search, by the public agency responsible for radioactive waste disposal (Nirex), for sites at which to bury low-level waste springs not

from a realistic assessment of the hazards but from the more familiar reluctance of those who enjoy the benefits of modern industry to put up with inconvenient side-effects. Deciding on rational policies for nuclear energy will require that those with an inner certainty that nuclear energy is an abomination should be restored to the pathways of rationality. The gravity of the accident at Chernobyl may, paradoxically, help by showing level-headed people that there are serious arguments on both sides of the question.

Research

Most governments will also recognize that it is a misfortune that so many of them have deliberately allowed research and development programmes in nuclear energy to shrink. In the design of thermal nuclear reactors for example, there has been hardly any research that matters for close on a quarter of a century, since most governments and their construction companies took the view (early in the 1960s) that they knew enough about the subject to make a go of it. The result is that the technology of nuclear power has been immovable for far too long, and in particular since before the potential seriousness of loss-of-coolant accidents (part of the trouble at Chernobyl) was recognized by studies carried out in the United States in the early 1970s. It is as if the technology of air transport had been fixed at the outbreak of the Second World War. Hopes by some of the laboratories with continued interest in reactor design, the Argonne National Laboratory for example, to attract funds for projects aimed at inherently safe reactor systems, have not been conspicuously successful.

Much the same is true of research on waste disposal. People either worry about the isolation from the rest of the environment of entire irradiated fuel elements or they worry about storing the mixed fission products from separation plants; in each case, there is a huge amount of radioactivity at the beginning, but it is also necessary to isolate some low-activity components (actinides) for millennia on end. Technically, the problem would be simplified if the wastes were separated chemically, but the only serious studies made of this possibility are desk studies purporting to show that such sophistication would be uneconomic on the basis of assumptions valid in the 1970s, not now when people may be prepared to spend more for safety. However they decide to generate electricity in the years ahead, governments have a responsibility to breathe new life into more imaginative research. It would be appropriate if they did so collaboratively. In Western Europe, Euratom is still looking for a function after 30 years. The International Atomic Energy Agency, which has played a valuable role in the response to Chernobyl, could become the vehicle for a research programme that would show more convincingly which are the safest ways to go.

Technical developments by themselves will not suffice. There must also be a better public understanding of the nature of the risks. So much has been plain since long before Chernobyl. But the well-meaning attempts of public authorities at general education have been ineffectual because of their failure to distinguish between enlightenment and reassurance. Reactor accidents apart, it is probable that the people most seriously affected by the routine operations of the nuclear industry in the few places at which it flourishes are the workers at nuclear plants, reactors and reprocessing plants. Radioactive waste and routine discharges from reactors (neutron irradiation of atmospheric argon produces beta-active argon-41) have much smaller effects when measured by the yardstick of the radiation dose to a population as a whole. The obvious difficulty is that public authorities cannot go about insisting that even small doses of radiation can cause trouble (delayed cancer induction, genetic defects) without unsettling those who work for them. Much easier to behave as if these risks do not exist or to pretend that they are negligible.

The truth is that (reactor accidents apart) the risks of radiation are for most members of a population small, much smaller than the effects of cosmic rays (a comparison valid only if there is no damage threshold) but not negligible to people who have become convinced that radiation risks, however small, are important. Sadly, the acute radiation deaths at Chernobyl (11 so far) may make ordinary people more receptive to the orders of magnitude of the different risks. Certainly, governments and public authorities cannot leave the task of public education to those now most active in the field, the environmentalists whose interest is to confuse the issue (as well as to confuse civil with military nuclear power).

None of this will, for the time being, persuade ordinary people not to fear what they have now come to fear most, the risk of a reactor accident. The fact that other reactors may differ in design from that at Chernobyl will cut no ice when the world knows that most accidents in the nuclear industry have been caused not so much by errors of design as by personal folly or incompetence, for which the euphemism is "human error". There was nothing in the design of the Brown's Ferry (Tennessee) reactor from which outsiders could infer that it would be set on fire by a man looking for a gas leak with a lighted candle. The long sequence of minor discharges of radioactivity from the British separation plant at Windscale (now Sellafield) has rightly raised in the public mind the question whether people who cannot be trusted to avoid small mishaps will ensure that large mishaps never happen.

So how are the nuclear establishments to re-establish public confidence in their competence? They could help themselves substantially by paying more attention to the design of reactors and their instrumentation with the objective of making them "user friendly", not user hostile as they tend to be at present. Whatever the technical defects of the Three Mile Island reactor that went wrong in 1978, there is no doubt in retrospect that an impending accident required the operators to behave in ways that seemed in the heat of the moment to be unreasonable. It is not surprising that they chose not to follow the instruction manual. The general technical question is that of how to design complicated machines in such a way that the human beings asked to supervise their operation are able to intervene constructively. The problem is by no means novel. Aircraft designers have grappled with it for years. Is it not time that nuclear engineers took a leaf out of this now well-read book?

Ambiguity

A further difficulty arises from the amibiguity of responsibility that afflicts those who are in charge of these complicated machines. The Challenger disaster in January seems clearly to have shown that trouble would have been avoided if it had been easier for unwelcome news to reach the top management of the US National Aeronautics and Space Administration. It will almost certainly emerge that part of the trouble at Chernobyl is that the local management was reluctant to admit to Moscow (especially on the eve of the May Day celebrations) that it had a nasty accident on its hands. What these and other accidents have shown is that there is an urgent need that technical people ostensibly in charge of complicated pieces of machinery should have more freedom in deciding how they should be operated safely, and a more direct responsibility for making sure that this is done. Their situation is not very different from that of the masters of merchant ships, who are still the ultimate arbiters of, for example, whether they should put to sea in rotten weather.

These are only some of the issues that governments and their agencies must face. All of them require a degree of flexibility and a habit of frankness that comes awkwardly to public authorities everywhere. The temptation will be to funk them. But the only course that people will respect will be to face them openly, accepting the promise of nuclear power for what it is, a potential boon that will be attainable only if people at large acknowledge that it is also safe. The task is not impossible, but will require more of governments than they have recently been inclined to show in this cause. □

Chernobyl

US physician tells heroic tale of Moscow

THE medical problems of dealing with the victims of the Chernobyl accident hospitalized in Moscow have turned out to be unexpectedly difficult, according to Dr Robert Gale, the Los Angeles physician who had been working at Moscow's Hospital No. 6 until a brief respite last weekend. Dr Gale, speaking on the telephone from Los Angeles earlier this week, said that the 299 patients at the hospital appear all to have received a damaging dose of radiation while working at or near the reactor damaged on 26 April.

According to Dr Gale, typical doses exceeded 2 Gy (1Gy=100 rad) with the doses received by the most seriously injured workers exceeding 5 Gy. Although most of the radiation exposure appeared to have been caused by gamma rays, Dr Gale explained that the difficulty of treating the patients in Hospital No. 6 arose from the variety of the means by which radiation doses had accumulated. Some people had breathed substantial doses into their lungs, others had ingested radioactive materials while other cases were complicated because the radiation appeared to have come from only one side of the body.

While emphasizing that he had no information about those in or near Chernobyl at the time of the accident apart from those in hospital in Moscow, Dr Gale thought if probable that between 50,000 and 100,000 people among the local population now evacuated would have received doses of radiation or of radioactivity large enough to warrant annual examinations.

Among those acutely injured by radiation, Dr Gale explained, the most common symptoms were gastrointestinal disturbance, liver toxicity and depression of haematopoiesis (blood-cell formation). One of the unexpected difficulties of planning to treat severely injured patients by bone-marrow transplantation had been that of tissue-typing in circumstances where blood-counts were falling rapidly.

Dr Gale's presence in Moscow apparently came about as a consequence of approaches to the Soviet authorities through Dr Armand Hammer, chairman of the Occidental Petroleum Company, and Dr Vincent de Vita, director of the US National Cancer Institute. His offer of help was apparently accepted within 24 hours. He speaks highly of the informality with which he, his colleagues and their equipment were allowed into the Soviet Union. With Dr Gale are two colleagues from the University of California at Los Angeles, Dr Paul Terasaki and Dr Richard Champlin, and Dr Yair Reissner from the Weizmann Institute in Israel.

Much of the activity in Moscow has been concerned with identifying potential donors from among those covered worldwide by the international transplant registry, which is a listing of people with known histocompatibility characteristics. He said it was impressive that it had been possible to identify donors and to deliver tissue for transplantation to Moscow in between 48 and 72 hours. Even so, he said, most of the 35 transplants performed in recent days had used marrow taken from relatives.

Some of the Moscow patients have also received transplants of fetal liver. He takes the view that the experience gathered in the past few weeks in Moscow will be invaluable in responding to future nuclear catastrophes, accidental or otherwise, and says that he is delighted that the Soviet authorities have agreed to full publication of the data now being gathered. He says that the information becoming available will at least double the extent of the pre-existing database.

On the preparedness of his Soviet colleagues, Dr Gale says it is plain that Soviet physicians had "given thought in advance" to the problems that would be posed by a nuclear accident on the scale of Chernobyl.

He also drew attention to the way in which the nuclear accident had stretched the resources of the international transplant registry. Matching tissue for 35 patients had had to be sought in 15 different countries. The problem of dealing with a larger accident could well be beyond present resources, he said.

SDI

Academics pledge opposition

Washington

LEADERS of a drive to discourage academic scientists and engineers from participating in research on the Strategic Defense Initiative (SDI) brought their case to Washington last week. They delivered a pledge to the White House, signed by more than 3,700 science and engineering professors, not to accept or solicit SDI funds. In addition, 2,800 graduate students signed a similar pledge not to participate in SDI-related projects.

The boycott pledge began early last summer on the campuses of Cornell University and the University of Illinois at Urbana–Champaign. Advocates of the pledge argue that it is fruitless to do research on a project that is "not technically feasible".

Furthermore, they suggest that treating SDI as a partial defence rather than a total nuclear shield against Soviet attack will make SDI merely a new weapon system guaranteed to escalate the arms race. At a press conference held in Washington last week, John Kogut, a physics professor at the University of Illinois at Urbana–Champaign and one of the instigators of the pledge, emphasized that SDI would jeopardize existing arms control agreements, such as the Anti-Ballistic Missile Treaty, and make future agreements more difficult to achieve.

Another consequence of a large funding effort for SDI, according to James Melcher, director of the electromagnetic and electronic system laboratory at Massachusetts Institute of Technology (MIT), is a gradual strangling of the US economy. Melcher sees more and more physicists, engineers and computer scientists being drawn into weapons-related research. At the same time, he fears that corporations are placing less emphasis on developing commercially viable technologies, choosing instead to take a "quick fix" from readily available defence funds.

Although spending on SDI research has increased dramatically in the three years since President Reagan announced the programme, only a small portion of that money has actually arrived at academic institutions. According to figures compiled by the Federation of American Scientists (FAS) for a forthcoming report on SDI spending, teaching institutions have received between two and four per cent of total expenditure on SDI. In 1985, for example, SDI payments to universities totalled $49.1 million, compared with total SDI expenditures of $1,464.8 million. The SDI Organization has provided funds to 69 US universities so far, with Utah State leading the list, having received £27.5 million since 1983. Frank Redd, associate director for Utah State's space engineering centre, says that the bulk of that money comes from existing defence contracts, and was only recently changed to come under the SDI umbrella.

Similarly, Robert Byers, a spokesman for Stanford University, the fourth leading recipient of SDI funds according to FAS figures, explains that the bulk of that money comes from a pre-existing Air Force contract for research on free-electron lasers. But support for the pledge drive was low among physicists at Stanford, only eight of twenty-one faculty members signing the pledge. **Joseph Palca**

Particle accelerators

US agency accused of bad costing

Washington

THE US Congress is likely to scrutinize more closely costs of building particle accelerators following the publication last week of a highly critical report accusing the Department of Energy (DoE) of providing only "fragmented and incomplete" cost estimates in its budget submissions. The report*, prepared by the US General Accounting Office (GAO), recommends that congressional appropriations committees direct DoE to provide full and timely cost estimates, as well as details of technical uncertainties, of current projects.

The GAO study was requested by Senator Bennett Johnston, a Louisiana Democrat on the Senate Appropriations Committee who has made no secret of his scepticism of big accelerator projects.

Prospects of an early start on the construction of the Superconducting Supercollider (SSC) have been dealt a blow by the report, which estimates the total cost of SSC to be 60 per cent higher than DoE has hitherto indicated. DoE has made a point-by-point rebuttal, but the GAO inspectors have seen fit to make only minor changes in the light of the DoE response.

The GAO report examines DoE's six largest high-energy and nuclear accelerator physics projects and finds that DoE consistently understated total and preconstruction costs in its formal budget submissions. Preconstruction research and development for these is, according to GAO, likely to amount of $440 million; only $88 million has so far been formally reported in budget documents.

Preconstruction work for SSC, for example, will cost $62 million more than the $58 million identified in budget submissions to Congress. The Tevatron I and II projects at Fermilab will, according to GAO, cost $180 million more than the $16 million that has been reported. Other projects likely to cost more than indicated are the Stanford Linear Collider and the Continuous Electron Beam Accelerator Facility at Newport News, Virginia, as well as the planned Brookhaven relativistic heavy-ion collider and the Los Alamos Meson Physics Facility II (LAMPF II).

The DoE response to the charges is that much accelerator research is generic in nature, and so need not be identified with a particular project until construction is approved by Congress. GAO disagrees, saying that formal "mission-need statements" should be prepared at an earlier stage than is DoE's practice. The essence of the disagreement is the uncertain definition of the start of a project.

GAO is equally critical of DoE when it comes to estimating total costs associated with a project, however. The total cost of SSC, according to GAO, will be $4,900 million, $1,900 million more than DoE estimated in testimony to Congress a year ago. GAO observes that full cost estimates for this and other projects are not presented to Congress in a coherent form before projects are approved; as a result, Congress gets no clear idea of the cost of a project until it is too late. The Stanford Linear Collider and Tevatron projects are given as examples for which Congress could have been better informed. And GAO specifically criticizes DoE for not fully explaining technical uncertainties in some projects. For Tevatron I the uncertainties led to a $71 million cost overrun.

DoE protests that some estimates have been presented at individual committee hearings, and disagrees with GAO's inclusion of ancillary equipment (for example, dedicated computing facilities) in project costs. But whichever way the issue is decided, the pressures of the Gramm–Rudman deficit reduction law suggest that Congress will want to look much harder at DoE's big science proposals in future. The administration's proposed budget for high-energy and nuclear physics in 1987 is $771 million, an increase of 17 per cent over this year's figure, but it is already clear that Congress is unlikely to countenance an increase on that scale.

Tim Beardsley

**Nuclear Science: Information on DoE accelerators should be better disclosed in the budget.* General Accounting Office, April 1986.

British research

Signs of a silver lining appear

IN a week in which it seemed as if the British government would relax its policy to enforce the continued contraction of universities, a committee of interested parties has produced a telling criticism of public policy on civil research. These developments coincide with a general feeling in the research community that the pressures on the British government to pursue a less rigorous policy on public spending cannot fail to benefit research.

Precisely how the universities will benefit cannot be foreseen from the events of this week. On Tuesday, however, the University Grants Committee (UGC) was due to send to all British universities a notice of payments of recurrent grants to be expected in the academic year beginning on 1 August. This is the year in which the first effects are apparent of UGC's new policy of concentrating resources on the universities with the best records in research. Although, for this year, there is a "built-in safety net" which will ensure that no university is more than 1.5 per cent worse off than the average university (in a total budget that is reduced by 2 per cent in real terms), universities destined for sharper reductions in later years are identifiable from the letters.

The government's concession, due to be announced by the Secretary of State for Education and Science, Sir Keith Joseph, on Tuesday, is that extra financial help will be provided outside the UGC budget for institutions threatened with hardship which are able to meet certain criteria, such as the demonstration of centres of excellence in fields to which insufficient attention has been paid. This broad formula is a means by which the government could avoid the prospect of particular universities being threatened with closure in advance of the next general election. It is understood that no decision has been made about the scale on which extra funds would be made available.

Meanwhile, criticism of government policy on civil research has come from a committee of the Advisory Board for the Research Councils (ABRC) under P. Mathias, professor of economic history at the University of Oxford, which was set up in 1984 to assess the potential importance of private funds as a means of supporting research at academic institutions and research institutes.

The committee says that in spite of the wide discussion of research policy in Britain during the past few years, it is impressed by the sharp contrast between British spending on civil science and that elsewhere. British civil science receives 1.6 per cent of gross domestic product (GDP), compared with 2.0–2.5 per cent in the United States, West Germany and France, according to the report, which notes that British spending is declining while that in other countries is growing.

The report also says that defence research and development consumes a higher proportion of total spending, and of government spending, in Britain than elsewhere, and that industrial companies in Britain account for a smaller proportion of total research spending than in other countries. The committee makes a particular point of the apparent decline of spending on research by private industry in the recession years of 1981–1983 (when the volume of research appears to have fallen by 6 per cent). It notes that the same trend appears to have continued in 1984 (for which final figures are not available) and wryly remarks that if the disinclination of British companies to spend money on research is a permanent phenomenon, this is hardly the best climate in which academic institutions might hope to raise more support from companies. □

Human genome

Department of Energy on the map

Washington

UNTIL recently, sequencing the human genome seemed an impossibly large project, almost like counting all the grains of sand on all the world's beaches. But today the Department of Energy (DoE) is giving serious consideration to a project to sequence all of the estimated 3,500 million base pairs making up the human genetic material. Initial estimates put the cost of the entire project at $1,800–$3,600, or about $1 per base pair.

Early in March, DoE held a conference in Santa Fe, New Mexico, to discuss the feasibility of undertaking the sequencing project. The conference, hosted by DoE's Los Alamos National Laboratory, produced a report outlining a strategy for accomplishing the task. According to David Smith of the Office of Health and Environment Research (OHER) at DoE, the department is expected to decide in a matter of weeks how and whether to proceed with the monumental project.

DoE has historically had an interest in the human genome, and has been supporting research into genetic damage from energy sources for some time. Together with Lawrence Livermore National Laboratory, Los Alamos has been involved in the National Laboratory Gene Library Project, an effort to construct a chromosome-specific gene library. So far, the small insert library — containing fragments of 5,000–10,000 base pairs — is complete, and work on the large insert library for fragments of up to 50,000 base pairs has begun. Los Alamos has also developed flow cytometry technology capable of rapidly separating large amounts of DNA by chromosome, a capability that Los Alamos senior fellow Mark Bitensky sees as important to the success of the project.

Bitensky is coordinating Los Alamos' effort to make the gene sequence a reality. He says the project will "require many laboratories, many funding agencies, and many technologies", but he believes it can be done, and that the time is right to do it.

Although DoE may seem like an unlikely agency to handle such a project, Bitensky and OHER head Charles DeLisi feel that DoE is well placed to take a lead role. In addition to the gene library project, DoE has the computational facilities necessary for such a large-scale project. And DoE believes it has the know-how to undertake large-scale scientific projects, pointing to the DoE-run Fermi National Laboratory as an example of its expertise.

Current plans call for a decentralized programme, with one coordinating facility organizing the work of many centres around the country. The organizers hope the sequence can be a multinational effort. Bitensky says European interest in the project is already high.

Two theoretical approaches to the sequencing project were considered at the Santa Fe meeting. One involved randomly sequencing fragments from the genome, and trying to determine the order of the fragments on a *post hoc* basis (see below). This was rejected in favour of a scheme where the genome is first sorted by chromosome, then digested with a restriction enzyme like *Sfi* I that will produce a relatively small number of relatively large fragments. The first task would be to order these large fragments by chromosome, with a small, pilot sequencing effort started while the ordering task was being completed. Having ordered fragments not only breaks the sequencing down to a size more easily managed conceptually, but will also provide a useful tool for investigating genetic diseases, Bitensky believes.

Critics of the sequencing project do not deny that the information would be useful. Rather they worry that spending so much money on such a large project may be an inefficient use of funds. George Church of the University of California at San Francisco, a participant at the conference, echoed the widely held concern that such a large project could draw money away from other research projects. Church is working on new DNA sequencing techniques, and would like to see the project proceed. Others, including Fred Blattner of the University of Wisconsin, feel that a complete sequence from a smaller organism would yield a great deal of information about cellular processes at a small fraction of the cost. Blattner is currently working on sequencing the *Escherichia coli* genome, and others are working on the yeast and nematode genomes. Another option would be to sequence just part of one human chromosome, providing a window into human genetic control without devoting so many resources to such a major project.

Still unresolved is what to use as a starting material for the sequence project. One possibility is the DNA from a hydatiform mole. Such DNA can be produced in large quantities, but may be inappropriate as it has aberrant genetic properties. A second possibility would be to use material from a variety of different sources, perhaps a different individual for each chromosome. But critics worry that any choice will necessarily exclude information on the diversity of human genetic material.

Bitensky says that one possible method for selecting the DNA to use mentioned at the Santa Fe meeting was to hold a competition among the world's men and women. The person coming up with the largest contribution to the project would have his or her DNA sequenced.

A major player in the sequencing project could be the Howard Hughes Medical Institute, which is already supporting restriction mapping work by Raymond White at the University of Utah Medical School and Frank Ruddle at Yale University. The institute's president Donald Fredrickson confirms that there is interest in the DoE project, but wonders if the time is right to begin such an endeavour.

DeLisi, described as the driving force behind DoE's efforts on this project, says nobody gave serious thought to the idea of sequencing the entire genome as little as five years ago. Now, it is technically feasible; all that is required is the will and the money.

Joseph Palca

The numbers game

Washington

SEQUENCING the estimated 3,500 million base pairs in the human genome is a mammoth undertaking. But Fred Blattner of the University of Wisconsin came away from the Department of Energy's March meeting on the sequence project optimistic about the prospects for completing the task in a reasonable length of time.

The approach that encourages Blattner does not require ordered clones or restriction maps. Instead, sequencing starts on random pieces of DNA. Sorting out repeating sequences may not be possible using this approach, but all the unique sequences would be uniquely assembled.

To show this approach is possible, Blattner presents the following scenario: Work-stations would be set up around the country to carry out the project. Each station would consist of two technicians and four automated sequencing machines. The machines would have 40 lanes, with each lane capable of recording 750 residues. Running the work stations in two eight-hour shifts five days per week gives: 750 residues × 40 lanes × 4 machines × 2 shifts × 5 days = 1.2 million base pairs per week, or 60 million per year.

To make sure the entire genome is covered, Blattner figures it will be necessary to calculate 10 times the number of residues in it, or 35,000 million base pairs. Using this scenario, 580 work-stations could complete the job in a year. With each station costing $500,000, the project would cost $290 million.

Automated sequencers with such capabilities will soon be on the market, says Blattner. Although the information produced by this random sequencing approach would not be as rich as a complete ordered sequence, it would still be extremely useful. A later step could be to put all the unique segments in order.

Despite the organizational problem of coordinating the work of so many laboratories, Blattner believes it can be done.

US research costs

White House to back down?

Washington

A STUDY by the White House Science Council calling for substantially increased federal support for university-based research met a favourable reception both in the White House and on Capitol Hill last week, amid signs that the administration may be moving towards modifying highly unpopular proposed changes to indirect cost reimbursement.

Allan Bromley, vice-chairman of the science council study, met officials of the Office of Management and Budget (OMB) and said later that he was "optimistic" that new proposals on indirect costs would be forthcoming. But there was still no word from the administration on how exactly it proposed to defuse the row over OMB's proposal to fix administrative cost reimbursement for university research at 26 per cent of direct costs in the current year (the national average), with reductions in years to come. Revised proposals are expected within the next few weeks, in time for implementation at the beginning of July.

The science council study, chaired by David Packard, is unambiguous about the need for an increase in support for university research without taking money from research elsewhere (see below). It was given an enthusiastic welcome by members of the House of Representatives' Science Policy Task Force last week, and President Reagan was said to be writing to David Packard accepting its principal recommendations.

The study proposed adopting a uniform percentage for indirect cost reimbursement as one of several measures designed in aggregate to benefit the universities. Packard has previously spoken out publicly against the OMB decision earlier this year to adopt the recommendation on indirect cost reimbursement while ignoring recommendations to reduce amortization periods for facilities and equipment. Bromley also pointedly told the task force last week that OMB's proposal was "not at all our recommendation" and that it could lead to "substantial hardship" for universities.

John McTague, acting science adviser to the President, made clear his personal support for the panel's report last week, telling a press conference that he would expect an increase in federal support for university research of a few tens of per cent in the President's proposed budget for 1988. And McTague reminded reporters that President Reagan, presenting awards during National Science Week last week, had said "...we understand the need to increase our investment in basic research".

McTague himself will not, however, be in the administration to see the completed 1988 budget: he is to leave the White House shortly to become chief of research at the Ford Motor Company. **Tim Beardsley**

US space

NRC board urges no skimping

Washington

THE Space Science Board of the National Research Council (NRC) has entered the debate over the future of the US space programme, calling for a "balanced fleet of launch vehicles", and urging a clarification of the goals of the manned and unmanned elements of the national effort.

In a statement released yesterday, the space science board concludes that by failing to identify accurately the resources needed by the manned and unmanned space programme, both have suffered. Thomas Donahue, chairman of the board and principal author of the report, says the country must decide how committed it is to a pioneering space programme. Donahue argues that if sufficient funds are not provided to carry out such a programme with "style and precision", then it should be abandoned. The space programme being a highly visible effort, failures brought on by inadequate funding or poor management are all the more glaring and devastating.

The space science board has been critical in the past of the decision to abandon the procurement of expendable launch vehicles before the shuttle became a proven, reliable system. The decisions not to pursue new unmanned launch sytems and to commit the shuttle to carrying major scientific missions made space science unduly dependent on manned spaceflight. Had the shuttle lived up to its expectations, space science would not have suffered too badly, according to Donahue. But the Challenger accident underscores the fact that there has been no unmanned launch vehicle for major scientific missions for almost a decade, a "devastating" situation for space science.

There are seven scientific missions that were supposed to be launched in the next two years. Of these, only the Hubble Space Telescope and the Gamma-ray Observatory specifically require the lift capacity of the shuttle. The Galileo mission to Jupiter would have required the shuttle with its original trajectory, but may be able to achieve its objectives using a fuel-saving trajectory and a combination of the Titan 34D-7 rocket and Centaur G-prime upper stage, both soon to be available. While the shuttle provides a powerful launch vehicle and the possibility of in-orbit repairs, Donahue questions the wisdom of having a manned spacecraft carry a fully fuelled satellite booster rocket.

The space science board produced its statement following meetings last month and this. Board members felt that the Challenger accident made it imperative for NRC to make suggestions on the course of the space programme. According to Donahue, the board's statement went through the NRC report review process in "world record time". **Joseph Palca**

Strident report

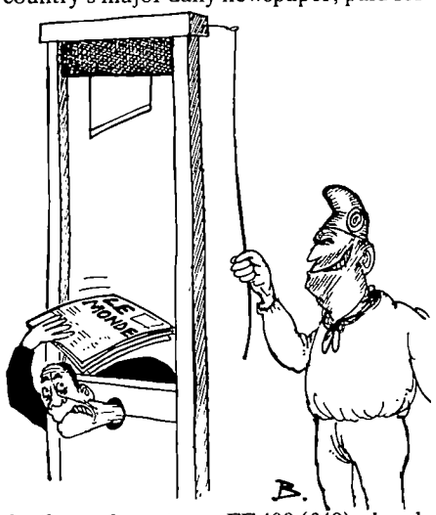
Washington

THE White House panel's report, released in draft form on 17 January but published formally last week, is strident in tone.

Universities now represent only $8,000 million of the $100,000 million in total national research and development, and the proportion is declining. After noting that "in any ranking of priorities for allocating R & D support... universities must come first", it declares that the federal government must make substantially greater investments in universities than it has in recent years. It also proposes a major new initiative to establish university interdisciplinary research centres.

Federal policies must, the panel says, recognize the cost of university research facilities. It proposes that the amortization period of buildings should be reduced from 50 to 20 years, while that for equipment should be reduced from 15 to 5 years. Recognizing widely felt alarm about the poor state of university buildings, it proposes a special facilities fund to be administered by the National Science Foundation, to disburse a total of $10,000 million over 10 years. All proposals to the fund would be peer-reviewed and made on a 50–50 matching basis with non-federal funds. Tax incentives for industrial sponsorship of university research are also proposed.

The study panel also makes the now-infamous recommendation that reimbursements for administrative costs should be fixed at a uniform percentage, rather than being allowed to vary from one institution to another. This is the only recommendation that has been acted upon so far. It also proposes that grant durations should be increased to three or even five years, and makes other recommendations aimed at reducing administrative burdens on universities and, especially, researchers. New "portable" scholarships for the most talented 1 per cent of undergraduates and national merit-based multi-year graduate fellowships are also urged.



Tim Beardsley

French science

Research directors form lobby

SOME 280 French directors of research — and the number is increasing daily — are making a public appeal to the government over what they consider to be swingeing cuts applied to science by the new Prime Minister, Jacques Chirac.

Last week, this new and spontaneous French pressure group published a half-page advertisement in *Le Monde*, the country's major daily newspaper, paid for

by themselves at over FF 400 (£40) a head, lambasting the government for applying over half the recent cuts in total government spending to one ministry, that for research. A further advertisement is planned in *Le Figaro*, an important right-wing paper read by many of Chirac's supporters, if further funds can be raised.

The petition's organizers, Paris astrophysicists Jean Audouze and Pierre Encrenaz, said last week that the response of the country's leading scientists to their hastily-organized appeal had been "very encouraging". Some 50–60 per cent of those polled had responded within a week with sums from FF 100 to FF 1,000 to support the campaign.

"It really means that the directors have been shocked by this government's actions", said Encrenaz. In terms of cuts in "*autorizations de programme*", a strong indicator for future budgets as it represents sums which may be planned to be spent next year and beyond rather than actual cuts in current spending, 54 per cent of the government's recent savings fell on research and development, even though that represents only 2.3 per cent of the country's gross national product. This was enough to stir researchers into action. But worse may be to come.

Chirac has now told ministers that he will quadruple the present cuts, when the 1987 budget is announced in September. It is not clear whether research will suffer further, but Chirac did say in a letter to his ministers last week that the "overriding necessity" to make major savings in government spending meant that "it will be impossible to satisfy the many sectional interests, however legitimate their arguments, that will certainly protest".

It is difficult to see this statement as anything but a mandate to the already powerful ministry of finance and budget to ignore all pleas, including those made in the form of advertisements in *Le Monde*. However, French scientists continue to hope for a softening of the government's line, even though Chirac's frosty embrace will include, he says, a cut of 1.5 per cent in all civil service positions (except education). This will strike a blow at scientists just like those who, unaware of the new policy, signed the new petition: researchers from the "*grandes organismes*" research councils, the Centre National de la Recherche Scientifique (CNRS), the Institut National de la Santé et de la Recherche Médicale (INSERM), and the Institut National de la Recherche Agronomique (INRA) who recently became civil servants after a great political battle.

Some scientists, indeed, see this winning of civil servant status as the prime cause of their present trouble, for some of the principal and hardest opponents of the deal were the senior officials of the ministry of finance. Only an intervention by the now virtually powerless President François Mitterrand secured researchers their cherished "security". Now the enlarged finance ministry is wreaking its revenge, the story goes.

Whether or not this particular story is merely paranoia among the scientists, there is certainly considerable evidence that research is now being singled out for harsh treatment in France, after a few years of exactly the reverse. Only university researchers outside the research council system seem to have been relatively protected in posts (as teachers) and budget; but this research sector, by common consent, represents the weakest part of French science. Even Chirac's most extreme scientific advisers before his election last March argued that the universities had to be reformed and strengthened before the research council system was attacked (their criticism was that the latter was too centralist); but even their caveats now seem to be being bypassed.

"There seems to have been very little thought behind these new policies — they are very hasty policies", says Audouze. "We hope our campaign will convince ministers that these decisions are jeopardizing French research." **Robert Walgate**

SDI

Abounding hypotheses floated

Washington

To students at the California Institute of Technology, satire has seemed the best way to express opposition to the Strategic Defense Initiative (SDI). Last month they held a competition for the most "destabilizing, unworkable or incredibly expensive" proposal to achieve SDI's goals.

The winner is planetary science graduate Greg Ojakangas. His proposal, estimated to cost $457 million, involves developing a genetically engineered strain of pygmy hippopotamus. Hippos would be fed on a diet enriched with suitable radioactive materials and kept in cages with cathodes embedded in the walls. A continuous flow of electrons neutralizes the alpha particles emitted by the hippos' radioactive diet, forming helium and making the hippos lighter than air.

In the event of missile attack, an "optically thick cascade of buoyant hippos" rises to form a shield. Upon reaching the "hippopause", the height at which the mean hippo density (MHD) equals the atmospheric density, the hippos would fan out, forming a protective ROOPH (Readily Operative Overhead Protection by Hippos). In his proposal, Ojakangas reckons the hippos will remain buoyant for two days. After that, they will float gently to earth where they can be collected.

Second prize went to physics graduate student David Palmer, whose proposal calls for splitting the Earth into hemispheres at the Equator. A large bearing allows the two hemispheres to be rotated. When radar detects a flight of missiles heading over the pole, large motors rotate the two hemispheres 180 degrees in opposite directions.

After this manoeuvre, the eastern and western hemispheres have changed places, and the missiles will land on the country from which they were originally launched.

Other less serious scenarios suggested putting everyone in the United States aboard dirigibles (since "no dirigible has been shot down in 20 years"); erecting a cardboard shield as the final layer of a multilayer defence (cardboard is lighter than plexiglass); and using a series of lenses to focus the ability of the Bermuda Triangle to make things disappear.

The Caltech competition was inspired by a similar effort at Cornell University last fall. The winning entry at Cornell proposed using a particle beam of tachyons, the particles arising in certain superstring theories which travel backwards in time. This would provide a pre-launch destruction capability even after an attack had been initiated. **Joseph Palca**

Supercomputers

India resents US strings

New Delhi

THE United States has imposed certain conditions on the sale of supercomputers to India. The offer was made by President Reagan ten months ago at the height of Indo-US cooperation, but the Pentagon subsequently raised objections.

Acting US Science Advisor Dr John P. McTague, who was recently in India, says the offer still stands but India must comply with a safeguards regime that has just been finalized by the US Departments of Commerce, State and Defense. According to McTague, the United States has not sold supercomputers outside the Western bloc, hence the safeguards. The conditions have been communicated to New Delhi and the ball is now in India's court.

The United States has simplified the procedures for the export of high-technology items since the two countries signed a memorandum of understanding in May 1985. Under the memorandum, the United States agreed to speedy clearance of high-technology equipment for civil and defence needs subject to assurances about its end use and a guarantee by the Indian government that such equipment would not be used for nuclear programmes or allowed to fall into the hands of the Soviets.

But the conditions for the sale of supercomputers go further. The United States is seeking assurance that a computer will be used for the specific purpose for which it is bought and not diverted for military or nuclear research. Programs to be run on the computer must have US approval, as must personnel with access to it. As well as the right of periodic inspection, the company supplying the supercomputer will have control over maintenance and repair and Indians will not be allowed to remove any part of the hardware or software.

Indian officials are studying the implications of the safeguard conditions and it is likely that they will be found unacceptable. "It would be demeaning to purchase a supercomputer under these conditions", one official said: "Inspection means that an American will be sitting at the computer centre checking every program we run. We should not accept this."

Indians have been interested in acquiring supercomputers for medium-range weather forecasting and monsoon research and possibly for computer-aided design of a light combat aircraft.

India has already entered into a $26 million deal with Control Data Corporation (CDC) under which the state-owned Electronics Corporation of India will manufacture 600 units of Cyber-810 and Cyber-830 mainframe computers during the next nine years. India awarded the contract to CDC against stiff competition from the French computer company Bull in the hope that CDC would also sell Cyber-205 supercomputers. Even if India accepts the safeguards, it is believed in India that the United States would be reluctant to supply the supercomputers because of India's opposition to the US bombing of Libya.

If the United States does refuse to sell supercomputers, India will turn to Japan or the Soviet Union. The Department of Electronics has already purchased four S-1000 supercomputers from NEC of Japan for its nationwide information network. And the Soviet Union has agreed to sell, without strings, its Elbrus parallel processing machine as soon as it leaves the factory early in 1987. **K.S. Jayaraman**

Japan Prize

Dutch winner attacks US policy

Tokyo

AT a memorial lecture on artificial organs by one of this year's winners of the Japan Prize, Japan's answer to the Nobel Prize, would one expect to see pictures of aircraft carriers and Trident submarines along with cartoons of star wars and the effects of nuclear winter? Dr Willem Johan Kolff, 1986 Japan Prize laureate for medical technology, apparently felt his lecture in Kyoto and Tokyo last month was a fitting occasion to lambast US defence policy and appeal for support for the anti-nuclear movement. But how does one turn a talk from kidney machines to killer satellites?

Kolff's speech began normally enough, with a historical review of the kidney machine he developed from 20 metres of artificial sausage skin in the Netherlands during the Second World War. With more than 66,000 Japanese now dependent on dialysis and the number doubling about every five years, there are many in Japan grateful for Kolff's invention and few would dispute his eligibility for a major international award.

From kidney machines, Kolff quickly switched to graver topics and a Rubens' picture was compared to the "life and death committees" that sprang up in the United States in the 1960s, when there were too few dialysis machines to go round and those to be saved had to be selected on the basis of age, occupation, number of children and so on. Then came a warning that the life and death committee is raising its ugly head again in the United States under the guise of "cost containment".

And why is cost containment necessary? In sailed slides of aircraft carriers and Trident submarines, along with the message that the United States is spending too much on defence and too little on treating its fellow citizens. In contrast, Kolff portrayed Japan as a haven where low defence spending allows high industrial productivity and where all who need kidney machines get them. But with kidney transplants virtually unobtainable, Japan is hardly a paradise for patients with renal disease (see *Nature* **313**, 338; 1985). And what of the defence the United States has provided for Japan for 40 years?

Kolff then turned to the membrane oxygenators developed from the artificial kidney after it was noticed that blue blood passing through the dialyser turned red. Who needs oxygenators? The 50,000 victims of nuclear war with scorched lungs. But, asserted Kolff, nobody would be interested in artificial lungs because they would all die anyway from the effects of nuclear winter. The stage now set, Kolff leapt back and forth from artificial hearts to nuclear fire power and star wars to artificial eyes and ears. In his abstract he threw in the greenhouse effect for good measure, but his listeners were spared the assertion that "the polar ice caps will melt" and "the coastal plains of Japan will be flooded". Kolff closed by urging the audience to join anti-nuclear movements such as International Physicians for the Prevention of Nuclear War, the controversial winners of last year's Nobel Peace Prize, and ended by asking "what good will an aritificial heart do us if we are all vaporized?".

The Japan Prize is awarded by the Science and Technology Foundation of Japan, a non-profit organization under the direction of the Japanese Prime Minister's office, and is intended to recognize significant and original achievements in science and technology that contribute to peace and prosperity for mankind. The foundation's dedication to peace provided Kolff with the platform for his anti-nuclear appeal, and as Japan is edging towards a decision to participate in the Strategic Defense Initiative under the enthusiastic backing of Prime Minister Yasuhiro Nakasone, Kolff's speech was timely. But will this lecture help elevate the Japan Prize to a comparable level of recognition with the Nobel Prize, one of the unstated aims of its founders? **David Swinbanks**

Correction

IN the article "Making radiation understood" (*Nature* **321**, 195; 1986), the relative value of curies and becquerels is incorrectly given: it should read 1 Ci = 3.7×10^{10} Bq. □

Japan's forests

Welshman begs respect for trees

Tokyo

C.W. NICOL must be Japan's most famous Welshman — indeed perhaps the only Welshman the average Japanese has ever heard of. A string of popular books on the natural world published in Japanese plus, at 45, an autobiography which includes words like "Pwllheli" which no Japanese (or Englishman) will ever be able to pronounce have made his name. Most recently, he has been in the public eye with an impassioned plea to the Forestry Agency to spare the forests that surround his home deep in the mountains of central Japan. The white paper (policy document) recently released from the Forestry Agency, which is assiduously cutting down the forests around Nicol's home, reveals that even without an infuriated Welshman to deal with, the Forest Agency, Japan's forests and the forestry industry are in dire straits.

Trees take a long time to grow and it is not easy to keep forestry policy in tune with a rapidly changing world. Some sympathy must thus go to the Forestry Agency. But there are many who have been telling the agency that its policies are mistaken for at least the past fifteen years.

The Forestry Agency found itself at the end of the Second World War with many mountains denuded of timber. Plantations, largely of *sugi*, the Japanese cedar, were begun. Then Japan entered its high-growth era and it seemed that the demand for timber would never stop growing. Clearance of natural forests began on a massive scale and huge numbers of cedar were planted.

Long before any of this timber was ready for the market, very much cheaper timber began to pour in from abroad. At the same time, new materials began to be used to build houses. Then Japan's growth began to slow; the Forestry Agency and private landowners found themselves with huge tracts of forest on their hands that may never be sold at a profit. Much the greater part of that forest is still young enough to need regular thinning and care to remain healthy. But instead, with no profit in sight, huge areas have been left to rot. The white paper admits that 40 per cent of man-made forests that need thinning are not being attended to.

Natural forest left along water courses in the national park near Tokyo.

Part of the reason why home-grown timber is expensive is that it is difficult to take out trees from Japan's steep mountain sides. Roads capable of carrying heavy timber lorries must be built and aerial ropeways set up. That adequate, cheap technology is not available is something critics have been saying for years. Nor, critics say, was adequate thought given to the suitability of cedar in the rush to plant forests.

Plantations in poor locations have been hit by mice, frost and insects, while too much reliance may have been placed on cedar. There is still plenty of demand for broad-leaved trees. The white paper argues for diversification, which critics have been demanding for years. Meanwhile, profits are being made by cutting existing natural broad-leaved forests, including trees hundreds of years old. That is what angers Nicol.

Letters of protest to the government from individuals do not normally evoke much response, but whether out of respect for a foreign "guest" or from sensitivity to foreign criticism, or because Nicol's letter was also published in the *Yomiuri* newspaper, the Forestry Agency director-general personally promised (according to *Yomiuri*) that the beeches and birches on the mountains around Nicol's home would not be cut. But this, it seems, was too good to be true. Forestry officials who visited Nicol's home revealed plans for cutting the forest on a scale beyond his worst imaginings. The only thing they appeared to take note of, he says, was not to litter the forest with discarded chain-saw blades.

But Nicol has discovered he is not alone in his love of the forest. Hundreds of letters of support and telephone calls have come to his home. The burgeoning enthusiasm for forests is also clearly recognized in the white paper, as it was in an advisory report to the agency published last August. Many Japanese have of course been proclaiming for years that they have a unique sensitivity to nature, but what they mean is cherry blossoms in parks, pot plants outside their homes and cut flowers impaled on spikes in vases and twisted into miniature imitations of nature. Love of nature in the raw, complete with the mosquitoes, snakes and bears that inhabit Japanese forests, is a very new phenomenon. Many new organizations concerned to protect forests and town greenery have sprung up recently, reflecting a change in Japan's society away from pure economic growth to concern for the quality of life. Gradually they are beginning to join forces but none is yet big enough to exert a powerful influence. The Forestry Agency has responded by decreasing the area of forest that can be cut at one time and by increasing emphasis on the selective cutting of forests so that natural regeneration can follow.

Catering for this new interest in forests would not be so difficult were it not that the Forestry Agency is expected both to be financially self-supporting and also to ensure the stability of mountain villages whose only source of income is from forestry. It is not surprising then that the white paper proposes that "the people bear some of the financial burden to improve the nation's woodland". A tax on water resources has been suggested as a way of financing protection forests planted to prevent flash floods. The tax is opposed by industry.

For all the letters he has received, Nicol is not going to try and join in public protest movements. He intends instead to charter a plane and photograph the forests near his home from the air and then from the ground and use his pen and the pictures to publicize the forest's plight. For changes in forest policy there is still time, for Japan is lucky in that large areas of natural forest do still remain — any European country with such forests would consider itself blessed indeed. Whether public awareness of the immense value of the forests will grow fast enough to prevent them disappearing remains the real question. And on top of that there may be some other problems — the white paper is the first to admit that acid rain may be causing forest damage in Japan.

Alun Anderson

Widespread forest

JAPAN'S total land area is 378,000 km². Of this, 250,000 km² is forest: by no coincidence this is a figure very close to the area that is mountainous, 268,000 km², and cannot be used for agriculture or habitation. Almost a third of the forest is owned by the state and a little over a third is man-made, nearly half of it Japanese cedar and a quarter *hinoki*, Japanese cypress. Various kinds of national park and nature park account for a remarkable 54,000 km² of land, an extremely high percentage. But only a small fraction of the park area is completely protected from interference; in other regions, permission can be given for selective cutting, or clear cutting, of forests. □

Safety of French nuclear plant

SIR—The safety record of COGEMA's reprocessing plant UP-2 at La Hague may be better than that of British Nuclear Fuel Limited's Sellafield plant in Britain (*Nature* **320**, 204; 1986), but is it really that much better?

In 1984, collective radiation exposure was the highest in the history of the La Hague plant (728.1 men-rem), surpassing the figure of 1981, when a fire in a waste silo caused significant contamination (and one of the exposed workers caught a dose of 5.7 rem).

The radiological situation on and around the site is anything but stable. The average tritium content in the water of a stream in the area increased 13-fold between May and December 1984, and average β-activity in another stream by a factor of 60 in the last four months of 1984. The official explanations for the presence of unusual quantities of tritium (seasonal rainfalls and air humidity) and β-activity (mainly cobalt-60 washed off the spent fuel cask storage site) are meagre.

There have been several other leaks and incidents in the past few years. The most recent was what COGEMA called a mini-leak in November 1985, when 400 m^3 of "slightly radioactive liquid" was spilled into the environment.

COGEMA's flexible approach to the "nominal capacity" of the plant is significant. In 1976, the official *Revue Générale Nucléaire* says of the processing of fuel from light-water reactors (LWR) that France had completed the UP-2 plant at La Hague by an oxide headend called HAO (Haute Activité Oxydes) which would reach its nominal capacity of 800 tonnes of oxide a year around 1979–80. In 1979, the actual throughput of the plant was 79.4 tonnes of oxide fuel and, in 1980, 104.9 tonnes were reprocessed, 10 per cent and 13 per cent respectively of the "nominal capacity".

In 1978, the optimistic goal of 800 tonnes a year was abandoned and the "new" nominal capacity was fixed at only 400 tonnes a year. In 1982, the Castaing commission, which was asked by the minister of industry to analyse the situation at La Hague, stated that it was more likely that HAO's capacity would be limited to 250 tonnes a year, and COGEMA said in its 1983 annual report that "UP-2 will be capable of reprocessing 250 tonnes a year of LWR fuel, once the reprocessing of other fuel types has been discontinued".

Since 1984 COGEMA has returned to the figure of 400 tonnes a year, as if there had never been anything else. COGEMA proudly announced that 418 tonnes had been reprocessed between November 1984 and November 1985, a performance "beyond its normal capacity". In other words, it took COGEMA ten years to reach 52 per cent of its initial design capacity.

Most of the LWR fuel reprocessed at La Hague was not French but foreign. By June 1982 only 11.5 tonnes (2.6 per cent of the total) were irradiated in a French reactor (Fessenheim). Two years later (June 1984) 82.3 tonnes of EDF (Electricité de France) fuel had been reprocessed and, by the end of 1985, the total quantity had reached 290 tonnes, 22 per cent of the 1,338 tonnes of oxide fuel reprocessed at HAO by the end of 1985, according to Maurice Delange, head of COGEMA's reprocessing branch.

The foreign fuel came from West Germany, Japan, Belgium, Switzerland, the Netherlands and Sweden. COGEMA argues that there was not enough French fuel available, although EDF has a contract with COGEMA for the reprocessing of 5,344 tonnes of LWR fuel; its continuing hesitation to commit itself fully to the reprocessing strategy of the Commission à l'Energie Atomique (CEA) made COGEMA look for additional contracts with foreign clients. According to M. Delange, COGEMA's offer of an additional 1,000 tonnes of capacity for 1986–90 on the international market led to some possible new contracts with the same clients.

The time has passed when CFDT union workers were "not slow to report accidents to their union", as Walgate puts it. Until 1981, CFDT used to be by far the strongest union in La Hague. But after the socialists came to power, it lost many members and half their votes at the elections of union representatives, to the profit of the conservative pro-nuclear FO (*Force Ouvrière*). The union's critical point of view has been turned against it. To be against foreign reprocessing contracts and in favour of the development of alternative waste management strategies has been regarded as "destroying the working tool", as a CFDT worker explained. The "chantage à l'emploi", literally employment blackmailing (threat of redundancy), has been used extensively by the reprocessing lobby, including competing unions. It works well in an area of high unemployment (8,000 people are registered unemployed in Cherbourg), where the only two important employers are the French Navy and COGEMA.

In France, independent information on the nuclear industry and especially on reprocessing is less easily available than ever. The nuclear lobby can give a more "open" appearance and its efforts to "inform" the public, over the past ten years, have indeed been enormous. Workers keep their mouths shut; nobody wants to lose his job.

One of their problems is the lack of strong national support; the national CFDT nuclear branch was "decapitated" in 1981, when highly qualified leaders took over the management of the Agence Française pour la Maîtrise d'Energie, a state energy management agency. For the CFDT section at La Hague this was a second blow. They had had to find new leaders when the organizers of the 1976 strike (to protest against existing safety conditions) left La Hague when COGEMA (100 per cent owned by CEA) took over the management of the plant; they feared repression from a new management which, unlike CEA, was not exempt from private law.

Today, union workers do not want to be telephoned for fear of telephones being tapped, letters stay unanswered and they prefer not to be mentioned in public at all. The few who remained active are gradually giving up; "If they want to eat plutonium, I can't help it", as one stated sarcastically. Another could not find anyone to help write, print and distribute an internal flyer. And nobody wants me to talk about all this...

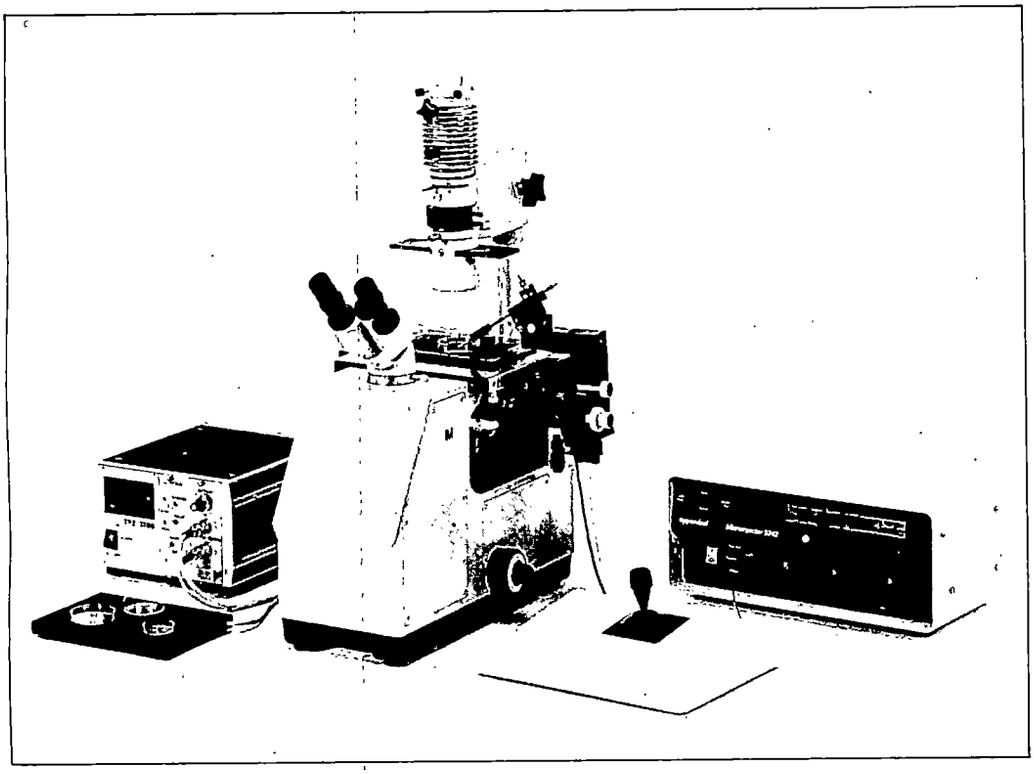
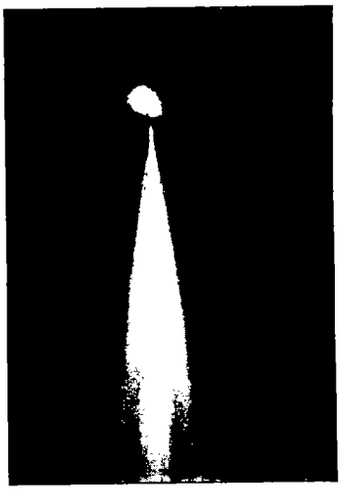
Pre-embryos

SIR—Anne McLaren (*Nature* **320**, 570; 1986) states that the human product of conception before the 14th day of intrauterine life should not be called an "embryo" because the cells are destined to develop into both the fetus and the placenta. By implication, experimenting with or throwing away a conceptus less than 14 days old does not constitute ill-treatment of a human embryo. It is maintained that the use of such terms as "pre-embryo" for these earliest stages of development is not euphemistic or "cosmetic", but scientifically valid terminology.



Later in intrauterine life, when obstetricians and perinatologists strive to save a life at risk, the togetherness of the baby and its placenta is emphasized by the currently fashionable term "feto-placenta unit". The placenta is then an essential organ that is discarded only when the baby can manage without it. It happens that before and immediately after implantation the cells that will form the placenta outnumber those that will form the baby, and one cannot look at an individual cell and recognize the organs that will be derived from its progeny.



Words like "pre-embryo" may have scientific precision, but they should not be used to foster the delusion that those few cells are anything less than a young feto-placental unit.

For your success in biology, molecular biology and medicine: the Inverted Microscopes from Zeiss.

The Inverted Microscopes IM, IM 35 and ICM 405 from Zeiss offer important advantages:

- large free working space
- extraordinary stability
- the superior quality of Zeiss optics for all optical contrast-enhancement methods
- 35 mm and large-format photomicrography and TV.

Zeiss sets the standards in optics, precision engineering, electronics.

PEPSYN REAGENTS FOR FMOC POLYAMIDE PEPTIDE SYNTHESIS. THE SIMPLER, MILDER ROUTE TO PURER PEPTIDES.

Safe, simple chemistry ideal for the molecular biologist. Efficiency and versatility to impress the experienced peptide chemist.

- Exceptionally mild reaction conditions, avoiding damaging repetitive acid treatments, lead to higher yields and higher product purity.
- Avoids the hazardous and frequently destructive final liquid hydrogen fluoride treatment.
- Unprecidented coupling efficiency results from the combined use of polar polyamide resins (traditionally polystyrene) and a freely permeating polar solvent providing complete compatibility between reaction medium and the growing peptide chain.

'PEPSYN REAGENTS – Avoid The Use Of Hazardous Hydrogen Fluoride

Prepared to the highest specification to ensure maximum performance and convenience. Supplied with batch specific data sheets as assurance of purity. Available as –

- Polyamide resins and Fmoc amino acids for any peptide synthesis system.
- Versatile linkage agents enabling cleavage under a variety of conditions without the use of hazardous hydrogen fluoride.
- NEW – highly reactive Fmoc amino acid esters as ready-to-use reagents, requiring no pre-activation for rapid, simpler synthesis.

PEPSYNTHESISER INSTRUMENTATION

- A range of manual and automated instruments employing rapid, efficient continuous flow peptide synthesis.
- Featuring a continuous UV monitoring facility for immediate indication of reaction progress.

CRB·THE LEADER IN FMOC POLYAMIDE PEPTIDE SYNTHESIS

Disappointment over double quasar

There now seems a high chance that what seemed, two weeks ago, to be a particularly interesting double-quasar image may simply be a record of two independent objects.

Two articles elsewhere in this issue (pp. 419 and 420) provide what appear to be plausible explanations of the remarkable report by E.L. Turner *et al.* (*Nature* **321**, 142; 1986) of the apparent identity of two quasar images separated from each other on the sky by more than two minutes of arc (2.6 minutes, to be precise). The significance of this report was quickly appreciated not merely by its authors but by many others. Although there has accumulated since the first observation in 1979 a handful of cases in which the image of a single quasar is split into two or even three by the interposition of a massive galaxy along the line of sight to the distant object, the angular separations previously reported have been very much smaller than that of the pair of images measured by Turner *et al.*, a few seconds of arc rather than a few minutes.

This week's authors, both Princeton colleagues of Turner, explore the possibility that the very large separation may be caused by the interposition either of a very massive black hole or, alternatively, of one of the galactic structures called a cosmic string. Readers will note that their calculations, interesting in their own right, are at once tentative and suffused with a sense of what good luck it must be that observations should have led so simply to such striking inferences. Now, unfortunately, it appears that these endeavours may have been misplaced.

In a field where it is never easy to be sure that quasar images have been accurately identified with each other, it is too soon for certainty. But stimulated by the report of Turner *et al.*, others have looked at the components of the supposed double quasar in spectral regions other than that on which the original identification was based, and they find enough discrepancies to suggest that the apparent identity of the two objects is in doubt.

Before jumping to the conclusion that Turner *et al.* are in some way to blame for having published their data too quickly, or that they have made an elementary mistake that might have been avoided by taking greater care, readers should consider carefully what is involved in the identification of a gravitationally split quasar image. That an intervening massive object can split one image into two or more follows from the way in which, in relativity, the gravitational field of a massive object distorts the usual straight-line paths open to light. The magnitude of the effect and the apparent separation of the two images depend on the mass of the intervening object. The known cases of split quasar images require intervening masses comparable with those of galaxies. Turner's separated images would require more massive objects, whence the speculation about black holes and cosmic strings.

To establish that a close pair of quasar images has indeed been generated by the interposition of a gravitational lens is, in reality, quite difficult. The first test is that the two images should have the same measured red-shift (which is not affected by the bending of the gravitational lens). One difficulty is that the red-shifts are usually so large that it is hard to tell which atomic transitions are ultimately responsible for the spectral lines observed in the emission from the quasar. Another is that the lines, even if accurately identified, may be so broad that the accuracy of inferences about their displacement is bound to be limited. Turner's two images were reported to have a red-shift defined by $z = 1.012$ on the strength of an emission line from magnesium which, while normally in the ultraviolet, has been displaced by the recession of its source to the middle of the visible light spectrum.

Those who search for double-quasar images also pay close attention to the general characteristics of the spectra of the two candidate images, but there are some important complications. Thus the spectra of quasars can vary rapidly on quite short timescales. Most of the variations show up in the continuum flux, but there may also be substantial variations in the strength of emission lines in the spectra. Because one of the consequences of the effect of a gravitational lens is that different images of the same quasar may reach the observer by paths which differ considerably in the traverse-time of light, there is room for some latitude in the comparison of the spectra of two images. In Turner's case, the two light paths may have differed by as much as 1,000 light years, ample to account for the spectral differences he and his associates reported in the two quasar images.

The new development is a set of measurements by P.A. Shaver and S. Christiani of the European Southern Observatory in a part of the spectrum extending towards the infrared from the longer wavelength limit of the range covered by Turner *et al.* An article describing these measurements will appear in *Nature* two weeks from now. In this previously unexplored region of the spectrum of the Turner quasar, there appear to be pronounced differences in the intensity of certain hydrogen lines. Readers will have to judge for themselves, when this evidence appears, whether the quasar images are indeed produced by a gravitational lens from the same single distant object. Advance notice of these measurements is being provided now, with the consent of its authors, merely because of the excitement generated by the original measurements.

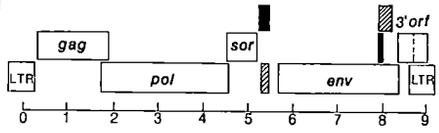
If Turner *et al.* were unlucky in their choice of a spectral range in which to carry out measurements of the components of the double quasar, there will be a widespread sense of disappointment that a potentially fascinating phenomenon has so quickly vanished. But that does not imply that the two quasar images concerned are without interest. The supposition that they might be gravitationally split images of the same object seems first to have been raised by Paczynski (*Nature* **319**, 567; 1986) on the basis of measurements originally due to C.H. Hazard.

If the two images are now gravitational artefacts, then they are most probably distinct quasars (with nearly identical red-shift) which are also members of a distinct galactic cluster. But the measured difference between the velocities of the two images is less than 200km s^{-1}, which is less than the spread of velocities found in typical galactic clusters, and which may therefore suggest some special relationship between the two quasars. That would be an interesting if less spectacular development in its own right, one that would no doubt bring comfort to those who, like H. Arp, have long argued for some systematic relationship between the positions of quasars in the sky.

Meanwhile, the urgent need is further to test the relationship between the two images of Turner's quasar. Detailed study of the relative intensity of the iron and magnesium lines in the two images will no doubt persuade most people one way or the other. When all this has been done, there will remain one logical ambiguity. If the travel times of widely split quasars may be of the order of 1,000 years, and very much greater than the timescale of substantial variability of individual quasars, will it ever be possible to prove (or disprove) that such widely split images are caused by gravitational lenses, however massive or peculiar?

AIDS virus

More and better *trans*-activation



from A. Burny

THE virus that causes acquired immune deficiency syndrome (AIDS) is a sophisticated weapon aimed at the human T4 lymphocyte, a key cell of the immune response. This highly cytopathic virus, called HTLV-III, LAV or, most recently, HIV (see ref. 1), is endowed with the means to stimulate its own replication in an infected cell. One gene involved in this autostimulation is *tat III* (refs 2–4), a bipartite gene encoding a protein that interacts with receptor sequences near the upstream (5′) end of the viral messenger (m)RNA. On page 412 of this issue[5], Bill Haseltine and his colleagues describe the discovery of a new bipartite gene, *art*, of HIV that is also involved in autostimulation. The product of the gene activates the expression of the *gag* and *env* genes of HIV (encoding, respectively, the capsid and envelope proteins) and thereby regulates virus replication.

The discovery of *art* (for anti-repressor translation) is an intellectual and technical achievement. Haseltine's group recently investigated[4] the mechanism of *trans*-activation by the *tat III* gene product and observed that elevation of long terminal repeat-directed gene expression in cells expressing the tat III protein reflects an increase in protein synthesis without a comparable rise in the steady-state level of the respective mRNAs. Deletion analysis of the HIV long terminal repeat demonstrated that the sequence necessary for *trans*-activation (the TAR sequence) is located between nucleotides −17 and +80, that is, 3′ (downstream) from the mRNA initiation site (the cap site). Taken together, the lack of effect of *tat III* on viral mRNA concentration and the presence at the 5′ side of viral mRNAs of nucleotide sequences responsive to tat III protein regulation prompted Haseltine and co-workers to establish experimentally that *trans*-activation by *tat III* is mediated via a post-translational mechanism[6].

Continuing their deletion analysis of the HIV proviral genome, Haseltine and colleagues have now identified a seventh viral gene. Their approach consists of the transfection of matched cell lines with intact or deleted proviral DNA constructs and determination of the amounts of virus and viral antigens produced. It became obvious that a new gene was involved when deletions located in the 3′ region of the first exon of the *tat III* gene, but not extending into the *env* gene, prevented virus production even in the presence of a functional tat III product supplied in *trans*. A second set of mutations (insertions and deletions) located further down the proviral DNA to the 3′ side of the second exon of *tat III* and overlapping *env* yielded proviruses that failed to express viral gag and env proteins. Finally, new plasmids designed to express the putative new open reading frame but not *env* were demonstrated to allow *env* production by proviruses containing mutations in the new open reading frame. As the phenotypes induced by both sets of mutations performed are similar, Haseltine and colleagues conclude that they have identified a new gene.

The protein product of the gene, 116 amino acids long, has no effect on viral

Map of the genes encoding the AIDS virus. Black boxes, the two coding exons of the *tat* gene; hatched boxes, those of the *art* gene; *pol, sor,* genes for other viral proteins; *orf,* open reading frame. Scale, kilobases.

mRNA concentrations but is required for expression of the HIV gag and env proteins. The inescapable conclusion of these experiments is that the *art* gene product specifically allows translation of HIV *gag* and *env* mRNAs, thus unlocking the block imposed on virus expression. The discovery of *trans*-activation of retroviral long terminal repeats or mRNAs will be important for understanding virus persistence and latency, cell killing and cell transformation.

The *tat* and *art* gene products are clearly potent regulators of viral gene expression, and are most probably involved in the successive cycles of latency and expression that characterize the life-span of the AIDS virus. Fine tuning of *tat* and *art* genes must allow silent accumulation of *gag* and *env* mRNAs. Expression of tat and art proteins switches on a burst of expression of *gag* and *env* components that initiates virus production. Such a mechanistic design predicts that *tat* and *art* mRNAs must be translatable in conditions that preclude translation of *gag* and *env* mRNAs. Detailed analysis of the 5′ end of the corresponding mRNAs, and identification of the tat and art protein interactions with their target nucleic acids, are urgent tasks.

As Haseltine and co-workers point out, the new data are highly suggestive of the existence of an early–late switch in HIV infections and in infections mediated by similar agents such as visna virus and caprine arthritis encephalitis virus. The two latter systems are characterized by persistence and latency[7–9], and *trans*-activation has been demonstrated in visna virus-infected cells[9].

Retroviruses, DNA viruses and other systems involving production of a lethal product obey the biological paradigm that production of the product is best achieved if delayed to late stages of the life-span of the cell. Regulation of translation of accumulated mRNAs is an elegant manner of complying with this requirement. □

Gravitational waves

Observatories of the future

from M.G. Edmunds

THE direct observation of gravitational waves, the ripples in space-time generated by the motions of masses, is one of the last-known windows that remains to be opened on the Universe. Although detections have been promised within five years for at least the past fifteen years, it does at last seem that the hopes will develop into real data within six years from now, as concluded at a recent meeting* by members of groups working on the problem. This optimism springs from a consensus on the theoretical estimates of the expected strength of cosmic sources of gravitational radiation, as well as growing confidence that the technological advances required for interferometric detectors of sufficient sensitivity can be made.

An interferometric gravitational-wave detector (see Fig. 1) basically consists of three suspended masses arranged at the corners of an L. The two arms of a Michelson interferometer formed with mirrors attached to the masses measure the rel-

*The Interferometric Gravitational Wave Detectors meeting was held at Cardiff University on 17 February 1986.

ative lengths of the two sides of the L. When a gravitational wave passes the detector it moves the masses on one arm apart and the masses on the other arm closer together, resulting in a shift of the interferometer fringe pattern. A parameter h is used to characterize the magnitude of the wave's interaction, defined as the induced difference in length of the two arms divided by the length of a single arm. Just to begin to see sources, values of h as small as 10^{-20} will probably need to be

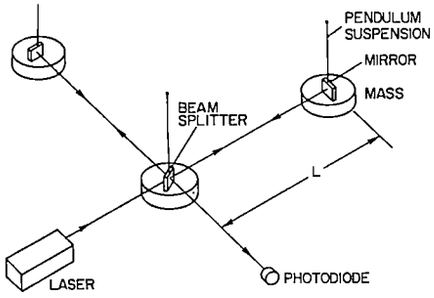

Fig. 1 Basic principle of the laser interferometer.

detected. Really useful astrophysical information will come when h can be measured at the 10^{-22} level. Because even the former of these limits implies measuring length changes of 10^{-2} fermi (about 1/100 the radius of a nucleus) in an interferometer with an arm length of 1 km, it is clear that the technological problems are considerable. Interferometric detectors work at wave frequencies within about a decade of 1,000 Hz, and are limited to optical or near-infrared light by consideration of the optic surface, the noise source and the photon detector.

As summarized at the meeting by Kip Thorne (California Institute of Technology; Caltech) the sources most likely to be seen as single events involve collapse of the core of a single star in a supernova explosion or coalescence of a close binary system of compact stars. Generation of gravitational waves is a strong function of the deviations from spherical and axial symmetry occuring during the collapse to form a neutron star or black hole, and the uncertain magnitude of these deviations leads to uncertainty in the predicted wave fluxes. A sensitivity of h of the order of 10^{-22} may allow collapsing black holes of 100 solar masses to be seen throughout the entire Universe accessible within the light-travel time since the Big Bang. Non-axisymmetrical neutron-star collapses may be seen out as far as galaxies in the Virgo cluster, yielding an expected several events per year. An advantage of interferometric detectors over resonating solid-bar detectors is the spectral information that can be deciphered. Recent numerical collapse calculations suggest very characteristic waveforms for both black-hole and neutron-star collapse; indeed detection of the wave 'signature' of a black-hole collapse may be our only way of unambiguously demonstrating the existence of black holes. If the supernova generating the waves is also detected visibly, the relative arrival times of the light and gravitational waves are a strong test of gravity theories. General relativity predicts the same speed of propagation, while some rivals predict differences of the order of one part in 10^6; the observations should place limits of the order of one part in 10^{10}.

Two neutron stars spiralling into each other should certainly be visible in gravitational waves at the Virgo distance if h limits are pushed to 10^{-22}. The stochastic background of gravitational waves left over from the early Universe may also be detected, perhaps allowing some probing back to the Planck era ($t \sim 10^{-43}$ s) where some estimates place the decoupling of gravitational radiation, or to later eras when the perturbations in density that eventually gave rise to galaxies were generated. Present-day regular periodic sources (such as fast-spinning pulsars) may be observed to much smaller h than 10^{-22} by integrating over many periods.

R.W.P. Drever (Caltech and Glasgow University) outlined some of the neat experimental techniques that have made the interferometric detectors a practical proposition since the first experimental prototype built at the Hughes Aircraft Corporation in 1971. The sensitivity of the detector increases with the arm length. The effective length of the arms is increased either by using multiple reflections to give multiple parallel paths along the arms or by making the arms into resonant cavities, effectively bouncing the light backwards and forwards many times within the period of a gravity wave. The programme in Germany (like that at Massachusetts Institute of Technology, and described by W. Winkler, Max-Planck Institute, Garching) uses a multiple path design of total path length 100 km, possibly in a three-arm triangle configuration. The current experimental rig in Glasgow has an arm length of 10 m, and the rig at Caltech a length of 40 m, both rigs using the resonant cavity approach in preparation for much larger instruments. The development of a servo-loop system by Drever's group to stabilize the laser frequency in these interferometers has led to a standard technique for laser stabilization in many other applications — surely an object lesson for those who doubt the technological advantages of pursuing 'pure' science.

A new technique to use a phase-modulation system to recycle the light used in the interferometer in such a way as to reinforce the laser light feed may reduce the required laser power by a factor of 100, which will require single-mode powers of perhaps 20 or 30 W — a not unreasonable target. Particularly useful in reducing the requirements of laser power is the reported development of robust mirrors with reflectivities of the order of 0.99995. In the more distant future there are real hopes of reducing the effects of photon noise by using a technique termed squeezed states, recently demonstrated experimentally at Bell Laboratories, which attempts to circumvent some of the limitations imposed by the uncertainty principle by careful choice of exactly what quantities are measured.

The practical realization of a working gravitational-wave observatory (see Fig. 2) is most likely to come first from the US and the Glasgow groups. The US project for a laser interferometer gravity-wave observatory should result in two 4-km instruments, one in Maine and one in California. The UK proposal is for a 1-km instrument in Scotland, to be fully operational in its first stage within about six years. These would be true 'observatories',

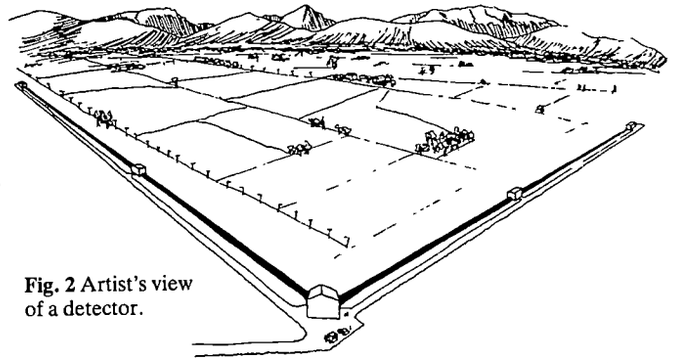

Fig. 2 Artist's view of a detector.

as most of the cost is in the provision of kilometre-length high-vacuum pipes for the interferometer arms. The pipes would be about 1 m in diameter and would work at vacuua of better than 10^{-7} Torr. These pipes will be able to carry several interferometers simultaneously, providing useful coincidence tests against seismic or other instrumental disturbances.

The value of international collaboration in gravitational-wave research was unanimously agreed. Apart from economies resulting from shared technology, there is a real need for several detectors both to obtain directional information and to eliminate spurious signals by correlation of data from different sites. The gravitational waves sweep past and through the Earth, and (as emphasized by B.F. Schutz, Cardiff University) the four principal detectors proposed can be optimally oriented to give good sky coverage and will maximize the rate of detection of the (initially) few events per year. □

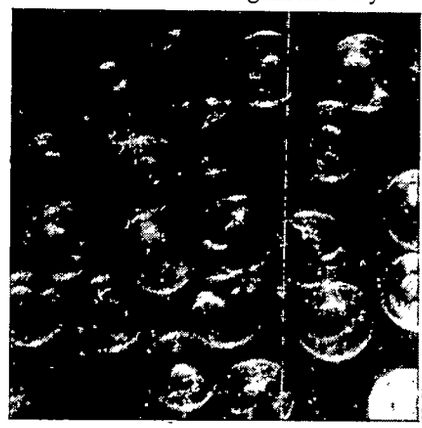
Developmental biology

Embryology goes fishing

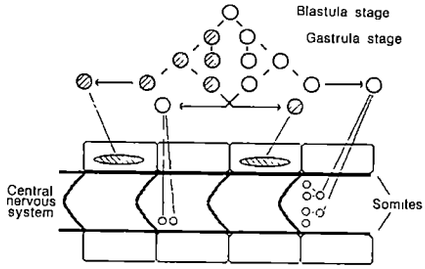


from David Marcey and Christiane Nüsslein-Volhard

In all multicellular organisms, embryonic cells with different developmental potentials arise from a series of cleavage divisions that begin with the first division of the nucleus of the fertilized egg. In some animals, for example the nematode worm *Caenorhabditis elegans*, the developmental fate of a particular embryonic cell is strictly tied to its ancestry, whereas in other systems (for example, the fruitfly *Drosophila melanogaster*), positions and/or cell interactions are instrumental in determining initial restrictions in developmental potential, although these restrictions can be inherited by daughter cells through subsequent cell divisions. But the relationship between embryonic cell fate and cell lineage has been examined extensively in few vertebrates, so the recent report by Kimmel and Warga[1], describing some early cell lineages in the zebra fish *Brachydanio rerio* (a long-time aquarium favourite), is therefore welcome.

Although the various organisms examined to date differ in the degree to which embryonic cell determination is linked to cell lineage, there is no reason to expect that, at the cellular level, fundamentally different determination mechanisms are used during the embryogenesis of diverse taxa. Significant increases in our understanding of development in different species are required before such comparative problems can be addressed. Recently, progress in elucidating embryonic cell-determination mechanisms has been more rapid for invertebrate systems (especially flies and nematodes) than for vertebrate systems. This is partly because of the higher complexity of, say, mouse than worm development, but has also resulted from the lack of a suitable vertebrate system in which the power of a genetic approach to ontogeny can be brought to bear.

In *Drosophila* and *Caenorhabditis*, the discovery of developmentally important genes by the recovery of mutations, followed by their molecular analysis, is permitting significant glimpses into the mechanisms responsible for pattern generation, including those involving cell-lineage restrictions. Are these mechanisms also operative in vertebrates? Two approaches are likely to help answer this question. One involves the analysis of vertebrate DNA sequences that show significant sequence homology with genes known to figure importantly in fly and/or worm development. The other is to perturb development genetically in a vertebrate, to screen systematically for embryonic defects and then to compare the classes of mutant phenotypes obtained with those available in other organisms. Such comparative, genetic embryology should provide valuable information about the evolution of developmental systems.



Fortunately, some of the genetic techniques devised by George Streisinger[2] (Fig. 1), coupled with the features of the zebra fish that provide for superb embryological analysis, make this species an ideal vertebrate for the genetic analysis of development. Mutagenesis screens, together with embryological analyses like those of Kimmel and Warga, promise to advance our knowledge of vertebrate ontogeny.

H. Howard, University of Oregon.

Fig. 1 Cloned zebra fish embryos.

Fig. 2 Schematic, simplified representation of sample cell lineages in the zebra fish embryo (the numbers of cell divisions shown are not necessarily real). Striped cells are of a muscle lineage, dotted cells are of a neural lineage. A blastula cell may give rise to both muscle and neural cells, but at the gastrula stage, separation of these lineages occurs. Subsequent divisions produce cells which can separate (arrows) and populate different levels along the anteroposterior axis. In the case of some neural cells, further divisions yield cells that lie on both sides of the nervous system midline.

Taking advantage of the transparency, small size and speedy development of zebra fish embryos, Kimmel and Warga[1] injected a conjugate of the fluorescent label rhodamine and the histochemical marker horseradish peroxidase (or fluorescent label alone) into single cells of the blastula and followed the subsequent fate of their descendants in both living and sectioned material. Confirming previous marker-injection[3] and genetic mosaic[4] studies, progeny of single blastomeres were seen to disperse throughout the embryo and to participate in the development of diverse tissues such as muscle, neural and epidermal tissue. In contrast, a detailed analysis of individual gastrula-stage lineages within a marked clone revealed that, with few exceptions, progeny of gastrula cells are confined to a particular tissue.

These observations fit well into the classical embryological framework for fish development. In teleosts such as *Brachydanio*, pronounced cellular mixing takes place during the spreading movements of the embryonic disk over the yolk that preceed and accompany gastrulation, termed epiboly. A result of this epibolic spreading is the juxtaposition in the blastula of cells having different origins. During and after this mixing, formation of both germ layers and the rudiments of primary organs occurs. Thus, although not surprising, Kimmel and Warga's new result helps to define the stage at which initial segregation of tissue-specific lineages occurs. The observed clonal restrictions might not simply be caused by spatial constraints because the authors have found that separate tissue-specific lineages sometimes produce cells that are near neighbours; gastrula-stage lineages are segregated into tissue types even when there is substantial cell mixing and division throughout the period of observation. These segregations could then reflect heritable choices in cell fate made by individual gastrula cells (see below).

Several clonal patterns in the central nervous system deserve special comment. Kimmel and Warga observe that cells arising from a common neuronal precursor can populate disparate axial levels. Data from one embryo show extensive anteroposterior movement of the descendants from sibling mid-gastrula neural progenitors such that clonal relatives are present as four clusters separated by as many as seven segment widths in the 24-hour-old embryo. One possible interpretation of this result is that the segmental identity of individual neural cells is assumed after a commitment to make nervous tissue. A test of this interpretation would involve making appropriate lesions to prevent the normal migration of neuronal precursors and then following the fate of thwarted cells. Kimmel and Warga found marked, if somewhat variable, periodicity in the clustering of clonal relatives in the spinal cord; sometimes relatives in adjacent segments differentiate into morphologically similar neurones. Another striking observation was the dispersal of some sibling

neural progenitor cells across the embryonic midline after migration of parental cells to a particular axial level. Judged by their morphology and rostro-caudal position within a particular segment in the spinal cord, these neurones appear homologous. The intriguing observations that clonal relatives in different segments and in separate halves of the embryo can differentiate similarly demands thought on the relationship of this differentiation to lineage.

Based on their analyses, Kimmel and Warga suggest a sequence of diverging lineages associated with cell-fate determinations in zebra fish (Fig. 2): although blastomeres mix extensively and are pluripotent with respect to the fate of their descendants, the first divisions of the early gastrula produce tissue-specific lineages; the next divisions produce cells that contribute to different axial levels; and subsequent divisions, at least in the central nervous system, yield sibling cells that form the bilateral halves of the brain and spinal cord. The tracing of cellular pedigrees with injectable markers[5] clearly yields much information about the embryonic fates of clonally related cells, but it must be stressed that cell lineage studies alone cannot establish connections between ancestry and fate. As with the *Xenopus* (clawed toad) central nervous system[6], tests of these relationships must wait for experiments in which particular lineages are challenged to produce derivates normally made by different clones, as has been accomplished in birds with ectopic grafts[7], in *Drosophila* with cell-autonomous growth-rate mutants[8] and in the grasshopper[9], nematode[10] and leech[11] with cell-ablation methods. Molecular probes for special developmental programmes, such as those for some sea-urchin embryonic lineages[12] would also be useful. □

Theoretical physics

Supertwistors and superstrings

from L.P. Hughston

ROGER Penrose's 'twistor' method[1] has been fashionable for about a decade among mathematicians and mathematical physicists as a powerful technique for analysing certain classes of partial differential equations and the manifolds or spaces that are naturally associated in various ways with them. The systems of differential equations to which the method is applicable are those arising in relativistic field theories, and thus there is a deep vein of interest in the theory which links these developments with advances in our understanding of elementary particles and gravitation. Although the method was originally devised with space-time modelled as a classical four-dimensional manifold, it has become increasingly clear that the theory can in several instances be developed in higher-dimensional spaces, and can be set up so as to admit supersymmetric degrees of freedom.

Points in space-time correspond to extended structures (complex projective lines) in twistor space. Space-time points which are null-separated correspond to lines which intersect. A relativistic string corresponds, in twistor space, to a type of holomorphic curve.

In particular, G.A.J. Sparling, on page 417 of this issue[2], formulates in simple terms the field equations of no less than five distinct important theories: the classical Einstein gravitational equations; the classical Einstein–Maxwell equations; the bosonic equations of eleven-dimensional supergravity; the curvature and torsional field equations of supergravity in dimension four; and the equations of graded Einstein–Maxwell theory in dimension four.

Sparling shows in each case that the relevant field equations correspond to the 'splitting' of a certain bundle structure (the bundle of local twistors or supertwistors). This characterization of field equations by means of a splitting condition is sufficiently compelling that we may view it in effect as providing an alternative to the time-honoured 'principle of least action'.

In his early work on twistor theory[3,4], Penrose showed how insight could be gained into the nature of the geometry of space-time by consideration of a second manifold, twistor space, which is related to space-time via an intricate transformation (see figure). The points of space-time correspond to extended structures (complex projective lines) in the associated twistor space; intersection of a pair of these lines corresponds in space-time to null-separation (that is, connectedness along a light-like trajectory). Penrose and others were able to demonstrate how the elementary linear equations of non-interacting relativistic fields in space-time could be solved, remarkably, by use of essentially 'free' holomorphic data specified on appropriate regions of twistor space.

A significant step forward came about ten years ago with the discovery of the so-called 'non-linear graviton' construction[5], which showed how certain classes of coupled non-linear partial differential equations could be solved by a kind of non-linear variant of the earlier ideas which had worked for linear theories.

Shortly thereafter it was shown by Atiyah and Ward[7,8], Yasskin and Green[9], Witten[10], and others how, with slight modifications of the basic ideas, theories of the Yang–Mills type could also be treated by twistor methods. Witten[10] played a key part in subsequent developments because, following on from the ideas of Ferber[11], he was the first systematically to wed supersymmetry techniques to the geometrical methods of twistor theory.

Since then there has been widespread activity in generalizing the Penrose transform and related ideas to higher-dimensional systems and to systems of interact-

ing fields. Witten, in particular, recently devised a supersymmetric twistor-like transform in ten dimensions[12], motivated by the possibility that such a transform may be "the proper starting point for understanding the geometrical meaning of superstring theory".

Sparling, following to some extent the prototype of C. R. LeBrun[13], now extends these investigations along a promising new line of enquiry, asking, via consideration of the geometry of twistor bundles, for a general characterization of the most significant field equations of relativistic physics.

As for the future, as both Witten and Sparling point out, an important line of development may be to establish further the links between superstring theory and twistor theory. In this connection another recent step forward is relevant: W.T. Shaw has shown[14] that the dynamical equations of classical string theory in four dimensions can be solved by means of a twistor transform. According to Shaw's scheme a string corresponds in twistor space to a type of holomorphic curve, specified essentially arbitrarily (see figure). Again here the physical object (the relativistic string) is described in terms of free data on the twistor space — the challenge which follows is that of constructing a consistent quantum theory from this essentially classical picture. □

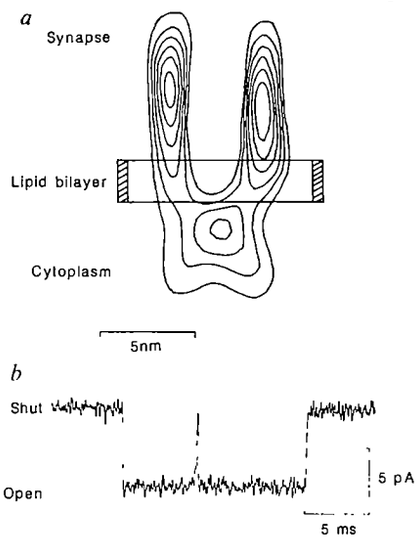
Molecular pharmacology

Structure and function of acetylcholine-receptor ion channels



from David Colquhoun

FOR much of this century pharmacologists have been saying that once they knew the structure of the cellular receptor, as well as that of the agonists and antagonists that combine with it, then it would be possible to understand the mechanisms of action of neurotransmitters, drugs and hormones. This dream is now being realized, thanks in no small part to the beautiful work of a group at Kyoto University on structure and of a group at the Max-Planck Institute, Göttingen on function of the acetylcholine receptor. In the latest work from these groups, reported elsewhere in this issue (Mishina, M. *et al. Nature* **321**, 406; 1986), Numa, Sakmann and their colleagues elucidate the structural basis of the difference between the fetal and adult forms of the acetylcholine receptor in bovine muscle.

The nicotinic acetylcholine receptor from electric fish is a pentameric protein, $\alpha_2\beta\gamma\delta$, made from four types of subunit which are arranged around a central ion channel; that from mammalian muscle is almost certainly similar. The primary sequences of all four subunits have now been found using recombinant DNA methods. The subunits span the cell membrane (*a* in the figure); when two acetylcholine molecules combine with sites on the extracellular parts of the α subunits, the ion channel opens for a millisecond or so, resulting in chemical synaptic transmission from nerve to muscle fibre of such rapidity and reliability that it allows us (well, a few of us) to play the Waldstein sonata.

Before the motor nerve reaches embryonic muscle fibres, the acetylcholine receptors are widely distributed over the whole surface of the developing myotube, but following innervation some remarkable changes take place (for a review see Dennis, M.J. *A. Rev. Neurosci.* **4**, 43; 1981). Around the time of birth (in the rat) the rapid turnover of the fetal acetylcholine receptors is slowed, the receptors become highly concentrated over a very small area of the muscle fibre immediately at the junction with the motor nerve ending, and the density of extrajunctional receptors becomes much lower. During the immediate post-natal period the characteristics of the acetylcholine-receptor ion channel change from the fetal to the adult form: the mean duration of an individual opening of the ion channel induced by acetylcholine is shorter by a factor of 3 or 4, and the conductance of the open state is about 50 per cent larger in the adult relative to the fetal form. It is thought that these changes are brought about by some substance released by the motor nerve and/or muscular activity. When the motor nerve of an adult fibre is cut, receptors reappear throughout the length of the muscle fibre membrane, and these new extrajunctional channels are remarkably similar to the fetal receptors in their turnover time, single-channel conductance properties and mean open lifetime.

There has been much discussion about whether the change from fetal to adult receptor during development results from modification of existing fetal-type receptors, for example by phosphorylation, or from synthesis and insertion into the membranes of new adult-type molecules. Some work has suggested that the turnover rate (and rate of insertion of new receptors) is too slow for the latter mechanisms to be correct. But the new work of Mishina *et al.* shows with beautiful clarity that the adult and the fetal receptors are different molecules. The adult protein contains, in place of the γ subunit found in the fetal protein, the recently discovered ε subunit which has a different primary sequence (Takai, T. *et al. Nature* **315**, 761; 1985). The ε subunit has rather more acidic, and fewer basic, amino acids than the γ subunit and it has only 53 per cent homology with the γ-subunit sequence (although this is greater than its homology with the α, β or δ sequences). Furthermore the messenger (m)RNA encoding the γ subunit is found mainly at the early fetal stage whereas the mRNA for the ε subunit becomes predominant after birth (contrary to the report of Takai *et al.*) A particularly nice feature of the new work is the direct com-

Static structure and rapid function. *a*, Electron image map of a cross section of the receptor-ion channel, perpendicular to the plane of the cell membrane; the wide mouth of the channel is clearly resolved (redrawn from Brisson, A. & Unwin, P.N.T. *Nature* **315**, 474; 1985). *b*, A single activation of the ion channel by acetylcholine causes rapid transition to the open state (downward deflection); this channel opening lasts for about 14 ms but the current is interrupted by a brief closure that lasts for about 100 μs (from Colquhoun, D. & Sakmann, B. *J. Physiol., Lond.* **369**, 501; 1985).

parison between the functional properties of the receptors (made in oocytes following injection of mRNAs encoding the pure subunits) and the receptors in their natural environment in fetal and adult muscle membranes. The properties are astonishingly similar — perhaps, after all, the environment of the receptor is not very important.

It now seems likely that during development the motor nerve somehow switches on expression of the gene encoding the ε subunit while stopping expression of the gene encoding the γ subunit. A few problems remain: it is just possible that the nerve might control expression of an enzyme that selectively breaks down the mRNA encoding one type of subunit; and it is conceivable that the γ subunit of an existing fetal-type receptor could be exchanged for an ε subunit while it is in the membrane, although neither of these possibilities seems very likely. There is some evidence to suggest that more than two sorts of channel can exist during development and after denervation. Perhaps this is why the variability of the mean open time of the channel for the fetal type receptor in oocytes is much greater than that of the adult type.

The work by Mishina *et al.* greatly improves our understanding of the relationship between structure and function at the relatively gross level of distinct receptor subtypes. Next, we would like to elucidate the molecular behaviour of a channel when an agonist binds to it. What are the structures of the 'discrete' states inferred from kinetic analysis — for example, what are the structures of the open and shut states; why is it that some agonists can hold the channel open for longer than others; and what is the structural explanation of the brief interruptions in channel openings? These events occur on a timescale of milliseconds or microseconds, whereas our picture of structure is still static (see figure).

Parts of the receptor molecule have already been changed by site-directed mutagenesis (Mishina, M. *et al. Nature* **313,** 364; 1985) and the function of subunit hybrids examined (Sakmann, B. *et al. Nature* **318,** 538; 1985). But clearly the substitution of one amino acid in the sequence could change the conformation of the whole subunit, or even that of adjacent subunits. Attempts to assign discrete functions to parts of the molecule will inevitably be ambiguous unless new methods of assessing the higher-order structure can be devised. Judging by experience with other molecules such as haemoglobin, it could be some time before clear answers emerge — but at least now the light is visible over the horizon. □

Ocean Drilling Program

A microcosm of ocean basin evolution in the Mediterranean

*from the Leg 107 shipboard scientific party**

THE Tyrrhenian is a small triangular sea surrounded by mainland Italy, Sicily, Sardinia and Corsica (Fig. 1). Leg 107 of the Ocean Drilling Program was the third scientific drilling study in the Mediterranean Sea, following the pioneering Deep Sea Drilling Project legs 13 and 42A in 1970 and 1975. The Leg 107 cruise had three main ojectives: to consider the Tyrrhenian Sea as a back-arc basin; as a young passive margin; and as a stratigraphic type locality.

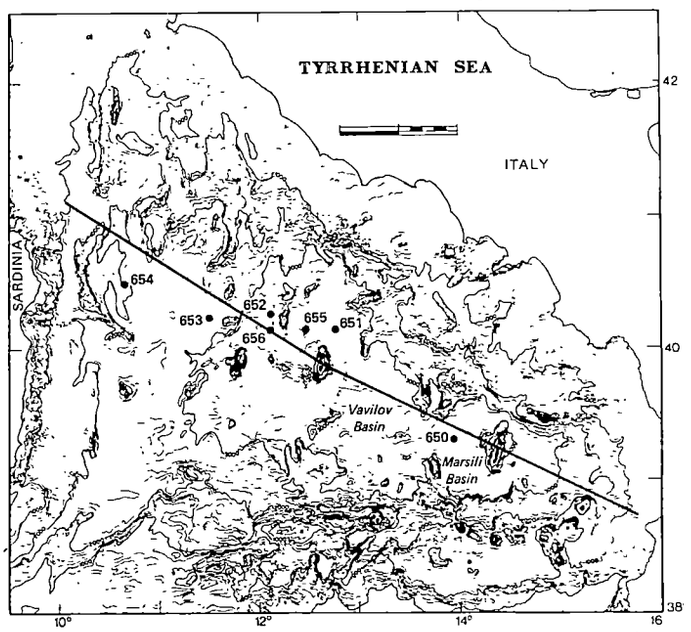

Fig. 1 Tyrrhenian Sea. Leg 107 drilled a north-west/south-east transect of seven sites (650–656) from the Sardinian passive margin (left) across two small deep oceanic basins. (Bathymetry after International Bathymetric chart of the Mediterranean; contour interval, 200 m; scale bar, 100 km).

The Tyrrhenian Sea is a small oceanic back-arc basin that has opened behind a volcanic arc and above a subduction zone. Widespread volcanism and frequent earthquakes indicate that the subduction plate boundary is still active and that the back-arc basin is still evolving. Leg 107 investigated how such a basin evolves in space and time. At the south-easternmost drill site (site 650; Fig. 2), we found evidence that the basin is geologically very young (less than 2 million years old). The basalt recovered at site 650 is very vesicular (full of gas bubbles) which implies that the basalt was erupted into water much shallower than its present 4,100-m depth below sea level. Thus, the eastern part of the Tyrrhenian Sea has subsided markedly since it was formed. At site 655, further north-west, Leg 107 recovered 110 m of basalt flows overlain by sediments that are about 3.5 million years old, and at site 651 the basement is unexpectedly complex — a cap of basalt flows overlies peridotite, a rock type normally associated with the Earth's upper mantle. Sampling the igneous basement and dating the overlying sediment at sites 650, 651 and 655 shows that the locus of oceanic accretion shifted through time from north-west to south-east, that is, towards the subduction zone.

The western Tyrrhenian Sea is a young, passive continental margin that was formed by stretching, faulting and subsidence of the continenetal crust. At site 654, we recovered a textbook example of a sequence of rock types that indicates a progressive transition through time from a continental to a marine environment. The rocks recovered from the bottom to the top of the hole are subaerial conglomerates overlain first by sandstone with oyster shells and then by open marine sediments. Subaerial, shallow-water and then deep-water environments ensue as the site sank relative to sea level. Lower on the continental margin, at sites 652 and 656, we again encountered evidence of significant subsidence within the oldest sediments drilled that appear to have been deposited

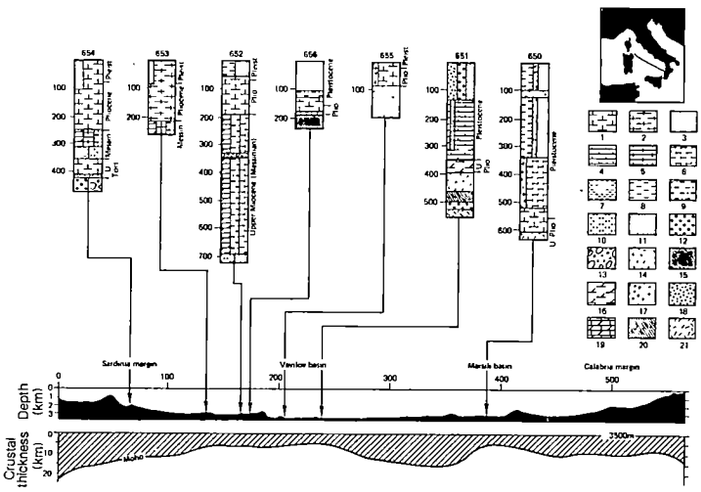

Fig. 2 Simplified lithological columns for each site are projected onto a bathymetric and crustal thickness cross-section of the Tyrrhenian Sea (cross-section after Steinmetz, L., Ferrucci, F., Hirn, A., Morelli, C. & Nicolich, R. *Geophys. Res. Lett.* **10**, 428; 1983). The position of the transect is shown in the insert. Symbols for lithological columns of sites 650–656: (1) nannofossil ooze; (2) nanno–foram or foram–nanno ooze; (3) calcareous ooze; (4) nannofossil chark; (5) nanno–foram or foram–nanno chalk; (6) calcareous chalk; (7) clay/claystone; (8) mud/mudstone; (9) sandy mud/sandy mudstone; (10) silt-siltstone; (11) sand/sandstone; (12) gravel; (13) conglomerate; (14) basic igneous; (15) pebbles and red carbonate mud matrix; (16) dolomite; (17) volcanic ash; (18) volcanic lapilli; (19) gypsum; (20) complex transition zone; (21) peridotite.

in a lake. Slumps, debris flows and small faults are common in the sediments deposited during subsidence and stretching of the crust. Subsidence seems to have occurred 1–2 million years later in the south-east (site 652) than further west (site 654).

The geological stages for the past 5 million years were all originally defined on the basis of outcrops around the Tyrrhenian Sea. These stages are now widely used outside the Mediterranean, but some doubt remains about the calibration between the boundaries of stratigraphic zones recognized in the Mediterranean Sea and the biozones of open oceans such as the Atlantic and Pacific oceans or Caribbean Sea. Thus, the third goal of Leg 107 was to recover nearly continuous sediment successions and to calibrate the various techniques used to date marine sediments. Such techniques are based on microfossils, reversals of the Earth's magnetic field, correlations of volcanic ash layers and ratios of stable isotopes contained in the sediments. Drilling at site 653, where we have successfully obtained two nearly continuous sequences of open marine sediments down to 5 million years old, should be suitable for this purpose.

Leg 107 has touched on many other geological subjects, including evidence for crustal heterogeneity, protrusion of upper mantle material, the chronology of volcanic ash layers, cyclic deposition of Messinian evaporites, the origin of organic-rich and metalliferous sediments, the definition of biostratigraphic boundaries and variation of heat flux through the sediment column. The Tyrrhenian Sea is clearly one of the best places for the study of many geological processes. Other areas of the Mediterranean Sea appear to hold similar promise. □

Parasitology

Spurious *Babesia* antigens

from F. E. G. Cox

A PROMISING approach to the development of a vaccine that would protect cattle against babesiosis has suffered a serious setback with the discovery that what seemed to be the dominant proteins recognized by the serum of babesiosis-infected animals merely reflect a host response to an inflammatory reaction[1]. Worse still, this discovery is a warning to parallel programmes of vaccine development against other parasitic diseases.

Babesiosis is an important tick-borne protozoal disease of erythrocytes in cattle, affecting several hundred million animals worldwide. Routine immunization can be achieved by vaccination with attenuated strains of the parasite[2] and there is also evidence that fractionated parasites can confer some protection[3]. The search for more satisfactory vaccines is currently following the procedures pioneered for malaria parasites — the identification of major antigens by immunoblotting techniques using immune sera, the isolation of the relevant messenger RNA, transcription to DNA and eventual cloning[4]. This kind of approach has attracted considerable attention and Australian scientists at the CSIRO laboratories at Indooroopilly in Queensland have over the past few years identified several antigens associated with *Babesia bovis*-infected erythrocytes that they now believe may be of host rather than parasite origin[1].

Calves with no history of babesiosis and with no detectable antibodies against the parasite were injected with turpentine to induce an acute inflammatory response. At the same time sera were collected from cattle immune to *B. bovis*. Nitrocellulose blots of *B. bovis* antigens treated with anti-babesial antisera from immune animals give rise to numerous reaction bands. The dominant bands revealed were of relative molecular mass 120,000–240,000 and were absent in similar antigen blots treated with control sera. But a similar test with sera from the turpentine-treated animals revealed the same bands. Precautions were taken to ensure that these reactions were not artefacts and the authors conclude that what are apparently *B. bovis* antigens can be detected by sera from animals experiencing a non-specific inflammatory reaction.

The conclusion from these experiments is that these dominant antigens recognized by specific immune sera cannot be of babesial origin, and furthermore that differences in their size range is consistent with their being isoantigens in genetically diverse cattle. Alternatively, these results may indicate interactions between babesias and naturally occurring autoantibodies. The authors suggest that, at the height of parasitaemia, the inflammatory reaction results in the release of acute-phase proteins simultaneously with the depression of the immune response to parasite antigens. Thus, the antigens recognized at this stage are those associated with inflammation and not infection.

These results also explain earlier findings that sera from uninfected cattle sometimes produce a positive immunofluorescence in the indirect fluorescence antibody test in which both *B. bovis*-infected erythrocytes and the parasites themselves fluoresce[5]. Overall, the significance of these findings is twofold. First, they pinpoint possible errors in immunodiagnosis; second, and most important, they suggest that immunoblotting techniques may identify spurious candidate antigens for the possible development of vaccines. This warning must be heeded in fields other than babesiosis for there have been reports that sera from uninfected animals react with various antigens of protozoan and helminth origin[6]. □

Predicting that comet Halley is dark

SIR—As I write this letter in early March only the scantiest information has come out of the Giotto mission. One of the most interesting preliminary findings was that comet Halley appeared to be quite dark. This may seem to be inconsistent with the high degree of reflectivity one might expect from an icy comet nucleus[1], implying that something extra is required to blacken the surface. I should like to show that a very low reflectivity is a predicted[2] and natural consequence of the comet nucleus being a fluffy aggregate of small solid intersteller particles[2] each of which is largely water ice and at least moderately reflecting. The reflectivity of the comet is low because it is an open structure and light which penetrates it is internally absorbed by being scattered many times by the individual small particles which are its components.

The first stage of interstellar particle coagulation in the presolar nebula which is assumed to lead ultimately to the comet nucleus is shown schematically in Fig. 1 by a model containing 91 individual particles. Each particle is a mean representative of a size distribution of interstellar grains which have fully accreted all the condensable molecules from the dense molecular cloud out of which the solar system was born. It consists of a silicate core, an inner mantle of complex organic refractory material which has evolved by ultraviolet photoprocessing over hundreds of millions of years before comet coagulation, and an outer mantle of volatile ices in which H_2O is dominant[3] and which contains S_2 molecules which could only have been produced in the interstellar dust before coagulation[4]. These particles are typically ~ 0.5 μm thick and at least three times as long[5]. Imbedded in the outer mantle are many small (~ 0.01 μm radius) particles (some strongly absorbing) which show up in space as blocking the ultraviolet radiation of stars[6].

The porosity shown in Fig. 1 was derived by comparing the density of comet dust with the mean density of meteors which are known to be comet debris. Although the mean density of the non-volatile silicate core–organic refractory mantle interstellar grains (no outer icy mantle) is about 1.9 g cm^{-3}, a characterisitic mean meteor density of 0.2 g cm^{-3} is observed[7]. This obviously implies a high degree of porosity. The organic refractory component is the largest part of the comet dust after the volatiles evaporate. Taking into account the volume of volatile ices in the precometary dust (and thus in the original comet matter) one arrives[2] at a mean packing factor for the comet of no more than about 0.4 (60% empty space). This is what has been pictured for the 4 μm aggregate in Fig. 1. An even fluffier comet nucleus structure is probable since the meteor particles must undergo some collapse after evaporation of the volatile components[8].

It is therefore reasonable to approximate the light scattering by a comet as if it were a cloud of small particles each of which is characterized by an albedo α and a scattering asymmetry factor g. The individual particle albedo is defined as the ratio of the light scattered by the particle to the light it both absorbs and scatters (no absorption: $\alpha = 1$; total absorption: $\alpha = 0$). The asymmetry factor, defined as the mean value of the cosine of the scattering angle, is essentially the difference between the forward scattered and the backward scattered light (spherically symmetric scattering: $g = 0$; no back scattering: $g = 1$). At visual wavelengths the normal interstellar grains (no icy coating) have an albedo $\alpha = 0.6 \pm 0.1$ and an asymmetry factor $g = 0.8 \pm 0.1$ (ref. 9). It is a well known property of the scattering of light by small particles that in the size to wavelength range of interstellar dust, a further increase of particle size by the addition of icy mantles leads to an increase in the asymmetry factor up to $g = 0.9$ (ref. 10). The very strongly forward directed scattering implies that light impinging on a particle at the comet surface mostly continues inward where it may be absorbed by repeated scatterings within the body.

Let the forward and backward scattering fractions be F and B so that $F + B = 1$. Using $g = F - B$ the backward scattered fraction is $B = (1-g)/2$. Since only a part, α, of the incident radiation per particle is scattered and, since we shall assume that all the forward scattered radiation is lost, the net back scattering by the sum of the individual particles filling the surface of the comet is the total reflected light. This gives a reflectivity of $A = \alpha\,(1-g)/2$. So for $\alpha = 0.6$ and $g = 0.9$ only about 3% of the light is reflected. This simple but physically reasonable approximation for the reflectivity matches remarkably closely the value $A = 0.028$ obtained from very accurate calculations of Van De Hulst[11].

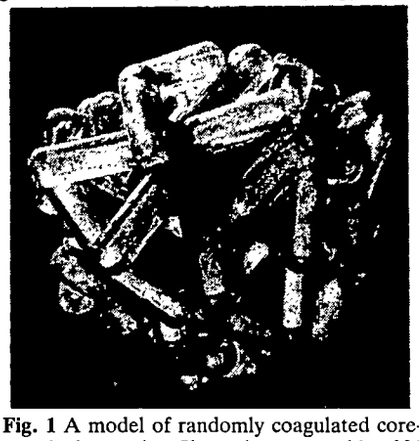

Fig. 1 A model of randomly coagulated core-mantle dust grains. Shown is an ensemble of 91 particles incorporating within their outer icy mantles the very small particles of the interstellar dust population accreted in the final stages of condensation. The degree of volumetric packing is 0.4 (60% open space) and the overall dimension is scaled to about 4 μm.

For the same reason, large comet dust particles should similarly exhibit low reflectivities, as may have been detected in comet Crommelin[12]. Judging by the high infrared emissivity of interplanetary particles well beyond the Earth's orbit (S.S Hong, personal communication) they too, as young comet debris, are highly absorbing because of their fluffy character.

Other critical predictions of this model of the nucleus are: (1) A preponderance of the organics C, O, N relative to the rocky elements Si, Mg, Fe by a factor of five or greater in comet dust grains because of the initially high ratio of the organic refractory to silicate volume in the interstellar core-mantle grains[2]. (2) Individual core-mantle particles of order 0.15 μm radius and mass about 3×10^{-14} g resulting from aggregate breakup. (3) A very large number of *very* small (~ 0.01 μm) particles of mass of about 2×10^{-17} g released from the evaporating icy material[13]. (4) A very low comet heat conductivity leading to high surface heating and a concomittant high vaporization rate due to the very porous surface area.

Should the Giotto and Vega missions confirm these predictions we may well be able to say that comets provide a direct observation of the interstellar dust as it existed 4.5×10^9 years ago and that a comet-nucleus-sample-return mission will accomplish what no amount of remote sensing of the interstellar medium will ever make possible.

Multiple sclerosis, viruses and glycolipids

SIR—For many years now, and again recently in *Nature* (**318**, November 1985 p101, p104, p154), there has been speculation as to the role of viruses in multiple sclerosis (MS). MS is often considered to be an autoimmune disease initiated by infection; the question has always been and remains, which of the many viruses implicated causes the disease? One possibility, which has perhaps not received sufficient attention, is that MS could be caused not by just one virus but by many enveloped viruses acting together or individually.

All the viruses that have been implicated in MS are capable of infecting the nervous system, and all are enveloped viruses. The membrane of an enveloped virus reflects that of the cell from which it has budded. Indeed it has been suggested that such viruses may be able to trigger autoimmune reactions by the incorporation of host protein into their viral envelope but, with a few possible exceptions, the budding virus takes only the virally-coded proteins which have been inserted into the cell membrane, and the lipid molecules surrounding them. It is the host-cell derived lipid molecules that could be the key to the problem.

The lipid molecules of cell membranes have suffered for too long by being represented as the homogeneous tadpole-like molecules of the cell membrane. In fact they are far from being homogeneous in either their biochemistry or their distribution. Neither are these molecules immunologically inert, they are haptens and can under the right circumstances induce an immune response.

In recent years it has been shown that antibodies to glycolipids are detectable in MS patients[1], that such antibodies can demyelinate cerebellar tissue cultures[2], that T-cell reactivity to glycolipids is present in MS patients[3], and relatively specific to this disease[4], and that rabbits inoculated with glycolipids succumb to a demyelinating encephalomyelitis[5]. Thus it is clear that anti-glycolipid activity is of importance in demyelinating disease.

The question is, how does this anti-glycolipid activity arise? One possibility, as we have suggested previously[6], centres on the possibility that budding viruses can initiate an immune response to glycolipids. We have shown that infection of mice with the budding, avirulent RNA, Semliki Forest virus induces a T-cell dependent demyelinating encephalomyelitis[7], although it is not yet clear whether the T-cells responsible for the demyelination react against viral or self antigens on the surface of central nervous system (CNS) cells and myelin. The virus replicates in CNS cells including oligodendrocytes, host-cell glycolipids are incorporated into the viral envelope[8], and these glycolipds are accessible to antibodies[9]. Infection with the virus and inoculation of inactivated brain derived virus both give rise to anti-glycolipid antibody (S. Amor and H.E.W., unpublished observations).

It is possible that several neurotropic budding viruses have the ability to replicate in the same CNS cell-type (for example oligodendrocytes) and on budding from this cell incorporate into their viral envelope the same host-cell glycolipid (for example galactocerebroside). It is possible that such a glycolipid (normally a hapten), associated on the surface of the virus with the 'foreign' carrier antigens of the viral proteins could be antigenic. In an MS susceptible individual, infection of the CNS with one of the many possible enveloped viruses could trigger an anti-glycolipid immune reaction, leading to demyelination and a first attack of MS. Subsequent relapses in MS, already known to have an association with intercurrent infection, could result from restimulation of the same anti-glycolipid autoimmune response following CNS infection with other enveloped viruses.

Perhaps in the search for the cause of MS, more attention should be given to the possibility that viral envelope glycolipids could induce an immune mediated demyelination, and by the immunologists to the possibility that this may trigger an autoimmune encephalomyelitis.

Ventral activation process in insect oocytes

SIR—In a recent *News and Views* article Woodland and Jones reviewed genetic evidence of an active ventral region in establishing the dorsoventral polarity and hence pattern in *Drosophila* eggs[1]. In particular, various recessive — and presumably loss of function — genes are all dorsalizing: not only the genes so lucidly discussed by Woodland and Jones but also the remarkable *K10* gene. Unlike the other dorsal mutants, *K10* acts on the growing oocyte so as to largely symmetrize the early movements of its follicle cells. Thus it produces an egg largely devoid of dorsoventral asymmetry in its shape and shell as well as dorsalizing its embryo[2,3]. Thus lack of *K10* function seems to disable the mechanisms for establishing a dorsoventral gradient. Since it does so by disabling some ventrally localized process, it acutely raises the question of just what this ventral process is.

A clue to this was provided by Kunkel in a study of an analogous growth stage of the cockroach oocyte[4]. He has discovered the presence of large, steady electrical (and thus ionic) currents entering its ventral region. Comparable steady currents rather generally enter regions of developmental action, and in the best studied case — that of the fucoid egg — they seem to establish this region by raising free calcium there[5,6]. So Kunkel's observations suggest that a key early event in *Drosophila* pattern formation is an influx of cations into its ventral region which raises free calcium there, activating gene products like those of *Toll*.

This hypothesis also suggests an explanation for the rather puzzling fact that *Toll*$^+$ cytoplasm from *anywhere* in the egg nevertheless induces a ventral region near the site of injection. Perhaps the *Toll*$^+$ precursor postulated by Anderson *et al.*[7] is artificially activated *during transfer* by contact with the high calcium found in the perivitelline fluid of the *Drosophila* egg[8]. This subsidiary hypothesis predicts that the ability of *Toll*$^+$ cytoplasm to rescue *Toll*$^-$ eggs would be greatly reduced if it were transferred in a way which somehow avoided any transient rise in its free calcium concentration. This postulated artefactual rise would be analogous to the rise in calcium which can destroy the so-called primary cytostatic factor in the cytoplasm of frog eggs[9].

In any case, the main hypothesis predicts the presence of a free calcium gradient across the dorso-ventral axis of the growing insect oocyte with free calcium high along its ventral face. This predicted ventral high calcium zone would be analogous to that already seen — with the aid of aequorin — at the vegetal pole of the early medaka fish egg.[10].

The hungry sheep look up

Walter Gratzer

How to Obtain Biomedical Research Funding. Edited by J.T. Dingle.
Elsevier Applied Science: 1986. Pp.56. Pbk £5.95, $10.

A NEW cottage industry appears to have established itself around the sleazier fringes of science in America, and I take it for an omen of the times: announcements have been appearing on notice-boards around the country proclaiming one- and two-day seminars ($200 a throw seems about average) on how to write successful grant applications. Now it must surely occur to all takers that the performers at these events have entered the business of explaining to other people how to get grants only because they have not lately managed it themselves. They are bald men selling hair-restorer. Successful scientists will in general be too busy insuring against failure the next time round. And besides, as Logan Pearsall Smith observed, "few things are more shocking to those who practice the arts of success than the frank description of those arts".

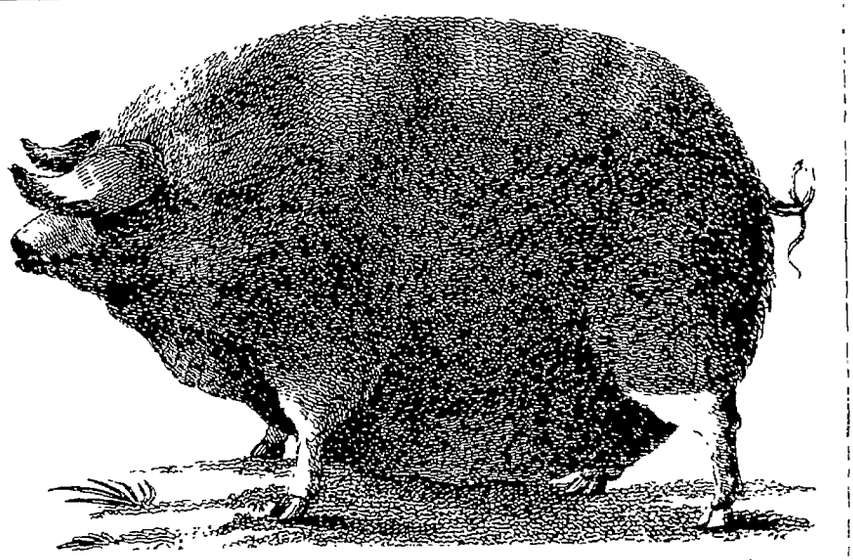
So what have we here? This appears to be the first guide to working the British grant market, and let me quickly add that I have no doubt the three highly respected scientists, who have contributed to this slender paperback (4 mm in its covers), all have abundant grant support, and no idle half-hours to fill for pecuniary gain. What then has motivated their endeavour? Not, for the most part, any unusual luminosity of insight. Slim this volume may be, but there are still indications of a certain desperation in the efforts to give value. The kind of advice that the editor, Dr J.T. Dingle, dispenses is too often along the lines of ". . . it must be concise, to the point and interesting". How so? Why, doctor, because "a dull and repetitive introduction, a turgid summary and incomprehensible experimental detail will not improve the chances of even the most original idea being accepted". Four pages on we are enjoined to "try to be concise and organise one's arguments in short but cohesive sentences", and on the next page, "the summary should state precisely and clearly the objectives of the study". Well, you could have knocked me down with an RG2A application form!

Dr J.L. Gordon from the Clinical Research Centre weighs in with a chapter about the referee's view of grant applications. "What", he asks, "determines whether a referee will agree to review an application?". And he has the answer: "he has to ask himself two questions: first, is this my field? And secondly . . ."; but there, I shall not spoil the impact of the narrative by giving away any more. You must buy the book.

Matters look up with the eruption onto the scene of Professor Jack Lucy, who gives a wholly convincing and distinctly diverting account of how the deliberations of a Medical Research Council Grant Committee might go, confronted with a typical (though imaginary) application. Here are two of the eleven evaluations by the committee members. Number 7 opines that

The applicant has worked in this field for many years but of late there have been diminishing returns. It seems highly likely, unless a new approach is developed, that there is little prospect of this research yielding any observations of significance, and it is suggested that the applicant might be advised that the most likely way of obtaining a further insight into this problem is by gene cloning.

And Number 8:



The applicant has a good record of many years of research in this field but now, quite correctly, judges that — if much further progress is to be made in this area — the newer techniques of recombinant DNA technology and site-directed mutagenesis need to be employed. Unfortunately, the applicant has no experience at all in the use of these techniques . . .. I therefore have serious reservations regarding the viability of this otherwise potentially-interesting project.

The ring of truth is unmistakable. This is much more the kind of thing one is looking for.

The last twenty pages of the book are by administrators, and there are no laughs but lots of information. They explain how the MRC and the private charities operate their grant systems, and an appendix lists eighty organizations that will disburse the moola when appropriately stimulated.

This small book then could with advantage have been even smaller, but it will have its uses. One question lingers in the mind: allow for the moment that such a publication as this might contain the key that will unlock the strong-room. Will it then work for the common weal? The Law of Conservation of Matter must surely operate: what each purchaser of the book collects will be snatched from you and me, and have we not all seen the undeserving flourish, yea, as the green bay tree in fact? I would incline to the view that those who cannot work out for themselves that the summary should be clear, concise and fit into the box provided, would do better selling stock in biotechnology, or even explaining to anxious young scientists How to Obtain Biomedical Research Funding.

Walter Gratzer is in the Medical Research Council's Cell Biophysics Unit, King's College London (KQC), 26–29 Drury Lane, London WC2B 5RL, UK.

Fat pig — the illustration, from an agricultural survey of Staffordshire in 1796, is of an animal that was 802lb liveweight at the age of 2½ years. It was by no means the largest recorded. The tendency towards breeding pigs that became excessively fat at a relatively young age began in the late eighteenth century with the introduction of early-maturing foreign breeds to Britain. Because of the demands of the show-ring and the lard industry, the problem became progressively worse through the nineteenth century: one judge at the Royal Show in 1881 felt obliged to comment that "it is painful to see the prostrate masses of fat grunting and sweating under a weary life in the heat". Such opinions went unheeded, many breeds became extinct and the British pig industry suffered accordingly. The picture and historical details are taken from Julian Wiseman's entertaining and informative book A History of the British Pig, *newly published by Duckworth. Price is £12.95.*

Crystallographers' proteins

Kenneth C. Holmes

Diffraction Methods for Biological Macromolecules, Parts A and B. Methods in Enzymology Vols 114 and 115. Edited by Harold W. Wyckoff, C.H.W. Hirs and Serge N. Timasheff. *Academic: 1985. Part A pp.588, $70.50, £59. Part B pp.485, $66.50, £50.50.*

THE structural investigation of protein crystals by X-ray diffraction started in 1934, when J.D. Bernal and Dorothy Crowfoot Hodgkin first successfully photographed a crystal of pepsin. The resulting X-ray diffraction patterns contained so many Bragg reflections that they resisted all known methods of interpretation for 20 years, until Max Perutz was able to show that the small changes in X-ray intensities induced by binding two mercury atoms per molecule of haemoglobin were enough to determine the phase of each reflection. With phases, the electron density can be calculated, albeit by evaluating a Fourier series of around 10,000 terms at each of 100,000 lattice points! Another five years elapsed before John Kendrew's team could carry out a Fourier synthesis for myoglobin to atomic resolution, revealing for the first time the intricacies of the three-dimensional structure of a protein.

Kendrew used programs devised to run on the Cambridge Mathematical Laboratory's EDSAC II. Without such a machine the calculation of the electron density of myoglobin would have been virtually impossible; indeed, the growth of protein crystallography is intimately entwined with the development of the computer.

In the 1950s, because of the influence of Sir Lawrence Bragg and the activities of Perutz and Kendrew, protein crystallography was synonymous with the Medical Research Council unit in the Cavendish Laboratory. (Later, other centres appeared, but even these, in most cases, trace back in apostolic succession to Bernal or Bragg.) In the late 1950s and 1960s, then, a stream of (mostly American) post-doctorate students descended on the MRC unit and worked feverishly to turn protein crystallography into an established science worthy of associate professorships. Now they and their acolytes, and some converts, have written it all down.

The articles in the resulting two volumes are rather technical or mathematical. They are also somewhat uneven in type, ranging from user's guides for various program packages to some thoughtful review papers. Thus, while specialists will find a wealth of useful detail here, those less familiar with the field could have trouble finding their way around. The contributions are grouped in sections: history (an engrossing article by Perutz); crystallization (the nearest we get to wet biochemistry); data collection; phasing; model building; and presentation of results.

Michael Rossmann, who was in at the start on EDSAC II, contributes a detailed and informative chapter on oscillation photography. Other mandarins also make interesting contributions: Fred Richards concerns himself with the problem of defining protein surfaces and, besides, reviews his folly. David Stuart and David Phillips present an excellent analysis of thermal motion and its relationship to molecular dynamics — otherwise hardly mentioned. Hal Wyckoff, also an editor, has provided a definitive review of diffractometry. Jane Richardson's stylized drawings of proteins are truly beautiful, while Lynn Ten Eyck deserves a prize for the most concise account of X-ray diffraction. A summary of the least-squares method has been contributed by Robert Sparks, though this is somewhat out of place in the "phasing" section. No less than 12 articles use the least-squares method and the consistent adoption of Sparks's notation throughout the book would have helped clarity.

The article by Joel Sussman on constrained least-squares refinement reawakened my memories of 1963, when Carl Branden and myself battled with an IBM 7090 for 16 hours to achieve one cycle of constrained refinement of myoglobin. Progress indeed! Once or twice elsewhere I experienced *déjà vu*; for example, mirror benders turn up attributed to all and sundry, but not to Tony Woollard who actually developed the present design in Cambridge. This reflects the fact that in the heady years of the 1960s the rate of innovation outstripped the rate of publication. The present volumes redress the balance with a little to spare. □

The common quest

A.R. Rees

Growth Factors and Transformation. Edited by James Feramisco, Brad Ozanne and Charles Stiles. *Cold Spring Harbor Laboratory: 1985. Pp.450. Pbk $70.*

IN its application to the study of oncogenic transformation, the inductive approach to science has perhaps come under closer scrutiny than in any other area of biology. While it is generally agreed that cancer is not a single disease, this has not prevented researchers from assuming that common mechanisms will emerge if we just look long enough and hard enough. This is by no means obvious. For example, that tyrosine phosphorylation is a causal event in transformation was and remains an attractive hypothesis; but there is still not a single example in which specific substrates of tyrosine kinases can be said to play a key role in the transformation process, although the presence of the kinase itself is often sufficient to transform the target cell. Even if plausible mechanisms for oncogenic transformation were to emerge, we are still left with the problem of how they would relate to transformation *in vivo* — despite the fact that some 30 oncogenes have been characterized that originate within the cell and 10 or so others from within oncogenic viruses.

It was against this background that, in the autumn of 1984, Cold Spring Harbor Laboratory organized its meeting on growth factors and transformation. The subject matter in the resulting book is arranged loosely into chapters, the first five of which survey the properties of growth factors (epidermal growth factor, transforming growth factors, insulin and the related insulin-like growth factors, platelet-derived growth factor and its oncogenic relatives, and, finally, the lymphokines). The second half of the proceedings is devoted to oncogenes and kinases, with a concluding chapter entitled "Futures". In the main each author provides an integrated account of the interplay between growth factors and oncogenes, but the existence of genes for which a growth factor connection (or in some instances, function) has not been established necessitated their collection into the separate chapter on oncogenes. For a number of these oncogenes (E1A, Ha-*ras*-1, c-*fos*, c-*myb*, for example) this biological apartheid would still be necessary.

There are always things to be said for and against conference proceedings, even up-market productions such as those emanating from Cold Spring Harbor. In a fast moving field like this, speed is crucial. Unless the proceedings appear within six months they are generally of dubious value to research workers, though they may be useful as background reading for those at the periphery. *Growth Factors and Transformation* appeared in Britain almost a year after the conference. This delay would have mattered less if some of the chapters had not been quite so repetitive. And this criticism might have been redundant if the meeting itself had not been so parochial — only four papers were contributed by groups working wholly outside the United States.

The repetitive element is at one of its high points in the opening chapter on epidermal growth factor, and is also a feature

of the three c-*fos* papers in the "Oncogenes" chapter. For all that, the discussions of the manner in which some transformed epithelial cell lines and their *in vivo* analogues seem genetically predisposed towards either aberrant or overexpression, or both, of EGF receptor transcripts suggest a potentially important correlate of epidermoid malignancy. The more mechanistic aspects of the action of EGF and other growth factors are presented in the "Kinases" chapter. Here the particular role of tyrosine kinases is explored, alone and in their relationship to that possible arbiter of tumour promotion, protein kinase C. It is here also that an organizational eccentricity placed the second of the two related accounts of phosphorylation of 40S ribosomal protein S6, the first being in the opening chapter on EGF.

If we are to take the "Futures" title of the concluding chapter literally, then we are faced with the prospect that studies of certain phenomena — Na^+/H^+ exchange, mitochondrial responses to growth factors, and growth factor effects in systems such as embryonal carcinoma and the developing nervous system — are the subjects of the future. In fact the manner in which growth control signals are developmentally regulated is an undeniably important area of research. But with the exception of the first paper in this chapter (which explores the thesis that "in the future it is likely that the level of biochemistry of cell proliferation, not as well developed now, will become ever more important"), the conclusion is a rather mixed bag of topics that the organizers obviously could not easily fit in elsewhere.

Many of the presentations in this volume are well worth reading, and the book should certainly be in every library pretending to cover the literature on cancer. Whether individuals in the field will find it of much value, I doubt, because most of the data it contains have now been published or even superseded. Non-specialists, however, may find the book a helpful summary of current problems in oncogene research and of the type of experimental approaches that are available to pursue the search for that elusive Holy Grail — the common mechanism. □

Down to the bones

Bernard Wood

The Human Skeleton. By Pat Shipman, Alan Walker and David Bichell. *Harvard University Press:1986. Pp.343. $27.50, £23.50.*

THE very word "skeleton" has macabre, if not sinister, associations, and its colloquial use also betrays our perceptions of the human frame; we have all experienced privations in hotels which have been excused by muttered references to the "skeleton" staff. Traditional (by which I mean old-fashioned) medical courses did little to enhance the image. Students were drilled in detailed osteology and every bony lump, bump, nook, cranny and crevice had a name which had to be memorized. Such minutiae provided aggressive examiners with the necessary ammunition to trip up even the most nimble student, but had few other merits for a general undergraduate education in anatomy. It is not surprising that the efforts of physiologists and biochemists to enliven teaching on the skeleton by reference to its metabolic relevance made little headway against this type of introduction.

The image of the skeleton is changing, and this book will help hasten the process. Research on the structure and function of hard tissues, at the levels of cell biology and whole animal studies, are invigorating our attitude to both bone and bones. The authors are particularly well-qualified to provide an applied and broad biological perspective on their subject matter. Pat Shipman has pioneered rigorous methods for assessing the implications of marks on bones found at archaeological sites, while Alan Walker has carried out innovative analyses of primate behaviour and has made important contributions to palaeoanthropology and palaeopathology. Their colleague, David Bichell, is an artist who is trained in anatomical drawing.

The book is in three sections. The first deals with the components and organization of bone and discusses its physical properties. The central, and largest, section is a series of regionally-based descriptions of the form of the normal skeleton, augmented by succinct, but useful, presentations of integrated activities such as breathing, walking and chewing. The third section covers the ways in which the skeleton, and its components, can be used in forensic and anthropological research. Predictably, the chapter on skeletal pathology is a strong one, and it was sensible to include an account of the structure and identification of teeth.

In terms of scientific content, the authors have wisely eschewed the exotic. One of the book's strengths is that it presents sound skeletal biology in a way that will stimulate students to learn more for themselves. The style is such that quite complex principles and ideas are introduced and discussed without intimidating the reader. There is little doubt that this volume will have a long life, and in any new edition the authors might consider setting the vertebrate skeleton in an even broader context than they have done. Their classification of joints is traditional and, for all its apparent complexities, they might consider making more explicit reference to MacConaill's analysis of joint surfaces.

For those of us who bemoan the demise of Le Gros Clark's *Tissues of the Body*, this new book provides a helpful account of hard tissues and the skeleton. Other textbooks and reference works will be needed to provide extra detail, but few are likely to offer a more stimulating introduction to the subject than that set out by Shipman, Walker and Bichell. □

New journals review

On 25 September *Nature* will publish the sixth annual review supplement devoted to science journals.

Criteria for inclusion of a journal in the 1986 issue are that:

(i) the first number appeared, or the journal was retitled, *between June 1984 and May 1985* (the second cut-off date allows at least three issues of a journal to have been published, the minimum number on which a reasonable judgement can be based);

(ii) it is published at least three times a year;

(iii) the main language used is English.

Publishers and learned societies are invited to send *four different issues of each suitable periodical, including the first and most recent numbers* (if from outside the United Kingdom, by air mail) to The Review Editor, *Nature*, 4 Little Essex Street, London WC2R 3LF, England. Subscription details for both 1986 and 1987 should be included.

Newts and nuclear winters

John H. Lawton

The Machinery of Nature. By Paul R. Ehrlich. *Simon & Schuster: 1986. Pp.320. $18.95.*

I MUST confess to breaking the law by catching great-crested newts, lovely, ugly creatures with orange bellies, warty backs and crests like those of a dragon. Under the British Wildlife and Countryside Act, catching great-crested newts even to admire them is now illegal, because they are rare, declining in numbers and endangered. So you need a permit to fish for them, and I didn't know. I do now, and promise to behave myself in future. But it is very sad; as a schoolboy I caught "water dragons" easily and kept them for a time in an old sink. There is nothing like having a dragon in the kitchen for learning about biology. Now it is illegal.

So what? Book reviews do not usually start with confessions of guilt, even of little crimes. There is however a purpose in my confessions, because these muddy little creatures symbolize the problems that confront conservationists as we struggle to hold back mankind's creeping extermination of thousands of endangered species throughout the world. We do not even know how many species of plants and animals there are, nor exactly how many have already been lost through human activities. We do know that the pace of exterminations is rising and that we need to take ever-more drastic steps to stop it. Laws against catching newts are a drop in the ocean compared with the action that needs to be taken. Which brings me logically, if indirectly, to Ehrlich's book.

The Machinery of Nature has several themes. One is an eloquent plea for a halt to the inexorable, blind destruction of the species of plants and animals that are the newt's and our fellow travellers on this planet, because some of them are beautiful and others are useful. But most are neither; we must conserve them simply because they are there, and because we do not know what they do and have only the sketchiest idea about how the machinery of nature really works. Once we have taken the machine to pieces and lost some of the bits, we should not gamble on being able to put it back together again. The biggest immediate threat comes from the growing human population, rising expectations and grubby, creeping degradation of all that is varied and beautiful in nature. But instant, cataclysmic destruction in the inconceivable horror of a nuclear war and the freezing terror of a nuclear winter is also a stark possibility, and is a second, recurring theme of the book. A third is the excitement and uncertainty of doing science, mixed with a passionate love of natural history — the newts-in-the-kitchen syndrome. Last is a plea for more funding for ecological research. How can we possibly understand the machinery of nature on miniscule budgets that are a direct result of government indifference to environmental science?

The components of the machinery as Ehrlich sees them are the usual mix of population ecology and evolution, sociobiology, "two-species" interactions (predation and so on), biogeography and the dynamics of communities and ecosystems, constrained by the physical environment. However this is no ordinary ecology textbook. What it aims to do is explain the science of ecology to the layman and to our political masters. The intention is fundamentally to change attitudes about what we can and cannot do to the planet and get away with; it is a scientific manifesto for the Green Party, written by a first-class scientist.

The book is certainly well written, although it does have some distracting features. One is Ehrlich's tendency to describe his friends, associates and graduate students as brilliant, and by default mark everybody else beta minus. It is clearly done to enliven and humanize the science; I found it mildly irritating. Also the chapters are too long and sometimes lack a sense of direction; basically they are walks through natural history and the science of ecology, with the path frequently deflected in unexpected, albeit interesting directions. My preference is to know where I am going, and why.

One criticism is more substantial. Ehrlich is American and the book is directed explicitly at his fellow countrymen. Yet the problems it addresses are global and concern everybody. It makes no sense to talk just to Americans, even though (for several reasons) that may be a good place to start.

Will the message have any effect? I hope so, but fear not. It has been preached many times before to little or no avail. For example, by coincidence I recently came across this:

> It is very certain that the earth is not the chief body in the material universe, and that the world is not subordinate to man's use. It is even more certain that nature is the expression of a definite order with which nothing interferes, and that the chief business of mankind is to learn that order and govern themselves accordingly.

The writer was Thomas Henry Huxley in 1880.

One hundred years later the message is the same but much more urgent. Whether the majority of mankind understand it well enough to respond is another matter. It takes time and effort even to start to understand the machinery of nature, and most decision-makers and politicians do not have that time, or care too little to find it. But the problem goes deeper than that. It is one thing to educate lay people about ecology, even assuming that they might be interested. It is quite another to translate that knowledge into a workable political philosophy, and even harder to put it into practice. Indeed, one reason why the great surge of environmental consciousness that swept through the 1960s fizzled out was because it was politically naive. With millions out of work in Europe, still more starving in Africa, grinding poverty, social unrest, terrorism and super-power confrontation, who cares about newts? The problem is getting decision-makers to understand enough of the machinery of nature to realize that we are slowly degrading the life-support systems of the planet, without being able to predict when things might start to go badly wrong (assuming that they haven't already) and to take a longer view about what is important. We also have to translate environmental science into practical, realistic political policies and, in Huxley's words, govern ourselves accordingly. Ehrlich's book is an attempt to educate, but it has nothing to say about welding science to practical politics.

Of course there is general agreement about some issues. Only lunatics want a nuclear war. Yet the body politic is conspicuously unable to reduce, let alone get rid of nuclear weapons. So we pass laws protecting newts, fiddling quietly whilst Rome teeters on the edge of the holocaust. Worse, we do not even take the laws that we have to protect nature as seriously as we should. It is irritating to have to change your behaviour or, worse, abandon a road-building project for the sake of a newt. Yet if rich, developed nations cannot look after their remnants of wild nature, how on Earth can we expect some of the poorest countries in the world to conserve great rain forests, coral reefs or swamps? Who is going to pay to keep the lions wild, and the deserts at bay?

The forces ranged against conservation are formidable. Some of them are evil, some greedy, some both. But most are simply ignorant of the dangers, and too preoccupied with the problems of today to care about the next generation. I do not pretend for a minute that Ehrlich's book will transform the picture overnight, or even over the next decade. But it will help to educate the growing number of people who want to know about the machinery of nature, and about the stark choices that confront mankind between now and the end of the century. Whether you are concerned about newts or nuclear winters, there must be a better way to manage the planet. The price of failure doesn't bear thinking about. □

John Lawton is a Professor in the Department of Biology, University of York, York YO1 5DD, UK.

Space observations of comet Halley

from John C. Brandt

Following the encounters by Soviet, Japanese and European spacecraft, the International Cometary Explorer took measurments of comet Halley on 22 March. The comet has also been observed by the Solar Maximum Mission, the International Ultraviolet Explorer, the Pioneer Venus Orbiter, the Dynamics Explorer 1, and by sounding rockets.

FOR several days before and after its encounter with comet Giacobini–Zinner on 11 September 1985, the International Cometary Explorer[1] (ICE) measured disturbances in electric and magnetic fields and energetic ions. Because the total gas production rate of comet Halley was expected to be 10 times higher than comet Giacobini–Zinner, direct measurements of comet Halley became plausible (see Fig. 1). This expectation was realized on 22 March 1986 at a distance of $\sim 35\times10^6$ km. Thus, ICE, the sixth spacecraft to measure comet Halley (the Giotto encounter occurring on 14 March), both opened and closed the first chapter in the direct exploration of comets.

Measurements of magnetic field fluctuations clearly associated with the comet are shown in Fig. 2. The data are from the plasma wave experiments on ICE (principal investigator F.L. Scarf, TRW, Inc). Evidence for detection of the comet was also obtained by the energetic particle anisotropy spectrometer on ICE (principal investigator R. Hynds, Imperial College, UK). Direct measurement of ion beams chanelled to the spacecraft from the comet by the interplanetary magnetic field lines at times later than closest approach is also a possibility (Fig. 1). The exact dates of measurement for comet Halley require data processing which is in progress.

Scarf also reports a possible detection of disturbances from comet Halley by the plasma wave experiment of the Pioneer Venus Orbiter (PVO) around the time of the comet's closest approach to Venus in early February 1986.

Visual wavelength observations

Ground-based images of comet Halley could not be obtained during an interval of some 6 weeks near perihelion when the comet was in angular proximity to the Sun. This gap was filled by the coronograph/polarimeter (C/P) experiment on the Earth-orbiting Solar Maximum Mission (SMM) (principal investigator R.M. MacQueen, High Altitude Observatory, Boulder, Colorado; the comet observations were obtained under the auspices of an SMM guest investigation headed by M.B. Niedner). The goal was to obtain a record of the comet's overall structure during the interval when no other visible-light imaging of the comet would be possible.

Because of its design as a solar instrument, the C/P's strong rejection of stray light permitted observations of the comet down to solar elongation of 10°. In principle, a gap of only 10 or 11 days would result when the comet penetrated the limit on 1 February and re-emerged on 11–12 February; Halley's perihelion was on 9 February. The original *C/P* timeline included comet observations starting on 10 January and ending in early March. These start and finish dates were set by spacecraft constraints established during 1985 engineering tests at a series of large offpoint angles for which SMM was not designed. Several days before the first scheduled observations two of the on-board computer memory cells failed, probably as a result of a cosmic-ray hit. Alternative operational procedures were implemented by the SMM operations team and only two and a half weeks of observations were lost.

Comet Halley observations began on 26 January, and the images taken through the 'wide-band blue' filter showed an extended coma elongated approximately in the anti-solar direction. The best of the pre-perihelion observations appear to have been taken on 28 January, and in these images there is definite evidence for both a plasma and a dust tail. The angular extent of the plasma tail was not large, around 0.5°, but the tail direction was strongly foreshortened at this time, resulting in a detected linear length of millions of kilometres. Detailed statements on structures and dimensions require full image processing which has not yet been completed.

The post-perihelion observations were degraded by the loss of the SMM high-gain antenna system. As a result of this second operational setback, it was not possible to carry out the comet observations using the tracking and data relay satellite (TDRS) in the normal manner. Reliance was on ground-station contacts. Many of the images show a plasma and a dust tail, similar in quality to the 28 January images; these should prove useful in correlative studies of the solar wind and comets. The last observation of the comet was made on 28 February 1986. Thus, the SMM observations should be useful in

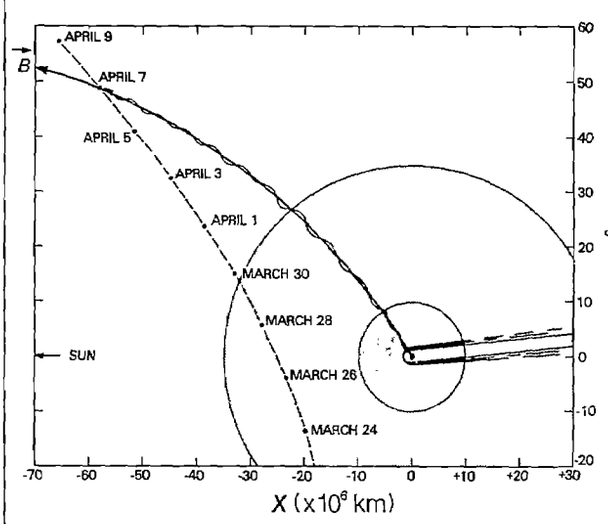

Fig. 1 The trajectory of the ICE spacecraft at closest approach to comet Halley. The distances are plotted in the comet's orbital plane. During the time interval shown, the spacecraft's distance above the orbital plane was 16.6–5.5×10⁶ km. The inner circle around the comet is 10×10^5 km in radius, representing the hydrogen cloud. The outer circle is 35×10^6 km in radius, representing the total comet/solar-wind interaction region based on measurements from Vega and ICE. The arc between the comet and ICE on 7 April illustrates the possibility of particle beams being channelled to the spacecraft. The connection shown is for a steady solar wind at 475 km s^{-1}.

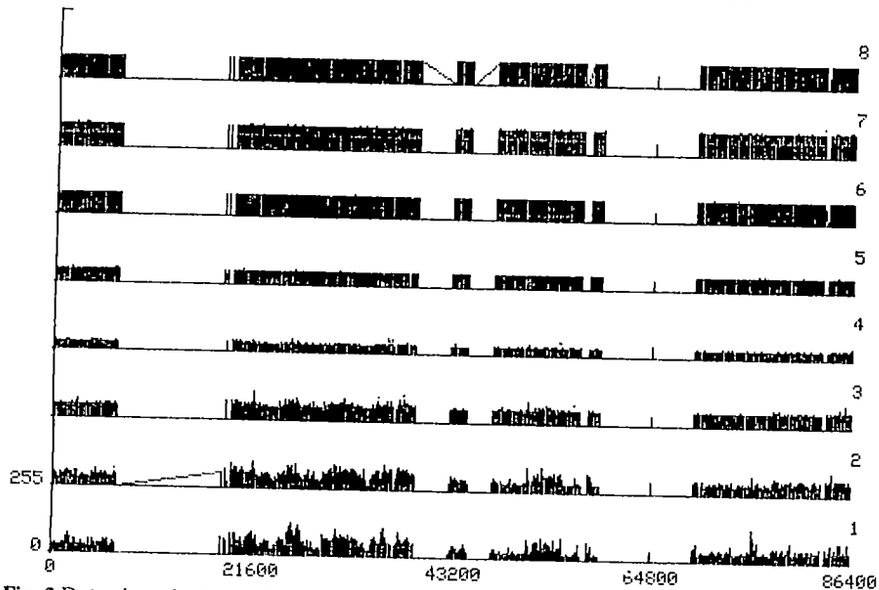

Fig. 2 Detection of enhanced magnetic wave levels on 26 March 1986, indicating traversal of the vast pickup region where cometary ions interact with the solar wind. The frequency sampled varies from 17.8 Hz for channel 1 to 1 kHz for channel 8, and the minimum to full scale spans 80 dB (0 to 255) for each channel. The abscissa is time on 26 March in s. (Courtesy: F.L. Scarf, TRW, Inc.)

providing a record of the structure and evolution of the comet during the last two weeks of February. Ground-based observations will be used to continue the record into March.

Additional visual-wavelength imaging was planned for encounter week from the Astro 1 observatory. The scheduled 6 March launch was cancelled after the loss of Challenger.

Ultraviolet observations

The first IUE star-tracker image of comet Halley was obtained on 11 September 1985, and the ultraviolet spectrum, which showed OH emission, was recorded on 12 September 1985. These are believed to be the first observations of comet Halley from space. The comet was observed every month during the rest of 1985. Due to the comet's angular proximity to the Sun in January and February 1986, it was not observed with IUE. The observations were not scheduled to resume until 13 March when they would support the Giotto encounter. However, when Astro 1, NASA's primary mission to study Halley in the vacuum ultraviolet, was cancelled due to the loss of Challenger, additional IUE observations (requiring new operational techniques) were added. The result was an intensive programme during the week of the Vega and Giotto encounters. Observations are planned to monitor the comet through mid-July 1986; IUE has scheduled 280 hours of observation for comet Halley, more than the telescope has devoted to any previous target in the past year.

Ultraviolet observations provide a means of determining the temporal behaviour of the primary constituents of the gaseous coma. Observations were made from the Goddard Space Flight Center by both the US team (P.D. Feldman, M.F. A'Hearn, H.A. Weaver and L.A. McFadden) on 9, 11, and 16 March, and by members of the European team (M.C. Festou, C. Arpigny and A.C. Danks) on 12, 13, and 14 March. A sample spectrum obtained on 11 March 1986 is shown in Fig. 3. The IUE fine error sensor, used for target acquisition and tracking, was used in a photometer mode to provide nearly continuous light curves over an 8-hour observing shift, a unique capability. During the encounter week, variations in brightness of a factor of two (in a region $\approx$ 7,000 km in radius projected at the comet) were found in a 24-hour period. At the time of the Giotto encounter, this activity was seen to be near a minimum. Preliminary analysis of the ultraviolet spectra, which are qualitatively similar to those of other comets observed by IUE during the past 6 years, shows similar day-to-day variations in both the gaseous emissions and in the continuum of sunlight reflected by cometary grains. The ultraviolet data can also be used to derive an estimate of the total gas production rate (assuming the gas to be primarily H_2O) even though the models generally used for this purpose assume a steady-state gas production. This is clearly not the case for Halley. At the time of the Giotto encounter, the gas production range was 5×10^{29} molecules^{-1}, with an uncertaintly of about a factor of 2. Additionally, the IUE data provide column abundances of carbon, oxygen, sulphur, OH, CO, CS, C_2, and CO^+ to compare with the *in situ* measurements of these species by Vega 2 and Giotto.

The hydrogen cloud surrounding comet Halley has been observed by the ultraviolet spectrometer orbiting Venus on PVO (principal investigator, I.A.F. Stewart, University of Colorado). Detailed observations were made for about 5 weeks in February and March 1986. The spectrometer was used as a spin-scan photometer to build up a Lyman-α image of the entire comet. A unique capability of PVO lies in the fact that, when the comet was behind the Sun near perihelion as seen from Earth, the view from Venus was unobstructed.

The data indicate an extensive hydrogen cloud extending to well over 10×10^6 km from the nucleus, as illustrated in Fig. 4. The derived water production rate for the comet showed very large changes around the time of perihelion, in contrast to a relatively quiescent period in late December 1985 and early January 1986. The trend of the measurements indicated that the total water molecule production rate would be $\approx 1\times10^{30}$ s^{-1} during encounter week. The last PVO observations of comet Halley were made on 7 March 1986.

The VUV-wavelength imaging photometer on DE 1 (in Earth orbit) has been used to map the comet's hydrogen cloud in Lyman-α emission were observed in January 1986. Extensive observations

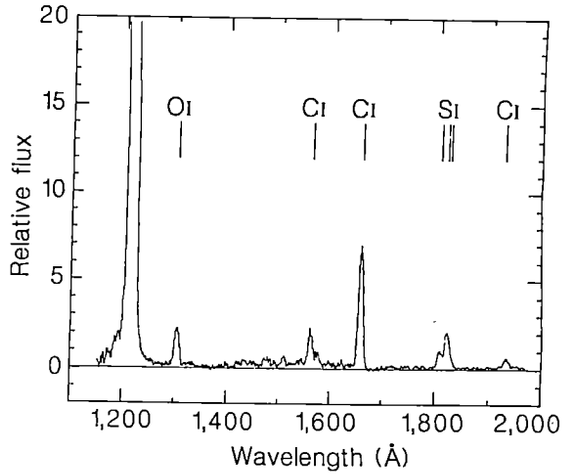

Fig. 3 Preliminary IUE spectrum of comet Halley on 11 March 1986. The saturated feature at 1,216 Å is hydrogen Lyman-β. (Courtesy: P.D. Feldman, Johns Hopkins University.)

were made from 27 February to 20 March 1986 and a last observing period is scheduled for 22 April into June, if possible.

Rocket observations

A sounding rocket experiment specifically designed for ultraviolet spectroscopy of comets and other extended astronomical sources was successfully flown to observe comet Halley from White Sands Missile Range on 26 February at 5:02 MST (12:02 UT). The scientific payload was recovered, refurbished in the field, and reflown on 13 March 1986 at 4:20 MST (11:20 UT), some 13 hours before the encounter of Giotto with comet Halley. The payload, designed and built at the Johns Hopkins University (P.D. Feldman, T.N. Woods, K. Dymond, and D. Sahnow) consists of a 40-cm diameter Dall-Kirkham telescope and Roland circle spectrograph with an ellipsoidal grating. The two-dimensional photon counting detector provides long-slit spectra of the comet with a projected slit length of 5×10^5 km and a resolution of 10^4 km and a spectral range from 1,200 to 1,750-Å, with 10Å spectral resolution. The primary objective of the experiment was to study carbon chemistry in the gaseous coma by measuring the spatial distribution of CO, C and C^+, all of which are detected by resonance fluorescence in this spectral region. Furthermore, by using the Earth's limb to occult the Sun, the rocket observation was possible near perihelion when the comet is most active and the effects of solar photodissociation and photoionization (which vary as the inverse square of the distance from the Sun) are most pronounced. Both rocket flights produced excellent quality data clearly showing, in addition to the strong H I (Lyman-β) O I, and C I emissions, several CO fourth positive bands and the C II emission at 1,335 Å extended into the tail. Also present in the spectra are several weak features, some probably due to atomic carbon, not identified in previous cometary spectra.

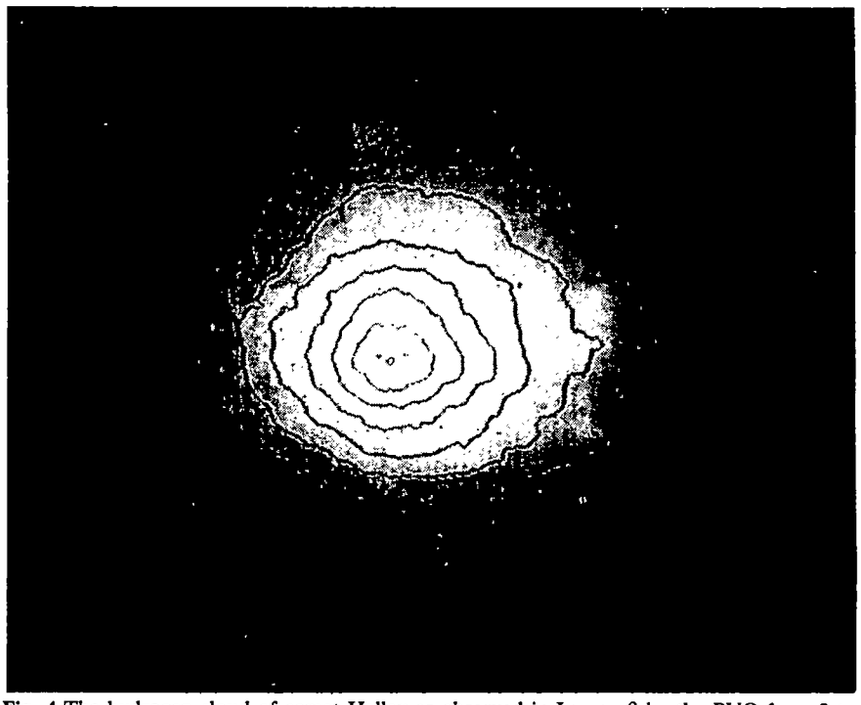

Fig. 4 The hydrogen cloud of comet Halley as observed in Lyman-β by the PVO from 2 to 6 February 1986. The solar direction is to the lower left; the size of the image shown is 0.15×0.15 AU. The crowding of the isophates on the solar side, and their separation on the anti-solar side, clearly show the effects of solar radiation pressure on the escaping hydrogen atoms; for quiet solar conditions this pressure produced an anti-sunward acceleration. The linear 'edge' near the top is an artefact of the image processing due to a large data gap on 3 February. (Courtesy I.A.F. Stewart, University of Colorado.)

An experiment to obtain images and objective spectra of comet Halley was developed by a team consisting of R.P. McCoy, G.R. Carruthers and R.R. Meier (Naval Research Laboratory), C.P. Opal (University of Texas), and M. Silbert (NASA/Goddard Space Flight Center-Wallops). One electrographic camera obtains images at Lyman-β with a 20° field-of-view and 3 arc min resolution. The second camera points at a grating and obtains objective spectra with a 12° field of view and 1 arc min resolution.

The experiment was successfully flown from White Sands Missile Range on 24 February 1986 at 4:53 MST (11:53 UT) and on 13 March 1986 at 3:54 MST (10:54 UT). Sample results are shown in Fig. 5.

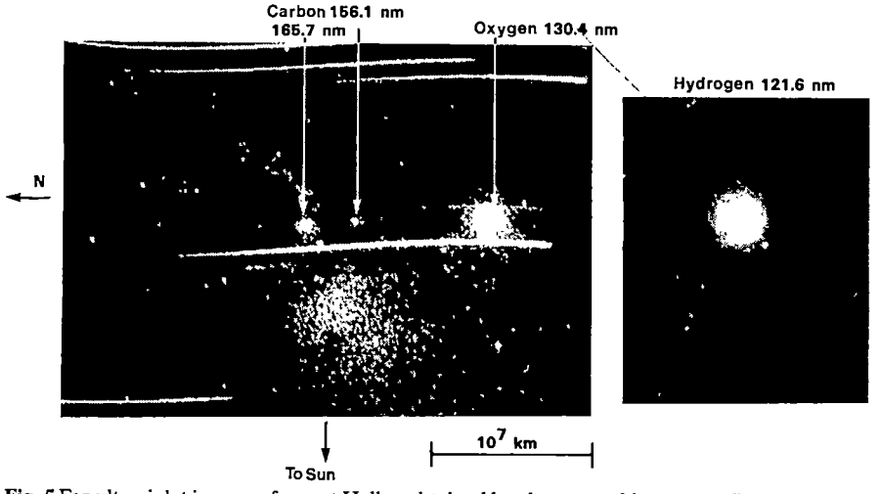

Fig. 5 Far-ultraviolet images of comet Halley obtained by electrographic cameras flow on a rocket launched 24 February, 1986. On the right is a direct image of hydrogen Lyman-β. It shows an extensive coman of hydrogen surrounding the nucleus of the comet and extending out a few million kilometres. On the left, to the same scale, is an objective spectro-gram showing images of the resonance line of atomic oxygen at 130.4 nm and the carbon resonance lines at 156.1 nm and 165.7 nm. The horizontal streaks in the image are the spectra of bright ultraviolet stars. North is to the left, and the Sun is below the images. (Courtesy R.P. McCoy, Naval Research Laboratory).

Conclusions

These diverse measurements and observations of comet Halley should greatly contribute to our physical picture of the comet as it appeared during the 1985–86 apparition. Detailed results will be published by the investigators. Additional contributions will come from a comparison with the results obtained by ICE[1] on the tailward side of comet Giacobini–Zinner during the 11 September 1985 flyby.

The excellent cooperation of the inves-tigators mentioned, demonstrated by their rapid communication of results, is gratefully noted. □

Chaos is an inherent feature of many nonlinear systems. In particular, the transition from a steady to chaotic state occurs independently of the physical properties of the system. Such behaviour occurs in optics, both in lasers and in nonlinear optical devices. Such devices, which are fundamentally simple both in construction and in the mathematics that describes them, provide excellent opportunities for investigating nonlinear phenomena as well as for technological innovation.

MATHEMATICAL discoveries have revolutionized our understanding of nonlinear science. The preconception that physical systems, in general, behave in a predictable manner is seriously in question. Rather than yielding regular and repeatable behaviour, many nonlinear systems also exhibit unstable, even chaotic, solutions. Furthermore, the transition from stable to chaotic behaviour, which may occur when varying a control parameter of the system, follows specific, well-defined routes which are universal in the sense that they are independent of the physical properties of the system they describe. It is these signatures which have been a major impetus to experimentalists in the subsequent search for physical systems that exhibit these phenomena. Such behaviour has now been observed in many branches of science and the number is rapidly growing.

The most recent exciting development is the discovery that such phenomena exist in optics. Here we are concerned, in general, with the nonlinear interaction of light with media contained in optical resonators; the physical properties of the medium, such as absorption and refractive index, being modified by the intensity of the incident radiation.

There are two major areas. The first are lasers or active systems, in which the optical signal is derived from stimulated emission generated within an optical cavity containing a gain medium. The second are passive systems for which the optical signal is but the transmission of an input light signal through an optical cavity containing, for example, an absorptive medium.

Instabilities in laser emission, notably in the form of spontaneously coherent pulsations, have been observed almost since the first demonstration of laser action. However, subsequent theoretical efforts towards understanding these phenomena have been at a modest level, due in part to the wide variety of alternative areas of investigation provided by lasers. It is only with the new mathematical discoveries that these instability phenomena have been investigated to give a deeper insight into the mechanisms of laser action and its deterministic chaotic behaviour. Re-examination of many of these systems show that such effects are quite abundant; the operating window for conventional stable emission in some systems often proving surprisingly small while in some cases, the instabilities are found to prevail just where the lasing emission is optimum.

On the other hand, passive systems which are being increasingly recognized for their potential application as bistable all-optical logic elements, may give rise to similar phenomena. It may, nevertheless, be possible to take advantage of the periodic instabilities that precede chaos in the development of ultra-high frequency all-optical modulators.

Of the variety of physical systems that exhibit deterministic instability phenomena, optical systems, both lasers and passive devices, provide nearly ideal systems for quantitative investigation due to their simplicity both in construction and in the mathematics that describe them, enriched by the possibility of a quantum description. Notable also is the very short timescale (nanosecond to microsecond) over which optical instabilities occur which, in contrast to many other systems, ensures essentially constant environmental conditions during data acquisition. This is particularly important since even small extraneous perturbations, such as noise, may dramatically alter the form of the subsequent temporal evolution of the instability process. These features are fundamental to the rapid establishment of optical systems in this multidisciplinary field.

Universality in chaos

In considering deterministic behaviour, one is tempted into the misconception that such behaviour must be regular since successive states evolve continuously from each other. However, as early as 1892 Poincare showed that particular mechanical systems, where time evolution is governed by hamiltonian equations, could display chaotic behaviour. The subsequent discovery by Lorentz[1] in 1963 that even a simple set of three coupled first-order, nonlinear differential equations can lead to completely chaotic trajectories is recognized as a landmark. This work is fundamental to our understanding of laser instabilities.

At first sight, such behaviour appears alien to our conception of many problems in physical science. This prejudice stems from the dominance of mathematical theory pertaining to linear systems and its subsequent successful application to many fundamental linear problems in the physical sciences. Unfortunately, however, this has led to a narrow vision of the physical world where nonlinear behaviour is the rule and linear behaviour the exception.

Unlike linear systems, nonlinear systems must be treated in their full complexity, and so there is no general analytical approach for solving them. The advances made in understanding many previously intractable nonlinear problems can largely be attributed to the power of contemporary computers, where simulated solutions of nonlinear equations have provided insights into their behaviour and suggested directions for future research.

The temporal evolution in the behaviour of a system can be characterized when presented as a trajectory of a point in the phase space of its dynamical variables. In this representation, consider a familiar dynamical system such as a periodically-forced pendulum in a frictional environment. Such a dynamical system is characterized by the fact that the rate of change of its variable is given as a function of the value of the variable at that time. The space defined by the variables is called the phase space. The pendulum's behaviour can be described by the motion of a point in a two-dimensional phase space whose coordinates are the position and velocity of the pendulum. In

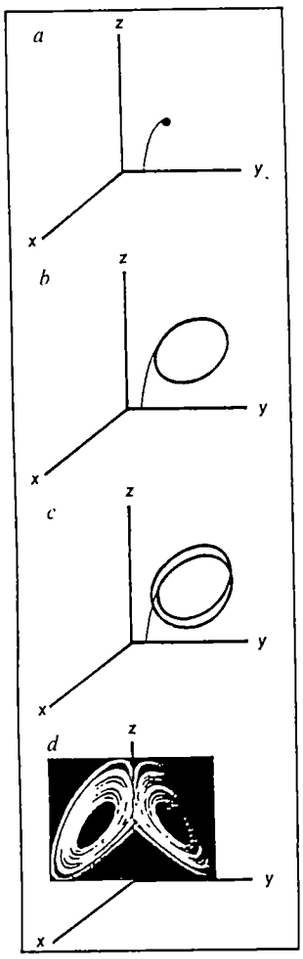

Fig. 1 Phase space portraits of the attractor for the dynamical variables x, y and z. *a*, Stable point corresponding to a steady state in time after initial transients have died out shown as the thin continuous line. *b*, Period-one limit cycle corresponding to a periodic solution in time of single frequency. *c*, Bifurcation to period-two limit cycle; a periodic solution in time with double the period of that in *b*. Successive period doubling bifurcations lead to an eventual chaotic colution. *d* Shows the strange or chaotic attractor for a Lorenz–Haken system describing a single mode laser with a homogeneously broadened two-level gain medium.

more complicated systems, involving many variables, the dimension of the phase space will, however, be considerably larger. If an initial condition of a dissipative dynamical system, such as the pendulum, is allowed to evolve for a long time, the system, after all the transients have died out, will eventually approach a restricted region of the phase space called an attractor. A dynamical system can have more than one attractor in which case different initial conditions lead to different types of long-time behaviour.

The simplest attractor in phase space is a fixed point. The system is attracted towards this point and stays there. This is the case for a simple pendulum in the presence of friction; regardless of its initial position, the pendulum will eventually come to rest in a vertical position. When the pendulum is under the influence of an external periodic driving force, the system is then fully nonlinear and leads to strikingly different behaviour. Irrespectively of the initial conditions the pendulum always ends up making a periodic motion. The limit or attractor of the motion is a periodic cycle called a limit cycle. However, when the driving force exceeds a certain critical value, the periodic motion of the pendulum breaks down into a more complex chaotic pattern which never repeats itself. This motion represents a third kind of attractor in phase space called a chaotic or strange attractor (see Fig. 1).

A trajectory on a chaotic attractor exhibits most of the properties intuitively associated with random functions, although no randomness is ever explicitly added. The equations of motion are purely deterministic; the random behaviour emerges spontaneously from the nonlinear system. Over short times, the trajectory of each point can be followed, but over longer periods small differences in position are greatly amplified making the predictions of long-term behaviour impossible. As such arbitrarily close initial conditions can lead to trajectories which after a sufficiently long time diverge widely; even for the simplest of systems in which all the parameters are determined exactly, long-term prediction is, therefore, impossible. This behaviour is in marked contrast to that of the fixed point and limits cycle attractors for which, irrespective of starting conditions, the system always settles down to the same solutions.

Irratic and aperiodic temporal behaviour of any of the systems' variables implies a corresponding continuous spectrum for its Fourier transform which is, therefore, also a further signature of chaotic motion. However, other factors including noise, can lead to continuous spectra, and distinguishing chaos from noise is one of the major problems of the field. Hence, although time series, power spectra and routes to chaos collectively provide strong evidence of deterministic behaviour further signatures are desirable for its full characterization and in discriminating it from stochastic behaviour. Here analysis of trajectories of a point in the phase space of its dynamical variables is required. However, for a system with, say, N degrees of freedom it seemed that it would be necessary to measure N independent variables; an awesome if not impossible task for complex system. Consequently mathematicians have long tried to develop practical techniques for extracting specific finite dimensional information from the limited output provided by experiment; typically the time record of a specific physical observable; that is, one variable of the system. Here embedding theorems[2] have been recently used to reconstruct phase portraits from which Lyapunov exponents may be determined that measure the average rate of exponential separation or contraction of nearby points on the attractor. These measure intrinsically dynamical properties, unlike power spectra, and provide quantitative measures by which chaotic motion may be distinguished from stochastic behaviour.

The discoveries that deterministic chaos proceeds through a limited number of specific routes when a control parameter of the nonlinear system is varied is profoundly significant as such behaviour is not restricted to a particular model description of a particular physical system. Rather, nonlinear physical systems in all branches of science which may be formally described by the same set of mathematical equations will give solutions that evolve identically in time through one or other routes to chaotic motion. The unique effect of such unification between many separate scientific diciplines forms the basis for the foundation of synergetics[3,4]. There are at least three common routes by which a nonlinear system may become chaotic. These are referred to as period doubling, intermittency and two-frequency scenarios.

Period doubling. From considering various difference equations, many of which can be reduced to simple one-dimensional maps, solutions have been found to oscillate between stable values, the period of which successively doubles at distinct values of the external control parameter[5,6,7]. This continues until the number of fixed points becomes infinite at a finite parameter value, where the variation in time of the solutions becomes irregular (see Fig. 1). One example showing such behaviour is the simple logistic map

$$X_{n+1} = rX_n(1 - X_n)$$

Perhaps the most popular application of this map is in describing

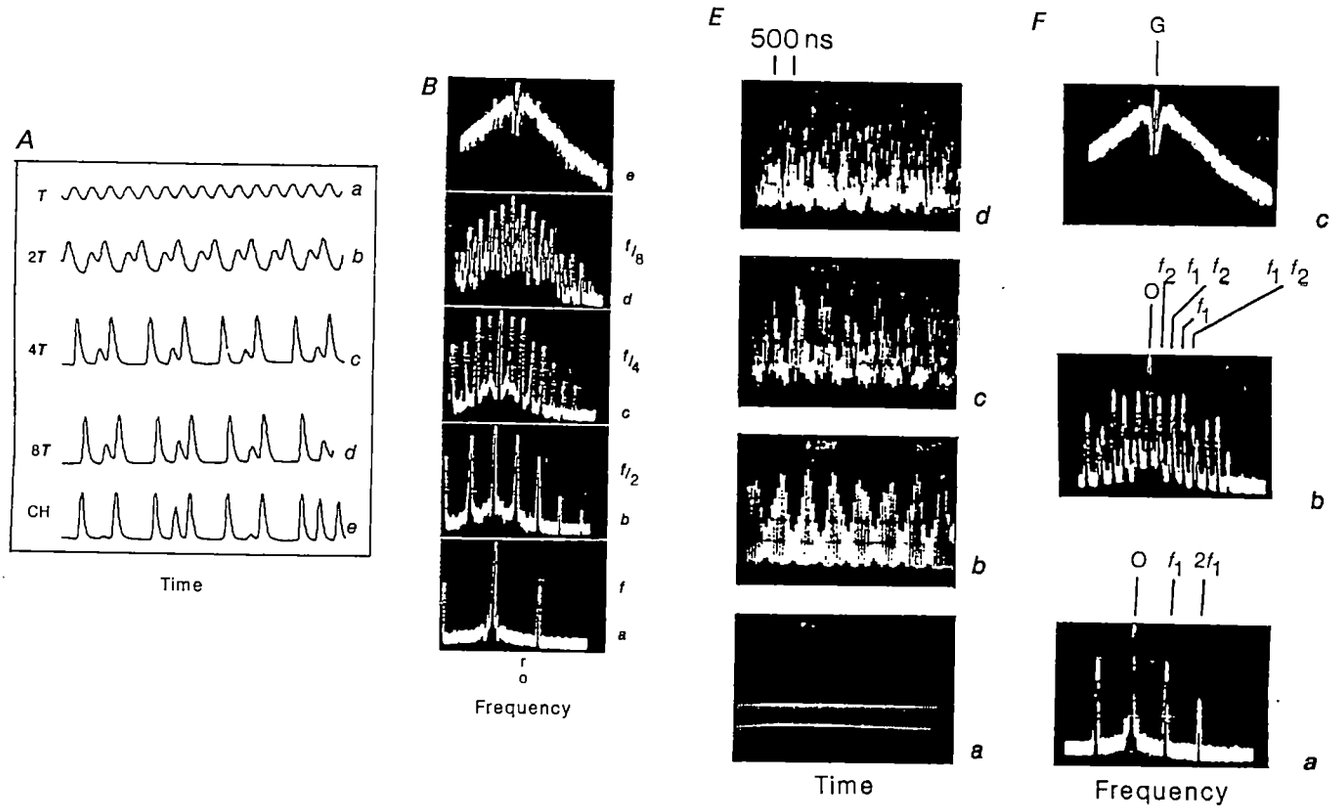

Fig. 2 *A, B* Examples of period doubling route to chaos for laser systems. The time recordings shown in *A* are for a CO_2 laser in which cavity length modulation is used as a control parameter for the generation of chaos (after ref. 20) and *B* shows a spectral recording of the lasing emission for an optically pumped far-infrared ammonia laser with cavity length tuning as a control parameter (after ref. 49). The steady-state solution as in Fig. 1*a* are not shown in these recordings. As seen initial oscillation (*Aa* and *Ba*) undergoes successive period doublings (*Ab–d*) or frequency halving (*Bb–d*) before culminating in chaos where in time the output is aperiodic (*Ae*) and in frequency is a broad continuum (*Be*). *C, D*, Examples of intermittent route to chaos in lasers. The time recordings shown in *C* are for a He–Ne laser in which cavity mirror tilt is used as the control parameter (after ref. 50, and *D* shows a spectral recording of the lasing emission for a He–Xe laser with laser gain as a control parameter (after ref. 25). Steady-state solutions are not shown in the recordings. The initial instability here is characterized by a narrow spectral peak in frequency and periodic pulsation in time. On varying the control parameter the intermittent bursts of chaos become increasingly frequent in time with a corresponding steady broadening of the peaks in the frequency followed by fully chaotic motion. *E, F*, Examples of Ruelle–Takens route to chaos in lasers. The time recordings shown in *E* are for a multimode CO_2 laser in which cavity length tuning is used as a control parameter (after ref. 51) and *F* shows a spectral recording of the lasing emission for a He–Ne laser with cavity mirror tilt as a control parameter (after ref. 50. Steady-state solutions are not shown in the recordings. Initial instability (periodic pulsation, *Ea*; one frequency and its harmonics, *Fa*) develops into quasiperiodic motion with two incommensurate frequencies (*Eb* and *Fb*) as the control parameter is varied before going into eventual chaos (*Ed* and *Fc*).

changes in population ($X_n \rightarrow X_{n+1}$) of an organism or species from year to year ($n \rightarrow n+1$) where there is no overlap between successive generations. The first term in the brackets describes population growth by birth and the second term, population decline due, for example, to preditorial or other environmental conditions. Dependent on the increase in the value of the control parameter r the population may be steady, oscillatory or chaotic the transition following a period doubling scenario (see refs 8, 9). More generally many complex physical systems, often described by large numbers of coupled differential equations, may be reduced in some conditions to the form of this or similar maps. Period doubling bifurcation to chaos has been experimentally observed in numerous systems (see Fig. 2*A*, *B*).

Intermittency. Intermittency[10] means that a signal which behaves regularly in time becomes interrupted by statistically-distributed periods of irregular motion. The average number of these intermittent bursts increases with the external control parameter until the condition becomes completely chaotic (see Fig. 2*C*, *D*).

Two frequency. Turbulence in time was originally considered as a limit of an infinite sequence of instabilities (Hopf bifurcation) evolving from an initial stable solution each of which creates a new basic frequencies[11,12]. However, it has been recently shown[13,14] that after only two or perhaps three instabilities in the third step the trajectory becomes attracted to a bounded region of phase space in which initially closed trajectories separates exponentially; as such the motion becomes chaotic (see 2*E*, *F*).

Chaos in lasers

Chaotic behaviour in lasers may exist in even the simplest of systems: one in which population inversion is established between two discrete energy levels of the medium and where the lasing transition between these two levels is homogeneously broadened. A variety of practical lasers may be controlled to operate in these conditions. A further simplification is that the laser cavity, a Fabry–Perot or ring resonator system surrounding the gain medium, be sufficiently short so that only one resonant frequency of the cavity lies within the bandwidth of the gain medium and that this mode be resonantly tuned to the gain centre frequency. The frequency spacing ($\Delta\nu$) between cavity modes for a Fabry-Perot cavity is given by:

$$\Delta\nu = cn/2L$$

where c is velocity of light, n the refractive index of the lasing medium and L the cavity length. Typical examples of single mode and many mode operation, for short and long cavity lengths respectively, are shown in Fig. 3. In conditions in which the gain or population inversion is maintained at a constant level by, for example, constant electrical or optical excitation, and for the single mode system, lasing occurs with a constant output power at the frequency of the single cavity mode. In this condition, the gain is reduced to a threshold level equal to the cavity losses. Note that even for a multimode system and in the absence of spatial hole burning, lasing is still restricted to a single mode, because the mode with highest gain, here at nor near gain centre, grows at the expense of all other modes. Such behaviour is the accepted operating characteristics of these systems.

However, the discovery[15] that for certain operating conditions emission could be periodic or even chaotic implies that the signal comprises more than one frequency, contrary to the accepted understanding of single mode operation. Prediction of such behaviour were initially identified by Haken through the mathematical equivalence of the equations describing laser action, the Maxwell–Bloch equations, and those derived earlier by Lorenz to describe chaotic motion in fluids. If we consider the trajectory of the Lorenz strange attractor (see Fig. 1*d*) where in the equivalent laser system the dynamic variables x, y and z are the field amplitude (E), polarization of the medium (P),

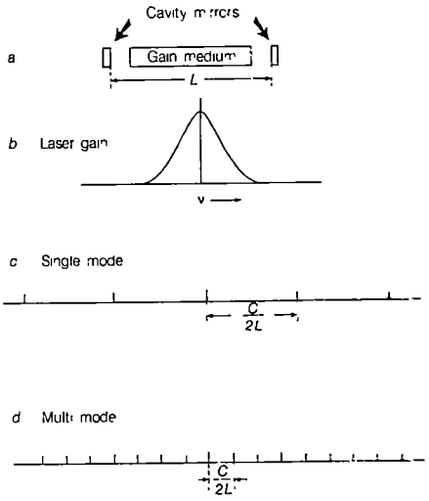

Fig. 3 *a*, A Fabry–Perot laser cavity system with a partially transmitting mirror for coupling out the laser emission; *b*, lorentzian gain profile for a simple two-level homogeneously broadened lasing medium for which each and every atom/molecule emits identically. *c*, Relative position of the cavity modes for a short optical cavity. Here only one mode lies within the gain bandwidth resulting in a single mode emission, *d*, Corresponding position of the modes for a long cavity for which several modes lie within the gain bandwidth.

and the population inversion (D), a point (x, y, z) circles in one region for a while, but then suddenly jumps into another region, where it moves for a while until it jumps, seemingly randomly, back into the first region, and so on; the trajectory never intersects. For the laser, such behaviour not only requires a cavity with high transmission but also a gain of at least nine times that required to produce lasing, making the experimental realization of such operation rather impracticable for most lasers of this simple type. A notable exception are optically-pumped far-infrared molecular lasers[16] which will probably become an important research area.

General prerequisites for the onset of deterministic chaos include: that apart from nonlinear interaction there is a sufficiently large phase space; the minimum requirement being that the system possesses at least three degrees of freedom. For example, the simple pendulum possesses only two degrees of freedom and exhibits at most periodic behaviour. In a two-dimensional phase space, described by the variables, velocity and displacement, it is then impossible for the trajectory to be restrained within a basin of attraction without intersecting itself; repetition of trajectory points resulting in only periodic or quasiperiodic solutions. The addition of one further degree of freedom, through the imposition of a modulated external force, leads to the possibility of a non-overlapping trajectory still in a limited phase space but now described by three variables; the so-called strange attractor (see ref. 17).

The Maxwell–Bloch equations described above for the special case of a single-mode laser with field tuned to the centre of the gain line such that both field and polarization are real quantities, satisfy the minimum condition of three independent variable equations, each of which has its own relaxation.

$$\frac{dE}{dt} = -\kappa E + \kappa P$$

$$\frac{dP}{dt} = \gamma_\perp ED - \gamma_\perp P$$

$$\frac{dD}{dt} = \gamma_\parallel(\lambda + 1) - \gamma_\parallel D - \gamma_\parallel \lambda EP$$

where κ is the cavity decay rate, $\gamma_\perp$ is the decay rate of atomic

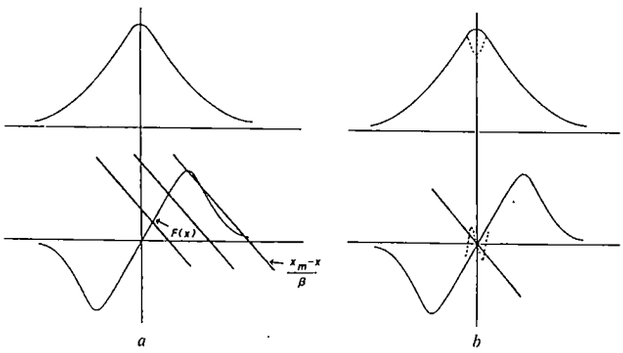

Fig. 4 Graphical solution of the equation of active cavity mode: $F(x) = (x - x_m)/\beta$. Top traces represent gain profile and the corresponding dispersion features associated with these is shown in the bottom traces. *a*, Graphical solution is illustrated for different detunings of the cavity mode. As seen only when the mode is tuned sufficiently away from the line centre, intersection on more than one point is possible resulting in the splitting of the mode into different frequencies all of which fill the same number of half-wavelengths between the cavity mirrors; spontaneous or passive mode splitting. *b*, When the oscillating cavity mode burns a spectral hole into the gain, the associated dispersion takes just the shape required for giving rise to more than one intersection point. As seen, the gain at the split frequencies are indeed higher than that at the original frequency; induced or active mode splitting.

polarization, $\gamma_\parallel$ is the decay rate of population inversion, λ is the pumping parameter, E is the field inside the cavity, D is the population inversion, and P is the atomic polarization.

However, if one variable relaxes faster than the others the stationary solution for that variable may be taken, so resulting in a reduced number of coupled differential equations; commonly termed adiabatic elimination of the fast variables[3,4] In many systems, polarization and population inversion have relaxation times much shorter than the cavity lifetime and both variables can be adiabatically eliminated. With just one variable describing the dynamics, the laser must show a stable behaviour (fixed point in phase space; see Fig. 1*a*). This group of lasers, comprises many common systems such as He-Ne, Ar^+, Dye and lasers. In some cases, only polarization is fast and hence two variables describe the dynamics. In this class, we find ruby, Nd and CO_2 lasers which exhibit oscillating behaviour in some conditions, although ringing is always damped.

Since many lasers are not described by the full set of Maxwell-Bloch equations normally chaotic behaviour from these systems cannot be obtained. For these systems with less than three variables the addition of independent external control parameters to the system, as for the pendulum considered above, have been extensively considered[18] as a means to provide the extra degrees of freedom. Active modulation of a parameter such as population inversion, field, or cavity length as well as injection of a constant field detuned from the cavity resonance and also the use of intracavity saturable absorbers have all been considered[19-21]. For multimode rather than single-mode lasers intrinsic modulation of inversion (or photon flux) by multimode parametric interaction ensures additional degrees of freedom[18]. When the field is detuned from gain centre the field amplitude, polarization and population inversion are complex, providing (in the absence of adiabatic elimination) five rather than three nonlinear equations for single mode systems which is more than sufficient to yield deterministic chaos for suitable parameter values[22]. Also of significance is the remarkably low threshold found for the generation of instabilities and chaos in single mode inhomogeneously broadened laser systems[23-25]. Compared with homogeneously-broadened systems this is attributed to the increased number of independent gain packets available in inhomogeneous systems. Pulsating instabilities and routes to chaos have also been reported for Raman lasers[26] where the instability threshold is again found to be reduced. Significantly, it is also found that instabilities are greatest in conditions for which the laser produces maximum output.

Physical mechanism

A transition from a steady laser output to an oscillatory and subsequently chaotic emission implies the generation of further oscillating frequencies to that of the original stable emission. That this should occur even for a so-called single frequency (single mode) laser seems to be a contradiction in terms. The explanation is in the phenomena of mode splitting[27,28]. This occurs in a region of rapidly varying dispersion when the oscillating cavity mode splits into more than one frequency all of which fill the same number of half-wavelengths between the cavity mirrors. Coupling between these several frequencies having common mode index is a prerequisite for single-mode pulsating instabilities. Dispersion changes its value rapidly near the wings of the gain curve and the splitting that occurs in this region is known as passive mode splitting. An oscillating cavity mode can also induce large variation in dispersion if it can locally saturate the gain curve, hence this splitting is termed induced mode splitting.

To understand spontaneous mode splitting we consider the equation of the oscillating active cavity mode

$$\frac{mc}{2L} = \nu n(\nu) \tag{1}$$

where, m is the mode index and $n(\nu)$ is the index of refraction at the laser oscillation frequency ν. In terms of the empty resonator mode frequencies, $\nu_m = mc/2L$ obtained by putting $n(\nu) = 1$ the above equation may be re-written as,

$$\nu_m - \nu = \nu[n(\nu) - 1] \tag{2}$$

When the value of $n(\nu)$, either for a lorentzian or gaussian gain profile which are common to most lasers, is substituted this equation may be re-expressed as,

$$x_m - x = \beta F(x) \tag{3}$$

where x and x_m are respectively the laser oscillation frequency and empty cavity resonant frequency normalized as a detuning from the atomic resonance. $F(x)$ has the same functional dependence with x as $n(\nu)$ has with ν and it depends on whether the gain is gaussian or lorentzian. The mode splitting factor, β, is dimensionless and is given by

$$\beta = K\frac{cg}{(\Delta\nu)} \tag{4}$$

where g is the peak small-signal incremental gain, $\Delta\nu$ is the FWHM (full width at half maximum) value of gain-width, c is the velocity of light in vacuum and K is a numerical factor equal to $\pi^{-3/2}\sqrt{\ln 2}$ for gaussian gain profile and π^{-1} for lorentzian gain profile. Equation (3) has been graphically solved for different detunings for a gaussian gain profile in Fig. 4*a*. Under certain detuning (near the wings of the gain) the equation is simultaneously satisfied by more than one value of x. Physically this means that the cavity mode is split into more than one frequency and all of which correspond to the same number of half-wavelengths within the resonator cavity. Such effects occur spontaneously at the wings of the gain curve and hence the name spontaneous mode splitting.

Induced mode splitting may be explained in terms of distortions in the dispersion caused by hole burning in the gain profile by a single mode operating above lasing threshold (see Fig. 4*b*). The dispersion may be so distorted that several new frequencies satisfy the boundary conditions. The onset of these sideband frequencies (the gain at which can be more than that at the parent oscillating frequency; see Fig. 4*b*) gives rise to pulsations

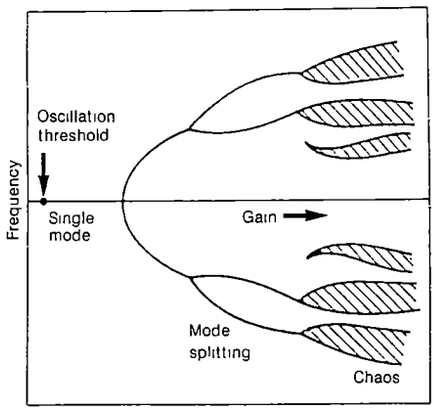

Fig. 5 Mode splitting sequence in which an initially single mode (single frequency lasing oscillation) successively bifurcates on varying gain to generate emission with increasing complex frequency context culminating in a broad band (chaotic) spectrum (after ref. 52).

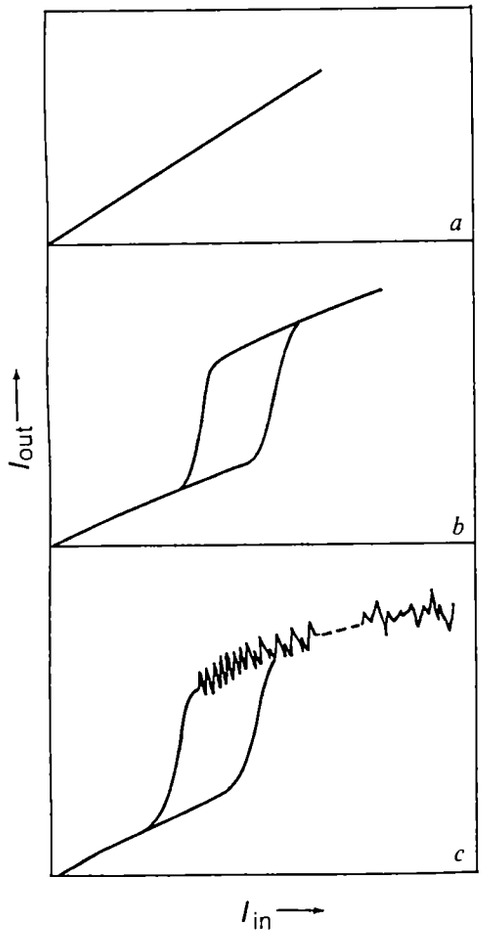

Fig. 6 Transmitted intensity as a function of input intensity for a simple optical resonator, for example, Fabry–Perot or ring cavity. *a*, An empty cavity showing characteristic linear behaviour; *b*, a characteristic optical bistable action and associated hysteresis; *c*, appearance of periodic and chaotic behaviour in the transmitted signal, on increasing the input signal intensity, that may occur in the form of trace *b* for different parameter conditions of the nonlinear cavity.

in the intensity output of the laser. Because the dispersive effects are caused by the oscillating mode itself, this splitting is termed 'induced mode splitting'. This effect should be strongest at line centre and probably exists over much of the lasing tuning range. In view of these effects we may now consider two line broadening situations common to most lasers—homogeneous and inhomogeneous broadening.

The saturating characteristics of an inhomogeneously broadened gain medium is ideal for the realization of mode splitting. In such a medium, unlike the homogeneously broadened case more than one frequency may naturally oscillate since independent sets of atoms/molecules are responsible for lasing at different frequencies across the gain-bandwidth and thus passive mode splitting may be readily observed. The oscillating frequency may also burn a spectral hole into the gain medium thus favouring induced mode splitting. Furthermore, the side bands split again as they again burn spectral holes. This process will continue and may eventually lead to chaos (see Fig. 5). On the other hand, when a homogeneously-broadened gain medium saturates, all the atoms or molecules actually contribute at the oscillating frequency thereby making the possibility of spectral hole burning almost impossible. In such a system, therefore, only the frequency with highest gain would eventually grow. However, for the Haken–Lorentz system, in an extremely high-gain medium survival of more than one frequency is possible.

Chaos in nonlinear optical devices

In parallel with work on laser instabilities, Ikeda predicted oscillation and chaos in passive optical systems[29]. In these systems, the cavity contains a medium whose refractive index is modified by the intensity of the input light signal. This may be expressed as

$$n(I) = n_0 + n_2 I \tag{5}$$

where n_0 and n_2 are respectively the ordinary and nonlinear contribution towards the refractive index and I is the light intensity.

To understand this phenomena we must consider how the light field within the cavity changes, according to the intensity dependent nonlinear phase shift produced by this refractive index, with successive round trips. The simplest case is one in which the intensity-dependent refractive index immediately responds to changes in intensity and where the cavity is of low finesse. The intensity of the signal inside the cavity, here a ring resonator, for successive round trips then obey the one-dimensional mapping rule[30]

$$I_{n+1} = I_{in}\left\{1 + C\cos\left[\frac{2\pi}{\lambda}(n_2 I_n)L + \phi_0\right]\right\}$$
$$= F(I_{in}, C, I_n) \tag{6}$$

where $\phi_0 = (2\pi/\lambda)n_0 L$, is the normal round trip optical phase shift experienced by the input signal in the cavity in the absence of nonlinearity, C is a constant for the particular cavity and we assume that the nonlinear medium fills the whole cavity of length L. The stationary solution of this mapping, denoted by I_s, occurs when $I_{n+1} = I_n$ and yields the relation

$$I_s = I_{in}\left\{1 + C\cos\left[\frac{2\pi L}{\lambda}(n_2 I_s) + \phi_0\right]\right\} \tag{7}$$

where the transmitted signal (I_T) is then simply given by $I_T = I_s T$, where T is the transmission of one of the cavity mirrors.

In the limit of low intensity, the nonlinear term is negligible and the transmitted signal of the ring cavity reduces to the standard expression

$$I_T = I_{in}\{1 + C\cos\phi_0\}T \tag{8}$$

for this optical cavity. Here the intensity of transmitted signal scales linearly with that of the input signal (see Fig. 6*a*) its

magnitude depending on the degree to which the input signal frequency is resonant with the cavity. Tuning the length of the cavity, thereby varying the phase ϕ_0, leads to the familiar resonant transmission peaks characteristic of optical cavities. Returning to the nonlinear equation a corresponding plot of transmitted intensity as a function of input intensity is shown in Fig. 6*b*. The nonlinear form of this curve is the signature of optical bistability, of interest because of its application to all optical logic elements. For example, this particular curve shows switching action and memory in which at a critical input intensity the output signal switches to a higher value but on the return cycle switches down for a reduced input intensity due to optical hysteresis. A stable and reproducible operation is required for such application. However, there are parameter conditions, for the input intensity, and cavity finesse for these systems for which the transmitted signal exhibits a behaviour far from this ideal, manifesting not only pulsating instabilities but also full chaotic characteristics. Such regions are schematically indicated on the bistability curve (Fig. 6*c*).

To understand this behaviour we need to examine more closely the mapping behaviour of equation (6) as shown in Fig. 7*a*. Intersection of this curve with the line $I_{n+1} = I_n$ gives the stationary solution to the mapping. Starting from an arbitrary value of I_n, the corresponding value of I_{n+1} (vertical intersection with $F(I_{in}; C; I_n)$) is then the new value of I_n (horizontal intersection with line $I_{n+1} = I_n$). Successive iteration generates a spiral of successively decreasing steps which converge to a single point intersection shown. This is then a stable single point solution. In time, the iteration steps are then transients which die out to this steady-state solution. Similar constructions are shown in Fig. 7*b* and *c* for two higher values of C; the input intensity could, of course, be used as an alternative control parameter. As seen in equation (6) this is manifested as an increase in amplitude of the map. In Fig. 7*b*, successive iterations, do not converge to a single point but stabilize to a two-point solution; shown by the intersection of the iterations with the mapping function $F(I_{in}; C; I_n)$. The corresponding signal in time, therefore, shows that after transients have died out the transmitted signal exhibits periodic oscillation or limit cycle behaviour. For further increase in C, the oscillatory signal successively bifurcates to yield oscillations which are each double the period of the preceeding ones; the so-called period doubling sequence, as shown in Fig. 2 for laser systems. Ultimately for sufficiently high C a chaotic solution is obtained for which, as seen in Fig. 7*d*, successive bifurcations never converge to fixed points. This figure also shows that a small change in the starting conditions, value of I_n, will soon result in wildly different iterative steps; unlike the stable and periodic solutions such behaviour which characterizes deterministic chaos is often referred to as being sensitive to initial conditions. As such a small difference in the initial condition is amplified by many operations. Mathematically, this is quantified by the Lyapunov exponent λ which for this sytem is

$$\lambda = \log \frac{I_{in} C}{2} \qquad (9)$$

In general, a positive Lyapunov exponent implies exponential separation of nearby trajectories, the signature of deterministic chaos, while a negative exponent implies exponential contraction, the signature of an attracting fixed point. For chaotic behaviour one, therefore, requires $I_{in}C/2 > 1$, whereas bistable action without the presence of instability requires $I_{in}C/2 < 1$. Evidently a transition to chaos may then occur on increasing the input intensity or the value of the parameter C. For convenience, we have assumed that the medium responds instantaneously to the field or more precisely the relaxation time of the medium is much shorter than the cavity round trip time of the field. For systems in which the converse situation applies bistable operation is favoured although even here sideband instabilities may arise.

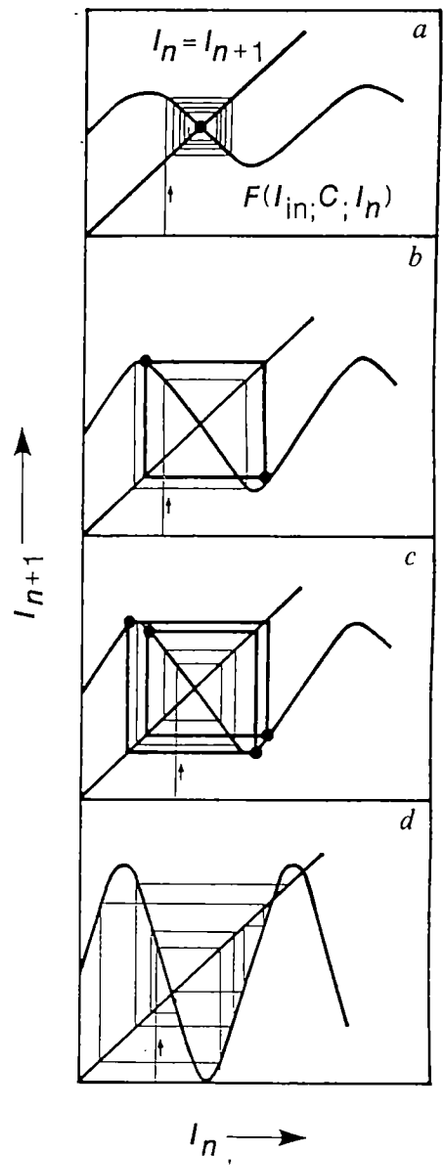

Fig. 7 Graphical solutions of one dimensional map $I_{n+1} = F(I_{in}, C, I_n)$ for various values of control parameter C. The line $I_n = I_{n+1}$ is the condition when the transmitted signal does not change with successive iterations. *a*, A fixed point or steady-state solution I_s for the field in the cavity since successive iterations converge to the single intersection point of the two curves. *b*, An increased value of C, shows the iterations to stabilize on a two-point solution corresponding to a periodic output in time. For further increase in the value of C, a four-point solution is obtained (*c*); that is iterations here have to cycle twice before repeating themselves so corresponding to a periodic oscillation of twice that for the trace *b*. This period doubling behaviour repeats as the control parameter C is further increased until a value is reached when iterations no longer repeat themselves. This is shown in the trace *d* which characterizes an example of chaotic behaviour. We note that the stable and periodic solutions (traces *a*–*c*) are invariant with the starting value of I_n. In contrast, the chaotic trajectory of trace *d* is very sensitive to this initial condition; following a very different path for even the smallest change. The time series of Fig. 2*A* are representative of the behaviour described here.

Observations of these phenomena, although still limited, have been made in various optical systems such as hybrid bistable devices, and all optical bistable systems. In the hybrid system, nonlinearity in a transparent dielectric medium is caused by an externally-applied voltage rather than by the laser signal itself. The impressed voltage is coupled to the transmitted light signal

through a controllable electronic delay with variable gain which serves as the control parameter of the system. On increasing the feedback gain the transmitted optical signal undergoes a period doubling bifurcation though only up to period eight before becoming chaotic. Here[31] as in many other systems, both passive and active, the effect of external noise[32] interrupts the otherwise infinite series of period doublings to create what is termed a bifurcation gap.

The first observation of bifurcation to periodic and chaotic states in an all optical bistable system was made with a single mode optical fibre as the transparent nonlinear medium in a ring cavity[33], the refractive index here being directly modified by the input intensity through the Kerr effect. Here, the high intensities required to induce sufficient nonlinearity precluded the use of a continuous wave (cw) input source and instead a mode-locked train of intense short pulses, separated in time by an amount equal to the round trip time of the ring cavity, was used. Each pulse is, in effect, an iterative step in which the signal of one pulse in circulating the ring cavity adds to the signal of the next incoming pulse, the process repeating for the whole train. Since bifurcations are caused by the interference between the incident field and cavity field which, suffers a nonlinear phase shift in each round trip of the cavity (see equation (6)), the transmitted signal is evidently modified by the intensity of the pulses. With this system period doubling followed by chaos was observed.

The most fundamental of all nonlinear optical systems is nevertheless, one containing a two-level medium as originally analysed by Ikeda for a ring cavity[33]. Near resonant excitation of the medium will, for a sufficiently intense incident signal, cause saturation of the absorption which thereby modifies the associated anomalous dispersion feature of the two-level transition. The mechanism is, in many respects, equivalent to that which gives rise to mode splitting in lasers described earlier for a two-level gain rather than absorptive medium. As for the laser, the intensity dependent change in refraction (dispersion) is resonantly enhanced resulting in considerably reduced power requirements to those used in the fibre experiments. Both atomic and molecular gases are potentially useful media for investigation here, providing discrete levels many of which are in near resonance with available laser lines and approximate reasonably closely to two-level systems. The first corroboration of period doubling routes to chaos in such systems were made in both ring and Fabry-Perot cavities containing ammonia gas near resonantly-excited by pulsed CO_2 radiation[34,35] Recently, experiments have been extended to cw pump laser conditions[36] in which sodium vapour was used as the nonlinear medium. Preliminary results show evidence of period doubling with additional instabilities yet to be fully characterized.

Recognizing the problems that chaotic behaviour may pose for fast all-optical bistable elements, yet, operated in the period doubling window and, in particular, period two oscillation, for which the operational parameter window is largest, they offer the attractive prospect of high-frequency all-optical modulators. But such an operation requires that the relaxation time of the nonlinear medium be much faster than the cavity round trip time, then for small devices (<1 mm in length) the frequency of modulation may, in principle, be in the THz range provided that nonlinear materials may be found with sufficiently short relaxation times. The search for fast large nonlinearities is one of the main efforts in this area.

Conclusions

Nonlinear optics is proving valuable to the fields of nonlinear dynamics and deterministic chaos. On one hand, basically simple optical systems can be constructed exhibiting the most interesting classes of chaotic behaviour enriched by the possibility of a quantum description. On the other hand, lasers and related nonlinear otical devices have a large and growing technical application, and the understanding, control and possible exploitation of sources of instability in these systems has considerable practical importance.

Experimental findings are, in general, not yet sufficiently comprehensive to permit the quantitative analysis necessary to fully test the theoretical models. More carefully controlled experiments are forthcoming from which, along with time series, power spectra and identification of routes to chaos, embedding procedures may be implemented to the attractors describing the dynamical behaviour of these systems.

More detailed discussions of points in this review can be found elsewhere. For laser instabilities see refs 37-39 and also refs 40, 41 which cover both active and passive systems. For passive systems see ref. 42. Comprehensive treatments on the more general principles of deterministic chaos can be found in refs 3, 4. See the recent text on deterministic chaos by Schuster[43]. See refs 8, 9, 44–46 for articles on the general aspects of deterministic chaos, and refs 47 and 48 for discussions on the device application of optical bistable systems.

Observation of an unexplained event from a magnetic monopole detector

A. D. Caplin, M. Hardiman*, M. Koratzinos & J. C. Schouten*

Blackett Laboratory, Imperial College, London SW7 2BZ, UK

A single event was recorded by our 0.18 m^2 inductive magnetic monopole detector, in a total effective observation time of 8,242 hours. None of the monitoring channels that record vibration, radiofrequency interference, and so on, indicated any extraneous cause for this event. An astrophysical estimate of the maximum number flux of monopoles suggests that the chances of a monopole having caused the event are less than 1 in 10^3. Alternative explanations for the candidate are considered, but none of them seem likely.

GRAND unification theories (GUTs) suggest that massive magnetic monopoles (mass $\sim 10^{16}$ GeV) were created profusely during the very early stages of the formation of the Universe, while it was still extremely hot. These electrically neutral monopoles should carry magnetic charge h/e, as do the magnetic monopoles introduced by Dirac[1] more than 50 years ago, or perhaps a small integer multiple of the Dirac charge. The question of how many monopoles are still to be found is much less certain[2]; at one extreme, theories of inflation[3] require that there is at most one monopole in our Universe. There is general agreement that any surviving GUTs monopoles should be moving rather slowly compared with the velocity of light, and consequently interact very weakly with matter; for this reason they are expected to be highly penetrating. The observation 4 years ago by Cabrera[4] of a candidate cosmic magnetic monopole, using a small (10 cm^2) inductive detector, stimulated considerable experimental and theoretical activity[2]. An immediate problem was that Cabrera's candidate, if genuine, implied a number flux of monopoles far higher than astrophysical estimates appeared to allow. This 'Parker' bound[5] arises from considering the outflow of energy from galactic magnetic fields to magnetic monopoles accelerated by passing through them, and comparing it with the rate at which the fields can be regenerated. Although there are some uncertainties[6], the limit seems to be $\sim 10^{-15}$ cm^{-2} sr^{-1} s^{-1}, equivalent, on average, to ~ 1 monopole per 10^6 yr through Cabrera's original detector.

Inductive detectors

The attractive feature of inductive detectors is that they are specific to magnetically-charged particles, and do not respond to electric charges or magnetic dipoles. A magnetic charge traversing a closed conducting loop induces a current, by Faraday's law of induction, that generates magnetic flux equal in magnitude to that carried by the magnetic charge. The magnetic flux associated with a Dirac monopole is 4.1×10^{-15} Wb, equal to $2\Phi_0$, where Φ_0 is the flux quantum of superconductivity. The size of the induced current is independent of monopole speed, and, for an isolated loop, of monopole trajectory. In practical detectors, the loop is made superconducting, so that the induced current is permanent and more easily measurable. The required current sensitivity of nA or better can be attained, non-dissipatively, with SQUIDs (superconducting quantum interference devices). One further use of superconductors in monopole detectors is the incorporation of a superconducting shield around the detector loops, which screens them from external field changes that would otherwise also induce currents. However, the presence of the shield complicates the response of the detector loop to a monopole: the size of induced current is then affected by trajectory, to a degree that depends on relative sizes of loop and shield. It is usual to include also some room temperature magnetic shielding (mu-metal or similar), to reduce the field acting on the superconducting shield.

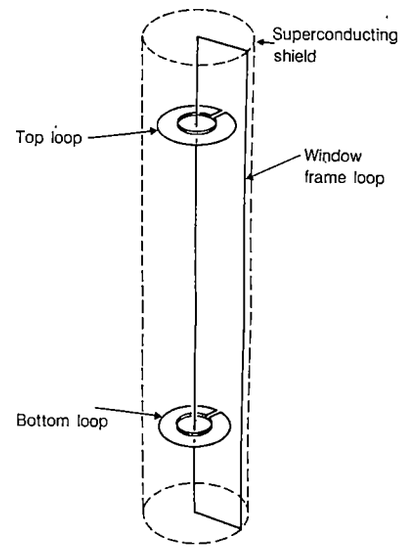

Fig. 1 Configuration of the three independent loops in the Imperial College monopole detector. The superconducting shield, indicated by the dashed line, is 960 mm high and 234 mm in diameter. For clarity, the SQUIDS (positioned near the top of the shield), calibration coils and other details have been omitted.

The design of recent inductive searches[7-10] (none of which reported any candidate monopoles) has been directed towards: (1) greatly enlarged detector area; (2) eliminating, or at least monitoring, as many as possible potential causes of spurious monopole-like events, and (3) the provision of multiple detector loops. Our detector[9,11], designed soon after Cabrera's original report, has three independent detector loops (Fig. 1). The two circular loops (the B and T loops) each has area averaged over 4π of 100 cm^2; if the number flux of magnetic monopoles were to be, for some reason, many orders of magnitude above the Parker limit, the B and T loops would detect events (relatively) frequently. Also, the presence or absence of coincident signals in the B and T loops would provide a limited degree of directional information. The third 'window-frame' (WF) loop serves two purposes: any monopole passing through one of the circular loops would give a confirmatory coincident signal in the WF loop. The other role of the WF loop is to maximize the effective detector area within the available low-temperature and magnetically-shielded volume; it is arranged so that any monopole track through the superconducting shield, even one that has not intersected the WF loop itself, gives a signal. However, the signal

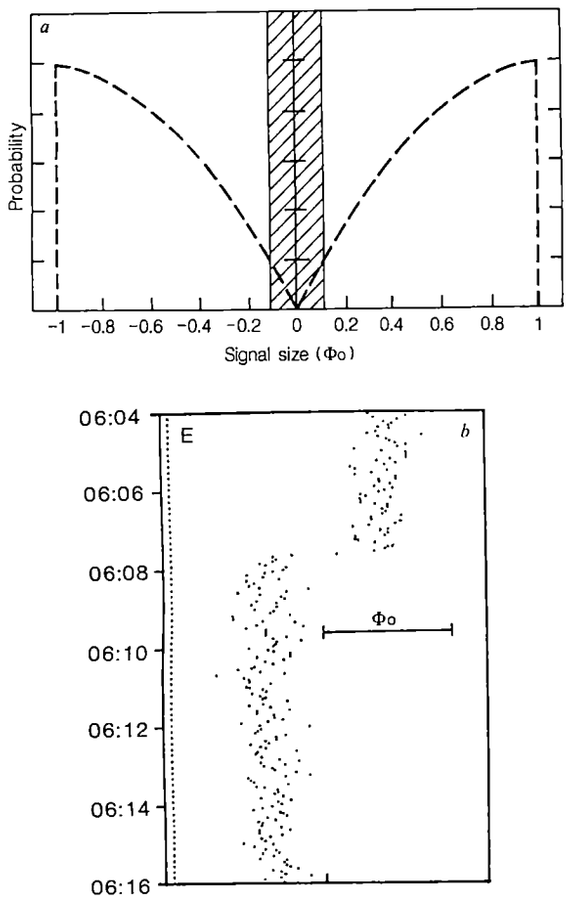

Fig. 2 *a*, The probability distribution of signal sizes in the WF loop, calculated for an isotropic influx of monopoles. Signals within the hatched region are too small to activate the event trigger. *b*, Section of the detailed high-frequency (20 samples per second) record, showing event-160 recorded at 07.06 h (BST) on 11 August 1985. Time is shown in minutes and seconds. The bar indicates the offset corresponding to a change in flux of Φ_0.

size in the WF loop does depend on monopole trajectory, and ranges between 0 and 1 Φ_0 (Fig. 2*a*), and less than half of all trajectories give a measurable coincident signal in the B or T loops[11].

We anticipated three main causes of spurious events: mechanical shock, radiofrequency (r.f.) interference and magnetic field changes. As far as possible, the detector design incorporated isolation from these factors, and in addition we included relevant monitors (accelerometer, r.f. detector and magnetometer). The detector was tested with deliberate external disturbance, at levels of at least two orders of magnitude greater than ambient, and found to be totally insensitive to r.f. interference and changes in external magnetic field. However, it did respond to pressure fluctuations within the helium cryostat, arising from other users of the helium return line; isolation was improved and a pressure monitor added.

The detector loop currents are amplified with a bandwidth of 10 Hz, chosen so that the peak-to-peak noise approaches Φ_0 in magnitude, and thus maximizing the amount of significant information that is collected. A computer controlled data acquisition system (DAS) samples each detector and monitor channel 20 times per second. Shifts in any one of the detector outputs of more than a fraction of a Φ_0 occurring in a period of <100 s trigger storage of the data on floppy disc; this record covers 300 s before the trigger and 100 s after it. Digital filtering of the recorded data allows the bandwidth to be narrowed to $\sim 10^{-2}$ Hz, and the r.m.s. noise to be reduced to $\sim 10^{-2}$ Φ_0. In addition, less detailed data, the maxima and minima in each channel for every 100-s period, are available as a permanent printed record. As a further precaution, the three detector outputs are recorded also on conventional chart recorders.

The detector became fully operational in September 1984, and we have reported previously[9] on its first half-year of operation. During that period, there were about 110 putative events recorded by the DAS; most had immediate and obvious causes, such as low helium level, or cryostat pressure fluctuations. However, there were 12 'non-trivial' events, of which eight were in the T loop (almost certainly caused by a 'weak-link' in the superconducting circuit), three in the WF loop (associated with preceding mechanical shock), and one in the B loop (at a time when that channel was unstable); thus, detailed examination of the record allowed all 12 'non-trivial' events to be discarded as candidate monopoles[9]. The detector continued to run until 30 September 1985, accumulating a total of 8,242 h of active observation. In the second half-year, there were a further 60 putative events, but apart from the one event considered here, there were none in the 'non-trivial' category.

Detailed analysis of the total 170 putative events will be published elsewhere[11], but note that not one of them could be ascribed to two of the anticipated sources of interference: r.f. spikes and external magnetic field changes (r.f. interference in our laboratory is substantial, with capacitor bank discharges in nearby rooms, and a powerful short-wave transmitter at a distance of 50 m; the local magnetic field fluctuates by about 10^{-6} T, with the largest contribution from nearby lifts). This immunity is consistent with the tests on the detector mentioned above. In July 1985, the magnetometer became needed urgently elsewhere, and was removed from the experiment.

11 August 1985 event

At 07.06 h BST on Sunday 11 August 1985, event-160 occurred (Fig. 2*b*), of magnitude $0.83 \pm 0.04\ \Phi_0$ (the uncertainty is primarily that in the calibration of the detector loop), close to the maximum in the calculated distribution of signal sizes in this loop (Fig. 2*a*).

At the time of event-160, the two other detector channels, the B and T loops, showed no obvious coincident offsets; detailed analysis of the data puts limits of 0.01 ± 0.04 (standard deviation, s.d.) and 0.02 ± 0.06 (s.d.) Φ_0 on the signals in those channels. The noise levels in all three detector channels had their usual magnitudes, and application of a range of statistical tests to the data revealed no anomalies. Nor was any obvious abnormal behaviour to be seen in the channels monitoring vibration, r.f. interference and cryostat pressure.

Inspection of the less detailed monitoring record and of the conventional chart records for the days before and after event-160 revealed nothing unusual. The weekly liquid helium refill had been on 6 August, with a moderately noisy period on 7–8 August which always occurs after a refill, and is probably caused by differential thermal expansion within the cryostat. From 11.00 h on 10 August to 09.00 h on 12 August conditions were very quiet, but not unusually so for a weekend. As soon as possible after the event occurred, the detector system, including the monitoring devices, was checked thoroughly for normal operation.

The detector was allowed to continue running normally until 30 September, and then subjected, while still at helium temperatures, to tests. Finally, it was warmed slowly to room temperature, so that an internal inspection could be made.

Later, detailed statistical analysis of the data for event-160 turned up one feature that had no immediate explanation: in quiet (night-time and weekend) conditions the output of the r.f. monitor has a characteristic pattern, with a mean of 5V and peak-to-peak fluctuations of 2V. The r.f. record for event-160 showed the usual pattern, but superimposed on it was a small,

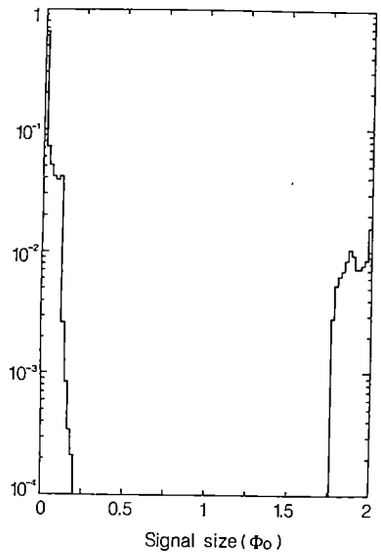

Fig. 3 The probability distribution of signal sizes in the B and T loops, calculated for those monopole trajectories, selected from an isotropic influx, that give a WF signal in the range 0.78–0.88 Φ_0. Positive and negative signals are equally likely.

though statistically highly significant, increase of 100 mV in the mean level, coincident in time with the event itself. We believe this shift to be a consequence of the offset in the WF channel, and it is, therefore, simply an instrumental artefact. The essence of the mechanism linking the two channels is as follows: in quiet conditions, ~90% of the recorded r.f. interference is self-generated, by the digital pulses transmitted between the DAS and its controlling computer. Thus, the pattern of binary digits representing the signals in the various channels is itself the prime determinant of the r.f. level. Event-160 caused a sign change in the output of the WF loop, and the sign is read by the DAS as the most significant bit. The sign bit was always positive before the event, and negative afterwards, and thereby altered the radiated r.f. interference in a systematic fashion. In practice, the mechanism so far described is complicated by the presence in the r.f. monitor of a peak sample- and-hold amplifier with 0.1 s time constant (its function is to ensure that fast r.f. spikes are recorded properly), so that there is in effect a convolution of the r.f. radiated over a period of a few tenths of a second. This complication removes the straight one-to-one relationship between the digit pattern in the WF channel, say, and the recorded r.f. level. However, a simple statistical test on the data for event-160 demonstrated that such an effect was present: because the mangetometer was at that time disconnected, its channel to the DAS was digitized as a small number fluctuating about zero. A correlation with the r.f. channel showed that the consequent alternation of sign sometimes produced changes in the r.f. level of ~150 mV in the correct sense. That the effect was not always present, and that when it was there it gave an offset slightly larger than the 100 mV increase associated with event-160, is understandable in terms of the effect of the peak sample-and-hold amplifier. An experimental test was then made in quiet nightime conditions, using a square-wave oscillator at about 0.5 Hz connected to the WF channel of the DAS. Again, a response in the r.f. channel could be produced.

Thus all our checks show that event-160 took place at a time when the detector was functioning properly, and in the absence of any indication of external interference.

The record of event-160 meets the 'risetime' criterion that can be imposed: relic monopoles, if they exist, are believed to be moving rather slowly, $v/c \sim 10^{-3}$, but it is unlikely that their speed is orders of magnitude less than that[2]. Consequently, the transit time of a monopole through our detector should be of the order of microseconds. The 10-Hz bandwidth of the amplified detector loop outputs is equivalent to a 65 ms risetime (0–90%) for a step input; the record of event-160 shows that its risetime is less than two sampling periods (100 ms), and is certainly consistent with a step input, as would be given by a monopole.

We have calculated the distribution of event sizes in the B and T channels for monopole trajectories giving WF signals in the range 0.78–0.88 Φ_0 (Fig. 3). About 70% of such tracks give signals that are $<0.1\ \Phi_0$, which would be below the noise level, so that the absence of a signal in either the B or T channels coincident with event-160 in the WF channel is consistent with that event being caused by a monopole. Furthermore, if some signal of improbable size had been seen in either of those two channels, it would have indicated the presence of a spurious cause for event-160.

Possible explanations

Unauthorized interference. Appropriately sized offsets can be induced manually, by adjusting the SQUID control unit, but our attempts to do so were not fast enough to be recorded as risetime limited events. Also, tests showed that it was practically impossible to enter and leave the laboratory without there being some trace on the accelerometer. On these two counts, we believe that this explanation can be discounted.

Electronic fault. An offset generated in the WF loop SQUID control unit could mimic a monopole. On one occasion we have had such a fault, which produced temporary offsets of $\sim 20\ \Phi_0$ that lasted for a few minutes, and recurred several times in a month. Faults of this kind could have any size up to $\sim 10^3\ \Phi_0$, and would be likely to recur, particularly if the control unit is given some mechanical shock. After event-160, none of these symptoms were apparent. At the end of our observation period, all three SQUID control units were examined for evidence of electrical and mechanical failure. None was found, apart from some mild corrosion on a printed circuit board in the WF unit; that particular board was remote from the section of the unit that could easily produce offsets.

A fault in the data acquisition system can be excluded because of the 'back-up' chart recorder which showed an appropriate offset corresponding to event-160.

Mechanical shock. As described previously[9], we have seen several events, particularly in the WF loop, that have been induced by mechanical shock; sometimes these have been accompanied by small offsets in the B loop. The mechanism for this response to shock is, we believe, small movements and distortions of the detector loop assembly within the superconducting shield, which alter slightly the coupling of residual flux into the loops; the design of the B and T loops makes them intrinsically less sensitive than the WF loop to this effect.

The accelerometer is mounted at the top of the cryostat, and responds to accelerations in a single direction (in directions perpendicular to its axis, the sensor response is down by about two orders of magnitude). Consequently, no quantitative correlation can be expected between the size of an event induced by this mechanism, and the recorded shock amplitude. However, we found a well-defined trend linking the two (Fig. 4).

Throughout the 400 s detailed record of event-160, the vibration level was $<5\times10^{-4}\ g$, and for the previous 20 h had not exceeded $2\times10^{-3}\ g$ (weekday peak levels are up to $10^{-1}\ g$). The low level of vibration at the time of event-160, and for an extended period before and after, sets it well away from the trend of Fig. 4, suggesting that the event was not caused by mechanical shock.

Motion of trapped flux in the shield. When it was cooled down, the superconducting shield surrounding the detector loops trapped the residual magnetic flux, estimated to correspond to a field of about 10^{-9} T (the field inside the room temperature

nagnetic shields). In principle, this flux is thermodynamically netastable, and if it were to move, it could simulate the passage of a monopole. Because the WF loop is coupled strongly to the shield, whereas the B and T loops are effectively decoupled, such flux motion would be likely to generate a larger signal in the WF loop than in the other two channels.

Movement of pinned flux can be activated thermally (although it may be possible to induce motion with mechanical shock, and in other ways), and so after the initial cooldown we followed the standard procedure of 'annealing' the shield, by maintaining it for some time above its usual operating temperature. Since then, there have been several occasions on which refilling with liquid helium has been delayed, and in consequence the shield has warmed slightly. Thus, any flux that was prone to move would most probably have done so during those periods. Also, the probability of flux depinning declines slowly (logarithmically[12]) with time.

Our detector is certainly much less stable when the helium level is low (and we, therefore, exclude such periods from the total of active observation time), but the data indicate that causes other than flux motion in the shield, such as mechanical movement arising from thermal expansion, are the main culprits. In any case, in those periods of low helium level, the offsets in the WF channel were usually $<0.2\,\Phi_0$; on just one occasion there was an offset of $0.4\,\Phi_0$.

Thus, even when the superconducting shield, which is made from 3-mm thick lead, is warmer than usual, we have seen no clear-cut evidence of flux moving in it. Our experience is similar to that of others (B. Cabrera, and H. Frisch, private communications), that low densities of trapped flux in thick superconducting shields are extremely stable.

While we cannot exclude flux motion in the shield as the cause of event-160, the empirical evidence is that it is unlikely.

Flux motion in SQUID sensor. The SQUID sensors are fabricated from blocks of superconductor (niobium), so that they also trap metastable magnetic flux.

Experiments have been carried out on SQUID sensors with short-circuited input terminals (so as to avoid confusion with effects generated external to the SQUID)[13], and it has been demonstrated that mechanical shock, either from the outside or internal shocks from thermal expansion, can induce offsets. These have been interpreted as arising from flux motion within the SQUID. However, those experiments were carried out in trapped fields of $\sim 10^{-4}$ T (ambient field), whereas our sensors are within the magnetic shields and in a field of only $\sim 10^{-9}$ T. There is some evidence (B. Cabrera, personal communication) that such offsets are larger and more frequent the higher the field.

In both the Stanford[7] and the Chicago[8] inductive detectors several offsets were seen, mostly soon after initial cool down, that were attributed tentatively to this cause (the absence of coincidence and also the signal sizes excluded those events as candidate monopoles). However, in those two experiments, the fields at the SQUIDs are respectively 2 and 3 orders of magnitude greater than in our detector, making them substantially more sensitive to this problem.

The evidence from our experiment indicates that mechanical shock from whatever source affects primarily the detector loops, rather than the SQUID sensors themselves: the WF channel responds most to mechanical shock, with occasional associated smaller offsets in the B and T channels; if it were the SQUID sensors that were being affected, we would expect to see uncorrelated offsets occurring at random in all three channels. As at Stanford and Chicago, our detector was much noisier in the first few days after initial cooldown (for example, events 0, 1 and 16, Fig. 4), and we believe that this was associated with relaxation of mechanical strain, in both the detector assembly and the cryostat, rather than in the SQUID sensors. The evidence of a year's experience with the detector, coupled with the reported behaviour of other experiments, gives us no reason to attribute event-160 to flux motion within the SQUID sensor.

Inadvertent excitation of calibration coils. Each detector loop is fitted with a toroidal calibration coil which can be energized externally. Event-160 could be simulated by a small current, of the order of 100 nA, being induced in the WF calibration coil. For example, if the insulation between the leads to the coil had broken down, thermoelectric voltages, which are invariably present at the microvolt level, could have generated sufficient current. When checked later, the insulation to these coils was in perfect condition, so we can exclude this possibility.

Mechanical fault in detector. When all other checks had been completed, the detector was warmed slowly to room temperature and examined carefully. Some small lead shavings, typically 1-mm in size, were found on the detector loop formers. Presumably, when the detector was originally assembled, and the close-fitting lead shield was pulled over the formers, these particles were scraped off. Because the particles would be quite strongly diamagnetic when superconducting, the flux coupled into a detector loop would alter if a particle were to move. However, an order of magnitude calculation shows that even in the worst possible case, with the particle adjacent to the wire of the detector loop, the particles would need to be at least 10^2 larger in volume to give an offset of the size required. Consequently, we can rule out this mechanism.

In all other respects, the detector assembly was found to be in pristine condition.

Cosmic rays. We consider the likely effect of cosmic ray radiation on both the detector electronics and the SQUID sensor. At sea level, the total flux of neutrons produced by cosmic-ray primaries is $\sim 4\times10^{-2}\,\mathrm{cm^{-2}\,s^{-1}}$ for energies >100 keV, and $\sim 3\times10^{-3}\,\mathrm{cm^{-2}\,s^{-1}}$ for energies above 50 MeV (ref. 14); the proton fluxes at those energies are much lower. In the interaction of cosmic ray particles with solid state electronics, the reaction n (or p) + Si → α + heavy nucleus is thought to be the important mechanism[14]. Both reaction products can generate large numbers of electrons, up to 10^6, by ionization, leading to 'soft errors' (spontaneous changes in logic state) in memory circuits. Recently, Nicholls *et al.*[15] have found that, as the incident

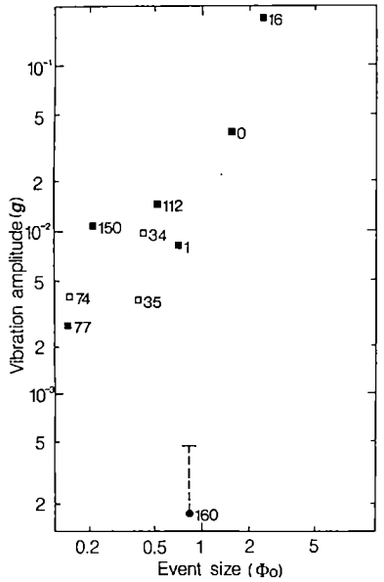

Fig. 4 Correlation between mechanical shock and event size in the WF channel. The shock is that measured at the top of the cryostat and the events are numbered in chronological order. ■, Events with simultaneous (within the 50-ms time resolution of the data acquisition system) shock and event; □, events with preceding shocks, as discussed in ref. 9. ●, Event-160 (the attached bar indicates the maximum shock during the entire 400 s detailed record of the event).

particle energy increases from 20 to 50 MeV, the soft error rate in a variety of devices rises sharply.

Ziegler *et al.*[16] have subjected a small superconducting inductive magnetic monopole detector (with identical SQUID electronics to ours) to bombardment with neutrons of energies 10–16 MeV, and a total dose of 8.6×10^8 neutrons cm^{-2} (equivalent to seven centuries of cosmic-ray dose), and observed no offsets in the detector output. However, in the light of Nicholls *et al.*'s most recent data on energy dependence[15], Ziegler has suggested (personal communication) that their experiment on a monopole detector should be repeated at higher neutron energies.

Our detector would have been subjected to a total flux of cosmic-ray neutrons with energies above 50 MeV of $\sim10^5$ cm^{-2}. The active area of semiconductor devices in significant sections of the circuitry is not more than 10^{-1} cm^2; in Si about 10^{-6} α particles are generated per cosmic-ray neutron[14], so we estimate the probability of a soft error type of charge burst as $\sim10^{-2}$ y^{-1}. However, the mechanism by which such an event might affect the SQUID electronics is unclear: any change in the SQUID control logic circuitry would almost certainly lead to offsets orders of magnitude larger than event-160. Another possibility is that defects created during a soft error type of event could change sufficiently the operating point of a device in the analogue section of the circuitry, and so induce an offset.

The behaviour of Josephson junctions under α-irradiation has been studied also[17]. Near the critical current of the junctions, the 'upset' rate per α particle approaches unity. The rate at which α particles are produced by cosmic-ray neutron bombardment is not strongly target dependent, so we may estimate the α-particle flux (generated by neutrons with energies above 50 MeV) incident on our SQUID sensors as 0.3 cm^{-2} yr^{-1}. The SQUID weak link has area $\sim10^{-6}$ cm^2, so that the probability of a cosmic-ray induced SQUID offset is no more than 10^{-6} yr^{-1}. Were such an offset to occur, we would again expect it to be much larger than event-160.

Although the probabilities of these cosmic-ray mechanisms are low, they are finite and cannot be discounted entirely.

Conclusions

So far, we have no obvious explanation for event-160. The total area-time product of our experiment corresponds to 400 'Cabreras', the unit of exposure equivalent to that of Cabrera's original experiment. The exposure of the three other large detectors now totals 800 'Cabreras' (refs 7, 8, 10 and B. Cabrera, personal communication), so that of itself, our candidate is not statistically at odds with the absence of events in the other experiments. At 90% confidence level, the three other experiments taken together give an upper bound on the cosmic monopole flux of 2×10^{-12} cm^{-2} sr^{-1} s^{-1}; if our experiment and its candidate event are included, there is a lower bound (at 90% confidence level) on the flux of 5×10^{-14} cm^{-2} sr^{-1} s^{-1}, which is still two orders of magnitude above the Parker limit. None of the alternative explanations that we have discussed here for event-160 seem particularly likely, and it is clearly possible that some yet unidentified cause was responsible for it. The results from the larger inductive detectors that are now under construction should help to resolve the puzzle.

Molecular distinction between fetal and adult forms of muscle acetylcholine receptor

Distinct classes of acetylcholine receptor channels are formed when Xenopus *oocytes are injected with combinations of the bovine α-, β-, γ- and δ- or the α-, β-, γ- and ε-subunit-specific messenger RNAs. The conductance and gating properties of the two classes of channels, in conjunction with the developmental changes in the muscular contents of the mRNAs, suggest that replacement of the γ-subunit by the ε-subunit is responsible for the functional alteration of the receptor during muscle development.*

DIFFERENT forms of the nicotinic acetylcholine receptor (AChR) occur in mammalian skeletal muscle during development. The AChR is present predominantly at the neuromuscular junction in adult muscle, whereas in fetal muscle, as well as in denervated adult muscle, the AChR is also found in the non-junctional membrane. The junctional and non-junctional types of AChR channels differ in conductance and gating properties[1-3]. During formation of the neuromuscular contact, two classes of AChR channels coexist in the same muscle fibre[4-7]. Some reports suggest that the different forms of the AChR are

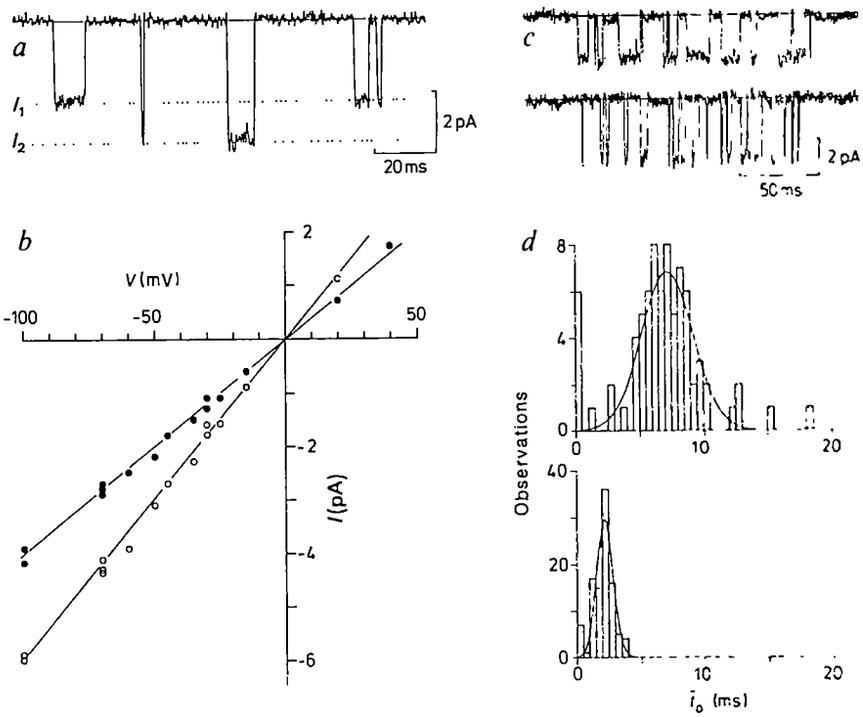

Fig. 1 Properties of ACh-activated single-channel currents in oocytes injected with the calf AChR α-, β-, γ-, δ- and ε-subunit-specific mRNAs. *a*, Single-channel currents activated by 0.5 μM ACh. Outside-out patch. Inward current downwards. Membrane potential, −60 mV. Low-pass filtering at 1 kHz (−3 dB). The short interruptions of the elementary currents occurring in the time range of tens of microseconds are largely attenuated. Two classes of elementary currents are observed and are marked by I_1 and I_2 (dotted lines). *b*, Single-channel I-V relations. Each point is the mean amplitude of at least 20 elementary currents. Data from four outside-out patches. Straight lines are linear regression lines and indicate channel conductances of 40 pS (filled symbols) and 60 pS (open symbols). Interpolated current reversal potentials are 0.6 mV and 0.5 mV, respectively. *c*, Bursts of single-channel currents activated by 10 μM ACh. Cell-attached patch recording. Two bursts recorded on the same patch are shown. Note that current pulses in the two bursts have different mean amplitudes of 2.3 pA and 3.4 pA. Membrane potential of −70 mV was estimated using single-channel conductances of 40 pS and 60 pS and the mean reversal potential of single-channel currents. In three experiments, the oocyte resting membrane potential was measured during patch current recording using an intracellular microelectrode. The reversal potential determined by interpolation of inward and outward currents was −10 ± 2 mV. *d*, Distribution histograms for the average durations of elementary currents during single bursts. Each entry represents the mean of the durations of all elementary currents occurring in a single burst ($\bar{t}_o$). Upper graph represents measurements on 40-pS conductance channel (77 bursts), lower graph on 60-pS conductance channel (101 bursts). Continuous lines are single gaussians. The left-most bins in both graphs and the two right-most bins in the upper graph were not taken into account. Means of the two distributions are 7.2 ± 2.0 ms (n = 69) and 2.3 ± 0.6 ms (n = 94). Cell-attached patch. Estimated membrane potential was −70 mV (that is, −60 mV driving potential). A burst was defined as any sequence of elementary currents separated by a closed interval longer than 50 ms. This value was chosen after inspection of the distribution of the closed intervals of the whole current record. It was characterized in both cases by a short component (5.4 ms and 6.4 ms average duration, >95% of the total area of the distribution in both cases) and two much longer components with durations of several hundreds of milliseconds. Bursts consisting of less than five current pulses were excluded.

Methods. The calf AChR α-, β-, γ-, δ- and ε-subunit-specific mRNAs were synthesized *in vitro*[25,28], combined in a molar ratio of 2:1:1.1:1 and injected into *Xenopus laevis* oocytes (total mRNA concentration, 160 ng μl^{-1}; average volume injected per oocyte, ~50 nl). Whole-cell current measurements[27,28] were made on oocytes after incubation[26] for 2–3 days. Single-channel current measurements were made on oocytes after 2–5 days' incubation followed by removal of the follicular cell layer and the vitelline membrane[28,36]. All single-channel current recordings were carried out at 21 ± 1 °C. In experiments with outside-out patches, pipettes[28] were filled with a solution of the following composition (in mM): KCl, 20; KF, 80; $MgCl_2$, 1; EGTA, 10; HEPES (*p*H 7.2), 10. The extracellular solution had the composition (in mM): NaCl, 115; KCl, 2.5; $CaCl_2$, 1.8; HEPES (*p*H 7.2), 10. Patch membrane potentials of outside-out patches were obtained by correcting the pipette potential by −5 mV for liquid junction potentials[37]. In records from cell-attached patches, the pipette was filled with extracellular solution with ACh added at 0.5–1 μM or 10 μM. Patch-clamp currents were stored on magnetic tape, filtered at 1 kHz (−3 dB), digitized at 0.2-ms intervals and analysed in a PDP 11/73 computer by a semi-automatic procedure to compute distributions of current amplitudes and durations[38]. Distributions of amplitudes were fitted with one or two gaussians and distributions of durations by one or two exponential components; those with two components were made by maximizing the likelihood function[39].

structurally distinct[8]. The mammalian muscle AChR is thought to have a subunit structure of $\alpha_2\beta\gamma\delta$, as is the case for the *Torpedo* electroplax AChR[9–11]. The primary structures of all four subunits of fish[12–17] and mammalian AChRs[18–24] have been elucidated by recombinant DNA techniques. In addition, a novel subunit, termed the ε-subunit, has been discovered by cloning and sequencing the DNA complementary to the calf muscle messenger RNA encoding it[25]. cDNA expression studies with *Xenopus* oocytes[25–27] have indicated that the calf ε-subunit, which shows higher sequence homology with the γ-subunit than with any other subunit, can replace the *Torpedo* γ-subunit to form the functional receptor in combination with the *Torpedo* α-, β- and δ-subunits. Single-channel current measurements have indicated that hybrid AChRs composed of subunits from the two species form channels possessing different gating behaviour[28]. These findings raise the intriguing possibility that the different forms of the AChR observed during muscle development may arise from different combinations of the subunits.

One approach to this issue would be to produce AChR channels in *Xenopus* oocytes by microinjection of various combinations of the subunit-specific mRNAs and to compare the conductance and gating properties of these channels with those of native AChR channels in fetal and adult muscle. We report here that oocytes injected with mRNAs specific for the α-, β-, γ-, δ- and ε-subunits of the calf muscle AChR yield two distinct classes of AChR channels. In contrast, only one of these two channel classes is formed in oocytes injected either with the α-, β-, γ- and δ-subunit-specific mRNAs or with the α-, β-, δ- and ε-subunit-specific mRNAs. The two classes of channels, designated $AChR_\gamma$ and $AChR_\varepsilon$ respectively, differ in conductance and gating behaviour; $AChR_\gamma$ is similar in single-channel properties to the AChR in fetal calf muscle, whereas $AChR_\varepsilon$ resembles the AChR in adult bovine muscle. This finding, together with the developmental changes observed in the contents of the γ- and ε-subunit mRNAs in bovine muscle, suggests that the different properties of the fetal and adult muscle AChRs are a result of the γ-subunit being replaced by the ε-subunit during muscle development.

AChR channels from five subunits

The mRNAs specific for the α-, β-, γ-, δ- and ε-subunits of the calf muscle AChR were synthesized by transcription *in vitro* of the respective cDNAs as described previously[25,28]. The five subunit-specific mRNAs were combined and injected into *Xenopus* oocytes. Figure 1*a* shows a record of acetylcholine (ACh)-activated single-channel currents from an outside-out membrane patch isolated from an oocyte implanted with the five AChR subunits. The distribution of current amplitudes is characterized by two well-separated peaks of mean amplitude 2.6 pA and 3.9 pA (at −60 mV membrane potential). The single-channel current–voltage (I–V) relations of both classes of

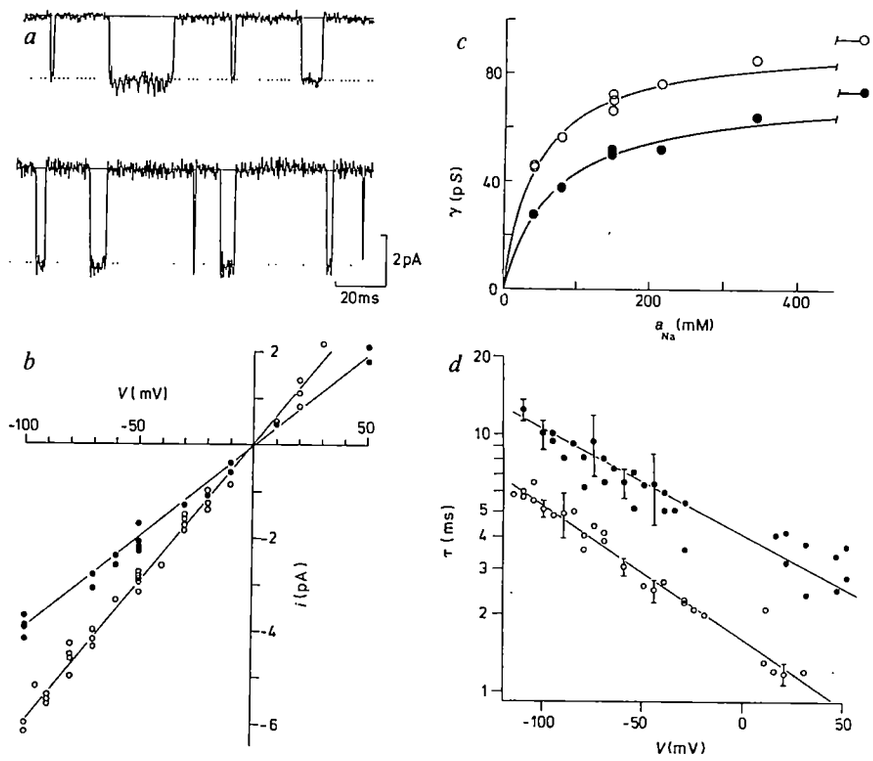

Fig. 2 Properties of ACh-activated single-channel currents in oocytes injected with the α-, β-, γ- and δ-subunit-specific mRNAs ($AChR_\gamma$) or with the α-, β-, δ- and ε-subunit-specifit mRNAs ($AChR_\varepsilon$). *a*, Single-channel currents activated by 0.5 μM ACh. Outside-out patches. Inward current downwards. Upper trace, recording from an oocyte with $AChR_\gamma$. Mean current amplitude, 2.4 pA. Lower trace, recording from an oocyte with $AChR_\varepsilon$. Mean current amplitude, 3.6 pA. Membrane potential, −60 mV in both experiments. Low-pass filtering at 1 kHz (−3 dB). *b*, Single-channel I-V relations of the $AChR_\gamma$ (filled symbols, 7 outside-out patches) and the $AChR_\varepsilon$ channel (open symbols, 6 outside-out patches). Straight lines are linear regression lines. Their slopes are 39 pS and 59 pS for the $AChR_\gamma$ and $AChR_\varepsilon$ channels, respectively. Interpolated current reversal potentials are 1.3 mV and −0.2 mV. *c*, Conductance (γ) versus Na^+ activity (a_{Na}) for $AChR_\gamma$ (filled symbols) and $AChR_\varepsilon$ (open symbols). Slope conductance was measured at −20 to −100 mV driving potential on outside-out patches. The I-V relations in this region were fitted by linear regression lines. The pipette solution was as described in Fig. 1 legend. The extracellular solution contained 50–500 mM Na^+ and 1.8 mM $CaCl_2$. The Na^+ activities are those for pure NaCl solutions[39]. No correction for the differences in osmolarity of various extracellular solutions was made. Continuous lines represent hyperbolas according to $\gamma = \gamma_{max} a_{Na}/(a_{Na} + K_m)$, where γ_{max} is the limiting conductance and K_m is the Na^+ activity at which the channel conductance is half-maximal. Limiting conductances of 75 pS for $AChR_\gamma$ and 93 pS for $AChR_\varepsilon$, obtained by a nonlinear least-squares fit, are indicated by the symbols on the right. Half-saturating Na^+ activities were 73 mM for $AChR_\gamma$ and 46 mM for $AChR_\varepsilon$. *d*, Average duration (τ) of elementary currents versus membrane potential in semilogarithmic coordinates. Filled symbols, $AChR_\gamma$ channel; open symbols, $AChR_\varepsilon$ channel. Data are from seven (filled symbols) and six (open symbols) cell-attached patch recordings. Each point represents a determination of τ from the distribution of single-channel currents or from noise analysis of the single-channel current record (see Methods). Bars indicate 1 s.d. from 3–7 patches. Lines represent linear regression fits as specified in Table 1.

Methods. To avoid slight contamination by aberrant AChR channels resulting from injection of the α-, β- and δ-subunit-specific mRNAs (see text), oocytes were injected either with the α-, β-, γ- and δ-subunit-specific mRNAs or with the α-, β-, ε- and δ-subunit-specific mRNAs in a molar ratio of 2:1:10:1 (total mRNA concentration, 6.4 ng μl^{-1}; average volume injected per oocyte, ~50 nl). Patch current recording as described in Fig. 1 legend. In cell-attached recordings, the oocyte membrane potential was usually measured with an intracellular microelectrode (filled with 3 M KCl, 10–20 MΩ d.c. resistance) during the patch current recording. In some experiments, the oocyte membrane potential was estimated from the channel slope conductance and an assumed reversal potential of −10 mV. The average slope conductances were 40 ± 1 pS ($n = 9$) for the $AChR_\gamma$ and 59 ± 2 pS ($n = 7$) for the $AChR_\varepsilon$ channel. Current reversal potentials from whole-cell I-V relations were −11 ± 2 mV ($n = 5$) for the $AChR_\gamma$ and −9 ± 4 mV ($n = 3$) for the $AChR_\varepsilon$ channel. Current reversal potentials from single-channel I-V relations were −9 mV and −10 mV (mean of two patches) for the two channels. The average duration of elementary currents was estimated in two ways. In recordings with low channel opening frequency, where few superpositions (<5%) of elementary currents occured, τ was estimated as the longer of the decay constants fitted to the distribution of current durations[28]. In recordings where elementary currents superimposed more frequently, τ was estimated using standard techniques of noise analysis[31]. Segments of current record were low-pass filtered (0.8 kHz, 4-pole Butterworth) and digitized at 0.5- or 1-ms intervals. Power spectral densities were calculated on 512-point data sections by an integer Fast Fourier Transform routine on a PDP 11/34 computer; 30–80 such spectra were averaged. For the single-channel records close to the reversal potential, control spectra obtained at the current reversal potential were subtracted. Single lorentzians were fitted by eye to the difference spectra. τ was calculated from the corner frequency, f_c, of the lorentzian as $\tau = 1/(2\pi f_c)$.

currents were linear, and their reversal potentials were close to 0 mV (Fig. 1*b*). These observations suggest that the two classes of ACh-activated currents reflect the opening of two distinct AChR channels coexisting in the oocyte membrane. Their conductances were 40 ± 1 pS and 60 ± 2 pS (mean ± s.d., $n = 4$).

The two classes of currents were clearly distinguishable from each other when activated by desensitizing concentrations of ACh (>5 μM). Figure 1*c* shows two examples of ACh-activated currents recorded from the same cell-attached membrane patch in the presence of 10 μM ACh. The currents occurred in bursts that lasted for hundreds of milliseconds and were separated by silent intervals of much longer duration. This pattern is comparable to that of ACh-activated currents observed in frog and rat muscle at high ACh concentrations (>5 μM)[29,30]. It reflects fluctuations of single AChR channels between long-lived inactive states (inter-burst intervals) and active states (bursts) where a given channel switches repeatedly between open and closed states. Within a given burst, all resolved elementary currents had a similar amplitude. However, bursts fell into two classes with respect to current amplitude. The average sizes of elementary currents in 178 bursts, measured in this patch at about −60 mV driving potential, were 2.3 pA and 3.4 pA, respectively, corresponding to the two current amplitudes observed at low ACh concentrations. A similar separation of bursts into two classes of amplitudes was observed in nine other patches examined at high ACh concentrations, the average ratio of large to small current amplitudes being 1.5 ± 0.04 ($n = 10$). The occurrence of two separate classes of bursts thus indicates that two populations of AChR channels characterized by differing conductances were formed in oocytes injected with the five subunit-specific mRNAs.

The relative frequency of occurrence of each class of currents varied with different oocytes and with different patches from a given oocyte. In every patch, however, the 40-pS conductance channel was observed more frequently than the 60-pS conductance channel. In records from 10 patches, 73 ± 10% of all currents were openings of the 40-pS conductance channel. This may be due to a higher density of the 40-pS conductance channel or to different activation kinetics of the two AChRs.

The two classes of AChR channels also differ in their gating properties. Figure 1*d* shows the distributions of average durations of elementary currents measured from one patch during bursts of the 40-pS (upper graph) and the 60-pS conductance channel (lower graph). The average duration was 7.2 ms for the 40-pS conductance channel and 2.3 ms for the 60-pS conductance channel.

AChR channels from four subunits

Oocytes were injected with various combinations of four of the five subunit-specific mRNAs and then tested for response to

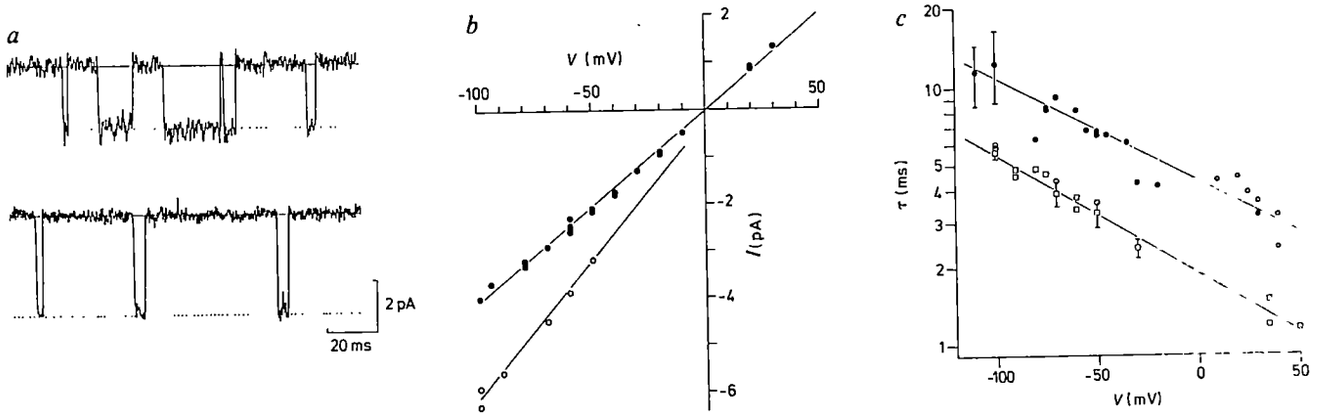

Fig. 3 Properties of ACh-activated single-channel currents in fetal and adult bovine muscle. *a*, Single-channel currents activated by 1 μM ACh in fetal (upper trace) and adult (lower trace) muscle. Outside-out patches. Inward current downwards. Membrane potential, −60 mV. Low-pass filtering at 1 kHz (−3 dB) Mean current amplitudes are 2.5 pA and 3.9 pA. *b*, Single-channel *I-V* relations of ACh-activated currents in fetal (filled symbols, four outside-out patches) and adult (open symbols, two outside-out patches) muscle. The regression lines indicate slope conductances of 40 pS and 59 pS for AChR channels in fetal and adult muscle, respectively. Interpolated current reversal potential is 1.2 mV for fetal muscle. Extrapolated reversal potential is 7 mV for adult muscle. *c*, Average duration of elementary currents against membrane potential in semilogarithmic coordinates from fetal (filled symbols) and adult (open symbols) muscle. In fetal muscle, the τ values were derived from four cell-attached patches as described in Fig. 2 legend. In adult muscle, the τ values were estimated from distribution of single-channel current durations (two outside-out patches, open circles) or from the m.e.p.c. decay time constant (four endplates, open squares). Bars indicate 1 s.d. from three or four different experiments. Lines represent linear regression fits as specified in Table 1.

Methods. Recordings of ACh-activated currents through fetal calf AChR channels were made on myoballs maintained in cell culture. Muscle tissue from the leg of a calf fetus (3–4 months gestation), obtained from a local abattoir, was minced, plated and maintained in cell culture as described for fetal rat muscle[40]. After 4–5 days, elongated myotubes had formed and were exposed to colchicine (10^{-7} M) for 12 h, resulting in the formation of rounded myoballs. All experiments were done 5–9 days after plating. Outside-out patches were isolated from myoballs using conventional patch pipettes containing either the same solution as described in Fig. 1 legend or with K^+ replaced by Na^+. This was necessary in experiments on myoballs maintained in culture for more than 6 days because outward currents carried by K^+ were activated at membrane potentials more positive than −60 mV. The membrane potential in cell-attached recordings was estimated from the slope conductance (40±2 pS, $n=4$), assuming a current reversal potential of −10 mV. ACh-activated single-channel currents in adult bovine muscle were measured on sacro-coccygeal tail muscle of cows (*Bos taurus*, 2–5 yr old) at 20±1 °C. Muscles were removed from the region of the last 10 coccygeal vertebrae (S10–S18)[41] and consisted of many bundles of 50–100 fibres. Such bundles were dissected to 'sheets' of 10–20 fibres each and incubated with 1 mg ml^{-1} collagenase (Sigma type I) at 18–22 °C for 3–4 h in Ringer's solution of the following composition (in mM): NaCl, 140; KCl, 4; $CaCl_2$, 1; $MgCl_2$, 1; HEPES (pH 7.2), 10. This was followed by a 10-min exposure to Ringer's solution containing 0.05 mg ml^{-1} protease (Sigma type VII). Myelinated nerves and nerve terminals still attached to the endplate were then visible in edge fibres viewed with Nomarski optics (×16 objective). Single-channel current recordings were made in the perijunctional region (within a distance of 20–30 μm of the endplate) of four fibres from two muscles. Patch pipettes had a tip diameter of 0.5–0.8 μm. Pipette and extracellular solutions were as described in Fig. 1 legend, except that 80 mM glucose was added to give the same osmolarity as Ringer's solution (290 mOsm). M.e.p.cs were measured in sacro-coccygeal muscle bathed in Ringer's solution at 20±1 °C, using a conventional two-microelectrode voltage-clamp circuit[2]. The placement of the two microelectrodes within 50 μm of the endplate was verified after each measurement by staining the endplate acetylcholinesterase[42] while the microelectrodes were left in place. M.e.p.cs were low-pass filtered (2 kHz, −3 dB) and digitized at 100-μs intervals. M.e.p.c. decay time courses were fitted by eye with single exponentials. In each fibre, 20–60 m.e.p.cs were measured at each membrane potential. In all experiments, the distribution of the decay time constants had a single peak. The τ values shown in Fig. 3*c* represent means of such distributions.

ACh. Whole-cell current measurements showed that omission of the α-, β- or δ-subunit-specific mRNA virtually abolished the ACh response, whereas omission of either the γ- or the ε-subunit-specific mRNA did not appreciably affect the response as compared with oocytes injected with all five subunit-specific mRNAs. Figure 2*a* shows records of ACh-activated single-channel currents from outside-out patches isolated from oocytes injected with the α-, β-, γ- and δ-subunit-specific mRNAs (upper trace) or with the α-, β-, δ- and ε-subunit-specific mRNAs (lower trace). These oocytes, in contrast to those injected with all five subunit-specific mRNAs, each exhibited only a single class of AChR channels ($AChR_\gamma$ or $AChR_\varepsilon$). The conductance and gating properties of the channels formed in a given oocyte depended on the mRNA combination with which it was injected. The distribution of current amplitudes for the AChR, as well as the $AChR_\varepsilon$ channel was characterized by a single peak at all membrane potentials. The *I-V* relations for both channels in outside-out patches were linear in the potential range of −100 mV to +50 mV (Fig. 2*b*). The average conductance, obtained from both outside-out and cell-attached patches, was 40±1 pS ($n=16$) for the $AChR_\gamma$ and 59±2 pS ($n=13$) for the $AChR_\varepsilon$ channel (Table 1).

The conductance sequence of the two AChR channels for monovalent metal cations was $K^+ > Cs^+ > Na^+ > Li^+$, the respective channel slope conductances, measured in cell-attached patches at low extracellular Ca^{2+} (ref. 28), being 72± 4 pS, 61±3 pS, 50±2 pS and 21±2 pS ($n=3$) for the $AChR_\gamma$ channel and 110±4 pS, 90±5 pS, 60±4 pS and 30±2 pS ($n=3$) for the $AChR_\varepsilon$ channel. Thus, the conductance ratios determined for the four cations were nearly identical for the two AChR channels.

With respect to their conductances, the $AChR_\gamma$ and $AChR_\varepsilon$ channels resemble the AChR channels in fetal and adult rat muscle, respectively[3]. This resemblance is further supported by the conductance–activity curves for Na^+ of the $AChR_\gamma$ and $AChR_\varepsilon$ channels (Fig. 2*c*). These curves were fitted by hyperbolic relations, indicating that the $AChR_\varepsilon$ channel has a larger limiting conductance (93 pS) than the $AChR_\gamma$ channel (75 pS).

The $AChR_\gamma$ and $AChR_\varepsilon$ channels differed not only in their conductance but also in their gating properties. The average duration of elementary currents was estimated from the distribution of current durations[28] and from power density spectra[1,31] of single-channel current records (Fig. 2*d*). In both channels, the average current duration decreased exponentially with more positive membrane potentials, but at all membrane potentials the average duration of $AChR_\varepsilon$ channel currents was shorter by a factor of two to three than that of $AChR_\gamma$ channel currents.

The results described above suggest that oocytes injected with all five subunit-specific mRNAs produce two types of AChR molecules which have different functional properties and are composed of the α-, β-, γ- and δ-subunits and of the α-, β-, δ- and ε-subunits, respectively. We also observed that oocytes injected with no more than the α-, β- and δ-subunit-specific mRNAs exhibited a strong response to ACh. Preliminary

analysis of the AChR channels formed in these oocytes indicates that their conductance and gating properties differ markedly from those of the $AChR_\gamma$ and $AChR_\varepsilon$ channels (our unpublished results).

AChR channels in muscle

To compare the two classes of AChR channels produced in *Xenopus* oocytes with the native bovine AChR channels, we examined the conductance and gating properties of ACh-activated channels in fetal and adult bovine muscle. The upper and lower traces in Fig. 3*a* show ACh-activated currents from outside-out patches isolated from fetal and adult muscle fibres, respectively. The distributions of current sizes in the two experiments were characterized by a single peak with different average values of 2.5 pA (fetal muscle) and 3.9 pA (adult muscle) at −60 mV membrane potential. The I-V relations were linear (Fig. 3*b*), and the average conductance was 40 ± 1 pS ($n = 8$) for the fetal AChR channel and 59 pS (mean of two patches) for the adult AChR channel (Table 1).

Table 1 Single-channel properties of two forms of bovine AChRs expressed in *Xenopus* oocytes and in muscle

AChR channels from	Conductance γ (pS)	Average duration $\tau(-100)$ (ms)	H (mV)
Oocytes with $AChR_\gamma$	39 (7)	10.4 (7)	106
Oocytes with $AChR_\varepsilon$	59 (6)	5.3 (6)	83
Fetal muscle	40 (4)	11.0 (4)	108
Adult muscle	59 (2)	5.6 (6)	93

Regression analysis of i-V and τ-V measurements is shown. Numbers in parentheses refer to numbers of patches, except that two patches and four endplates were used for adult muscle. γ represents the slope of i-V relations measured on outside-out patches. $\tau(-100)$ represents the calculated duration of elementary currents at −100 mV membrane potential obtained from the τ-V relation plotted in semilogarithmic coordinates and fitted by the equation $\tau(V) = \tau(0)\exp(-V/H)$, where $\tau(0)$ is the τ value at 0 mV membrane potential. H represents the shift in membrane potential that causes an e-fold change in the average duration of elementary currents. The $\tau(0)$ values were 4.0 ms ($AChR_\gamma$) and 1.6 ms ($AChR_\varepsilon$) in Fig. 2*d* and 4.4 ms (fetal muscle) and 1.9 ms (adult muscle) in Fig. 3*c*. The correlation coefficients, r^2, were 0.88 and 0.96 (Fig. 2*d*), and 0.92 and 0.98 (Fig. 3*c*). The averages of individual slope conductances, measured between the current reversal potential and −100 mV driving potential in both outside-out and cell-attached patches, were 40 ± 1 pS ($n = 16$) and 59 ± 2 pS ($n = 13$) for the $AChR_\gamma$ and $AChR_\varepsilon$ channels in oocytes, and 40 ± 1 pS ($n = 8$) and 59 pS (mean of 2 patches) for AChR channels in fetal and adult muscle, respectively. The averages of measured τ values at −100 mV membrane potential were 10.2 ± 1.4 ms ($n = 4$) and 5.2 ± 0.4 ms ($n = 3$) for the $AChR_\gamma$ and $AChR_\varepsilon$ channels in oocytes, and 12.5 ± 3.8 ms ($n = 4$) and 5.7 ± 0.4 ms ($n = 6$) for AChR channels in fetal and adult muscle, respectively.

The conductance sequence of the AChR channel in fetal muscle for monovalent metal cations was $K^+ > Cs^+ > Na^+ > Li^+$, with slope conductance values (measured in cell-attached patches at low extracellular Ca^{2+}) of 79 pS, 65 pS, 55 pS and 20 pS (one patch). For the AChR channel in adult muscle, the sequence was $K^+ > Cs^+ > Na^+$ with conductance values of 110 pS, 90 pS and 60 pS, respectively (one patch).

The average duration of ACh-activated elementary currents in fetal as well as adult muscle decreased exponentially with more positive membrane potentials (Fig. 3*c*, filled and open circles). The currents were shorter in adult muscle than in fetal muscle. For example, the average duration at −100 mV membrane potential was 12.5 ± 3.8 ms ($n = 4$) in fetal muscle and 6.0 ms (mean of two recordings) on the perijunctional region of adult muscle. The latter duration is considerably longer than that inferred for junctional channels in adult rat muscle from miniature endplate current (m.e.p.c.) decay times[4–6,32]. We therefore measured m.e.p.c. decay time constant in adult bovine muscle (Fig. 3*c*, open squares). At −100 mV membrane potential, it was 5.6 ± 0.4 ms (four endplates), in good agreement with the average duration determined directly from single-channel current recordings. The voltage dependence of the m.e.p.c. decay time constant was similar to that of the duration of elementary currents (Fig. 3*c*). Thus, the estimates of the size and duration of elementary currents and their voltage dependence in bovine muscle indicate that the AChR channel in fetal muscle is similar

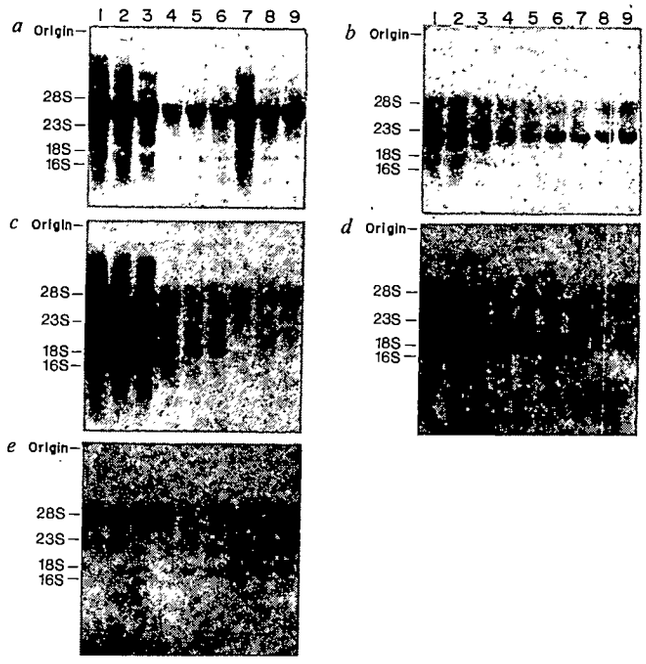

Fig. 4 Autoradiograms of blot hybridization analysis of total RNA from bovine diaphragms at various developmental stages using calf AChR α- (*a*), β- (*b*), γ- (*c*), δ- (*d*) and ε-subunit (*e*) cDNA probes. Bovine diaphragms obtained from a local abattoir were frozen quickly in liquid nitrogen and stored at −70 °C. Fetal age was estimated by fetal body length[43]. Total RNA was extracted by the guanidine thiocyanate method[44]. Samples of total RNA (30 μg each) from diaphragms at various fetal (lanes 1–6) and postnatal (lanes 7–9) stages were denatured with 1 M glyoxal and 50% dimethyl sulphoxide[45], electrophoresed on an 1.5% agarose gel and transferred[46] to a Biodyne nylon membrane (Pall); the ages of the animals were 3.4 months (lane 1), 4.4 months (lane 2), 5.3 months (lane 3), 5.7 months (lane 4), 7.1 months (lane 5) and 8.3 months (lane 6) of gestation and 5 h (lane 7), 25 days (lane 8) and ~2 yr (lane 9) after birth. The hybridization probes used were the 786-base-pair (bp) *BglII*/*ClaI* fragment from clone pcACRα18 (ref. 18; specific activity, 4.6×10^8 c.p.m. μg^{-1}) (*a*), the 1,791-bp *BanI* fragment from pSPcβ (ref. 28; 6.6×10^8 c.p.m. μg^{-1}) (*b*), the 980-bp *HinfI*/*AccI* fragment from pcACRγ5 (ref. 20; 8.4×10^8 c.p.m. μg^{-1}) (*c*), the 1,565-bp *EcoRI*/*XbaI* fragment from pSPcδ (ref. 28; 9.3×10^8 c.p.m. μg^{-1}) (*d*) and the 1,533-bp *BamHI*/*EcoRI* fragment from pSPcε (ref. 25; 8.1×10^8 c.p.m. μg^{-1}) (*e*); the probes were labelled by nick translation[47] with [α-^{32}P]dCTP. After prehybridization, the blots were incubated at 42 °C for 21 h in a solution containing 50 mM sodium phosphate buffer (*p*H 6.5), 5 × SSC (SSC: 150 mM NaCl, 15 mM trisodium citrate), 50% formamide, 0.1% polyvinylpyrrolidone, 0.1% Ficoll 400 (Pharmacia), 0.1% bovine serum albumin, 250 μg ml^{-1} sonicated salmon sperm DNA, 0.1% SDS and 10 ng ml^{-1} ^{32}P-labelled probe. The blots were washed three times, for 5 min each, in 2 × SSC containing 0.1% SDS at room temperature and twice, for 15 min each, in 0.1 × SSC containing 0.1% SDS at 50 °C. Autoradiography was performed at −70 °C for 70 h (*a*, *b*) or 140 h (*c*, *d*, *e*) with an intensifying screen. The size markers used were bovine and *Escherichia coli* ribosomal RNA. The estimated sizes of the α-, β-, γ-, δ- and ε-subunit mRNAs were ~4,500 (ref. 18), ~3,200 (ref. 19), ~2,000 (ref. 20), ~2,200 (ref. 21) and ~1,900 nucleotides, respectively. The ~1,900-nucleotide ε-subunit mRNA was found in both diaphragm and leg muscle RNA. Our previous failure to detect this mRNA species[25] can be ascribed to the use of nitrocellulose filter, which yields weaker hybridization signals than Biodyne nylon membrane; the previous observation of the ~4,200-nucleotide RNA species[25] in poly(A)$^+$ RNA from leg muscle from a fetal calf (4 months gestation) was not reproducible.

to the $AChR_\gamma$ channel expressed in oocytes, whereas the AChR channel in adult muscle and the $AChR_\varepsilon$ channel produced in oocytes share similar properties (Table 1).

AChR subunit mRNAs in muscle

We examined developmental changes in the contents of the five AChR subunit mRNAs in bovine muscle. Total RNA was extracted from diaphragms at various stages of fetal and postnatal development and subjected to blot hybridization analysis using the respective cDNA probes (Fig. 4). One major hybridizable RNA species was observed with the α- (Fig. 4*a*), β- (*b*) or ε-subunit (*e*) cDNA probe, whereas two (or three) major RNA species hybridized with the γ- (Fig. 4*c*) or δ-subunit (*d*) cDNA probe, especially at earlier fetal stages. The larger RNA species hybridizable with the γ- and δ-subunit cDNA probes, as well as the minor, larger RNA species hybridizable with the other cDNA probes, presumably represent incompletely spliced RNA[20,21]. At all the developmental stages studied, significant amounts of the α- (Fig. 4*a*), β- (*b*) and δ-subunit (*d*) mRNAs were found, although the content of the δ-subunit mRNA was smaller at postnatal stages (especially 25 days and ~2 yr) than at fetal stages. In contrast, the contents of the γ- and ε-subunit mRNAs varied markedly during muscle development, showing reciprocal changes. The γ-subunit mRNA was found abundantly at earlier fetal stages (3–5 months gestation), but was hardly or not detectable after birth (Fig. 4*c*). Conversely, considerable amounts of the ε-subunit mRNA appeared only at postnatal stages, and it was not detectable at earlier fetal stages (3–4 months gestation) (Fig. 4*e*). At later fetal stages (7–8 months gestation), appreciable amounts of the γ- and ε-subunit mRNAs coexisted. Analogous experiments with poly(A)$^+$ RNA from bovine leg muscles at different fetal and postnatal stages showed generally similar developmental changes in the contents of the five subunit mRNAs. These results support the notion that replacement of the γ-subunit by the ε-subunit in the AChR complex is responsible for the changes in the properties of the AChR that occur during muscle development[4–6]. The reason for the low content of the δ-subunit mRNA observed at postnatal stages is not known. The possibility that replacement of the δ-subunit may also occur during muscle development cannot be excluded.

Conclusions

Two classes of AChR channels, defined by different conductances and gating properties, are formed in *Xenopus* oocytes injected with the five bovine AChR subunit-specific mRNAs. Only one of these two classes of AChR channels ($AChR_\gamma$) is produced by injection of the α-, β-, γ- and δ-subunit-specific mRNAs, whereas only the other class ($AChR_\varepsilon$) is produced by injection of the α-, β-, δ- and ε-subunit-specific mRNAs. These results suggest that $AChR_\gamma$ and $AChR_\varepsilon$ represent a complex of the α-, β-, γ- and δ-subunits and of the α-, β-, δ- and ε-subunits, respectively.

The two classes of channels, $AChR_\gamma$ and $AChR_\varepsilon$, formed in oocytes have functional properties similar to those of the native bovine AChR channels present in fetal and adult muscle, respectively. This finding, in conjunction with the reciprocal changes in the contents of the γ- and ε-subunit mRNAs observed during muscle development, suggests that the AChR channel in fetal muscle is assembled from the α-, β-, γ- and δ-subunits, whereas the endplate channel in adult muscle is assembled from the α-, β-, δ- and ε-subunits. This conclusion is supported by the observation that the junctional AChR is slightly more acidic than the non-junctional AChR[33]: the bovine ε-subunit contains more acidic residues and less basic residues than does the bovine γ-subunit[25].

The relative contents of the two classes of AChR channels, for example in rat muscle, depend on innervation of the muscle by spinal motoneurones[4,34,35]. Before innervation, the fetal class of channels predominates; during synapse formation, the two AChR classes coexist in the muscle; at later stages of synapse formation, the fetal class is fully replaced by the adult class[5–7,33]. Thus, the shift of the two AChR classes may occur concurrently with the reciprocal changes in the contents of the γ- and ε-subunit mRNAs. It seems plausible to postulate that the nerve terminal exerts control over the synthesis of the γ- and ε-subunits by switching the expression of their genes or by modulating some post-transcriptional events.

We thank Dr R. Eckert for reading the manuscript. This investigation was supported in part by research grants from the Ministry of Education, Science and Culture of Japan, the Mitsubishi Foundation and the Japanese Foundation of Metabolism and Diseases.

Evidence is provided for the existence of a seventh gene in the genome of human T-lymphotropic virus type III/lymphadenopathy-associated virus. The gene is necessary for replication and acts post-transcriptionally to relieve negative regulation of the messenger RNA for the virion capsid and envelope proteins. These observations suggest mechanisms for regulating both the latent and lytic phases of the virus life cycle.

THE retrovirus human T-lymphotropic virus type III/lymphadenopathy-associated virus (HTLV-III/LAV) is the primary aetiological agent of AIDS (acquired immune deficiency syndrome) and associated disorders[1-6]. The clinical consequences of HTLV-III infection range from prolonged asymptomatic states to severe depletion of $T4^+$ helper lymphocytes, characteristic of frank AIDS, and profound degeneration of the central nervous system[1-7]. The variable course of HTLV-III-related disease may reflect the complex life cycle of the virus, now thought to include both latent and lytic states in $T4^+$ lymphocytes as well as a state of limited replication in monocytes and macrophages[8].

To analyse viral factors affecting the HTLV-III life cycle, the effects of defined mutations of the viral genome on the replication and cytopathic potential of the virus have been studied. The HTLV-III genome, like that of other retroviruses, contains three open reading frames, *gag*, *env* and *pol*, which encode, respectively, the capsid proteins, the envelope proteins and non-structural proteins necessary for replication[9-17]. In addition, the HTLV-III genome contains other open reading frames that encode at least three additional proteins not common to most retroviruses[9-12,18,19]. Mutations in two of these open reading frames, the *sor* gene which encodes a protein of relative molecular mass (M_r) 23,000 (23K)[20,21] and the 3′ *orf* gene which encodes a 27K protein[22], do not eliminate the ability of the virus to replicate in and kill T lymphocytes[20]. The *trans*-activator (*tat*-III) gene encodes a 14K protein[23] that post-transcriptionally[24] stimulates HTLV-III long terminal repeat (LTR)-directed gene expression[18,19,25] via an interaction with specific target sequences in the leader of viral messages[26]. Mutations in the 5′ portion of the first coding exon of the bipartite *tat*-III gene destroy the ability of the virus to efficiently synthesize structural proteins and to replicate[27]. These mutations can be complemented in *trans* in cell lines that constitutively express the *tat*-III protein[27].

During these experiments, we found that an additional set of

Fig. 1 Structure and properties of the HTLV-III proviral mutants. The complete HTLV-III provirus on plasmid pHXBc2 (ref. 28), together with the known genes, is shown at the upper left. The solid boxes represent the two coding exons of the *tat*-III gene. The vertical broken line in the 3′ *orf* gene represents a stop codon present in the pHXBc2 provirus[20]. The scale beneath the viral genes represents kilobases. Numbers correspond to those in ref. 9, where the RNA cap site is designated +1. For proviral deletion mutants, the numbers in the plasmid name correspond to the endpoints of the corresponding deletion. All plasmids were made using restriction and modification enzymes, according to manufacturers' suggestions. The 4-bp insertion in the pFS8053 plasmid resulted from treating a *Bam*HI-digested provirus with the large fragment of DNA polymerase I in the presence of nucleotide triphosphates and re-ligating prior to transfection of *Escherichia coli*. Replicative potential of the proviruses was tested by transfection of CsCl-banded DNA into Jurkat (*tat*-III) cells[29] using the DEAE-dextran technique[31]. The values for membrane immunofluorescence (MIF) and cytopathic effect (CPE) represent the number of days after transfection that >95% HTLV-III-specific membrane immunofluorescence and >95% cytopathicity, respectively, were noted in a typical experiment. These values were assessed as described previously[20]; >30 days indicates that no more than 2% HTLV-III-related membrane immunofluorescence or cytopathic effect was observed in the cultures, even up to 30 days after transfection. Reverse transcriptase assays[32] of cell supernatants in these cases did not rise above background during the observation period. ND, not done. Production of viral RNA was assessed as described in Fig. 2 legend. Viral protein production was assessed by transfecting cells with 10 μg of plasmid DNA using the DEAE-dextran procedure[31] and labelling with ^{35}S-cysteine at 48–72 h post-transfection. Labelled cell lysates were precipitated using antisera from patients (RV119 for Jurkat (*tat*-III) cells and 38-1 for Raji cells) and assessed for *gag*, *env* and *tat*-III protein production on SDS-polyacrylamide gels[33]. + Indicates detectable *gag* (p55, p38, p24 and/or p17), *env* (gp160/120) or *tat*-III (p14) bands; – indicates no detectable level of these proteins above background. *Trans*-activating ability (TA) was assessed by co-transfecting 10 μg of the proviral plasmid with 10 μg of plasmid pU3R-III, containing HTLV-III LTR sequences from −457 to +80 5′ to the chloramphenicol acetyltransferase gene (*cat*), into Raji cells[34,35]; 48 h after transfection, cell lysates were assayed for *cat* enzyme activity as described. Values represent the percentage conversion of chloramphenicol to acetylated forms in 1 h using equivalent amounts of protein lysate in a typical experiment. No effect on *cat* activity directed by the pSV_2cat plasmid, containing the simian virus 40 (SV40) early region promoter 5′ to *cat*[35], was observed with any of the mutant proviruses tested (data not shown).

mutations near the two coding exons of the *tat*-III gene dramatically attenuated the ability of the virus to express *gag* and *env* proteins. The observation that these mutations could not be complemented by the *tat*-III gene product alone led to the discovery of a second post-transcriptional control pathway governing HTLV-III expression. This pathway is controlled by a *trans*-acting product specified by a novel gene that partly overlaps the *tat*-III and *env* genes.

Replication of proviral mutants

To identify HTLV-III genomic regions important for viral replication, mutations were introduced into the pHXBc2 plasmid, which contains a complete HTLV-III provirus[28]. On transfection of either primary lymphocytes or $T4^+$ lymphocyte lines with this plasmid, infectious cytopathic virus is produced[20,27,28]. The recipient cell used for these experiments is the Jurkat (*tat*-III) cell line, designed to express constitutively the *tat*-III protein[29]. This cell line was chosen as it functionally complements deletions in the 5′ coding exon of the *tat*-III gene and because it is highly sensitive to the cytopathic effects of HTLV-III[27]. By 5 days after transfection with the pHXBc2 plasmid, Jurkat (*tat*-III) cells express HTLV-III proteins in addition to *tat*-III, exhibit cytopathic changes leading to demise of the culture, and produce extracellular virion particles detectable by electron microscopy or reverse transcriptase assays[27]. A similar result with approximately the same time course was obtained after transfection with plasmid pΔ(5365–5496), which contains a deletion in the 5′ portion of the *tat*-III first coding exon (Fig. 1). By contrast, no evidence of virus production was observed after transfection of the Jurkat (*tat*-III) cells with plasmid pΔ(5365–5551) or pΔ(5365–5702); these plasmids contain deletions in the *tat*-III gene which have the same 5′ boundary as that of plasmid pΔ(5365–5496), but extend farther in the 3′ direction. These deletions do not extend into the *env* gene. Apparently a region between nucleotides 5,496 and 5,551 is required for HTLV-III replication, even in the presence of a functional *tat*-III product supplied in *trans*.

Mutations of the pHXBc2 plasmid in the region near the unique *Bam*HI site (position 8,053), including a 4-base pair (bp) insertion at this site, also inactivate viral replication in the Jurkat (*tat*-III) cells (Fig. 1). By contrast, a virus that contains a deletion in the 3′ *orf* gene extending to within 188 nucleotides 3′ to the *Bam*HI site retains the ability to replicate, albeit at a reduced rate compared with wild-type virus (plasmid pΔ(8241–8634) in Fig. 1). This observation suggests that a function necessary for viral replication is located very near the *Bam*HI site, 5′ to nucleotide 8,241. Thus, mutations affecting two separate regions of the HTLV-III genome result in the inability of the provirus to replicate, even in the presence of the *tat*-III gene product.

RNA and protein synthesis of mutants

To investigate the nature of the mutations that could not be complemented by the *tat*-III product, the levels of virus-specific RNA and proteins synthesized by the proviral mutants were measured. The human B-lymphocyte cell line, Raji, was chosen for these experiments as previous experience demonstrated that significant levels of both virus-specific RNA and protein could be detected after transfection of this cell line with the HTLV-III proviral DNA[24].

For these experiments, RNAs and proteins were isolated 48 h after transfection of a single culture. Virus-specific RNA was measured using radiolabelled DNA complementary to HTLV-III RNA. The amount of globin RNA produced by the plasmid

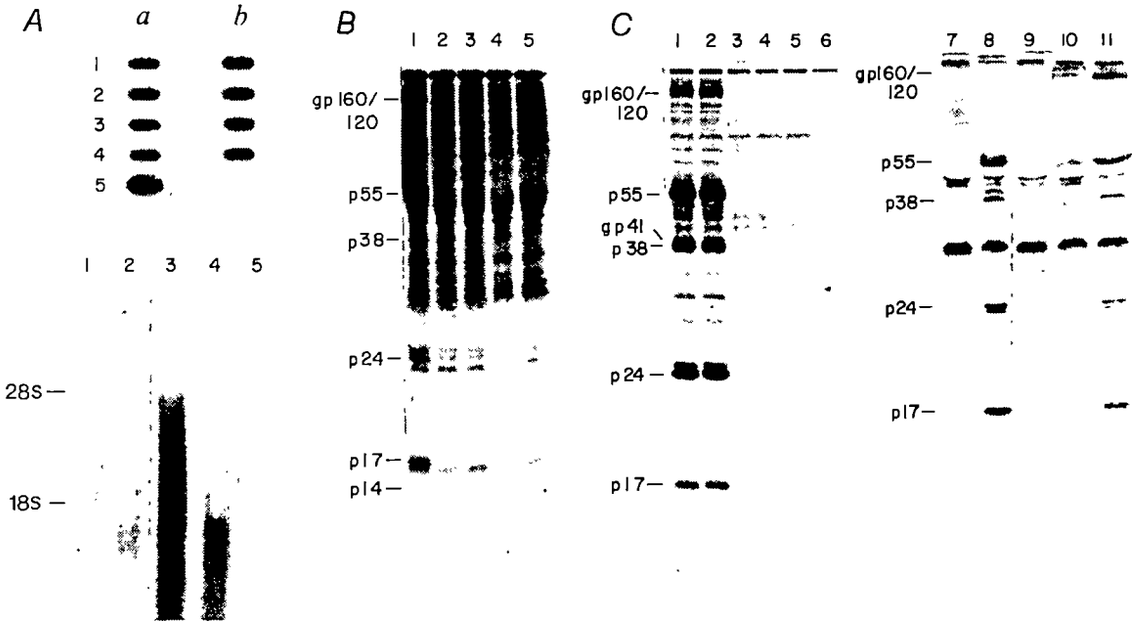

Fig. 2 RNA and protein production following transfection. Approximately 5×10^7 Raji cells were transfected with 10 μg of test plasmid DNA and 10 μg of $pSV_2\beta$-globin DNA using the DEAE-dextran technique[31]; 48 h after transfection, half of the cells were labelled with ^{35}S-cysteine and immunoprecipitated with patient antiserum 38-1, as described elsewhere[33]. The other half of the cells was used for total RNA isolation using the guanidine thiocyanate–CsCl method[36]. *A*, RNA (5 μg) was slot-blotted onto duplicate nitrocellulose filters and 10 μg was size-separated on formaldehyde gels and transferred to nitrocellulose[37]. One slot blot was hybridized to a probe derived from the complete β-globin complementary DNA sequence (*a*); the other slot blot (*b*) and the Northern blot (lower figure) were hybridized to a probe made from a pooled collection of *Bgl*II internal proviral fragments derived from the plasmid pHXBc2. Filters were washed as described elsewhere[37] prior to autoradiography. *B*, Proteins immunoprecipitated from the Raji transfectants. Transfected test plasmids for the Northern blot, slot blots and protein gel were: lane 1, pHXBc2; 2, pΔ(8053–8474); 3, pFS8053; 4, pΔ(5365–5496); and 5, a plasmid, pCR1, containing an incomplete HTLV-I provirus. The control lanes (1 and 4) have been published as part of a separate study[24]. *C*, Immunoprecipitates of Jurkat (*tat*-III) cells transfected with proviral plasmids using patient antiserum RV119, as described in Fig. 1 legend. Transfected plasmids were: lanes 1, 11, pHXBc2; lane 2, pΔ(5365–5496); 3, pΔ(5365–5702); 4, pΔ(8053–8474); 5, pFS8053; 6, 7, pIIIβ-globin, containing an HTLV-III LTR 5′ to rabbit β-globin cDNA sequences[24]; 8, pΔ(6617–7198); 9, pΔ(5365–5551); and 10, pΔ(5365–5539).

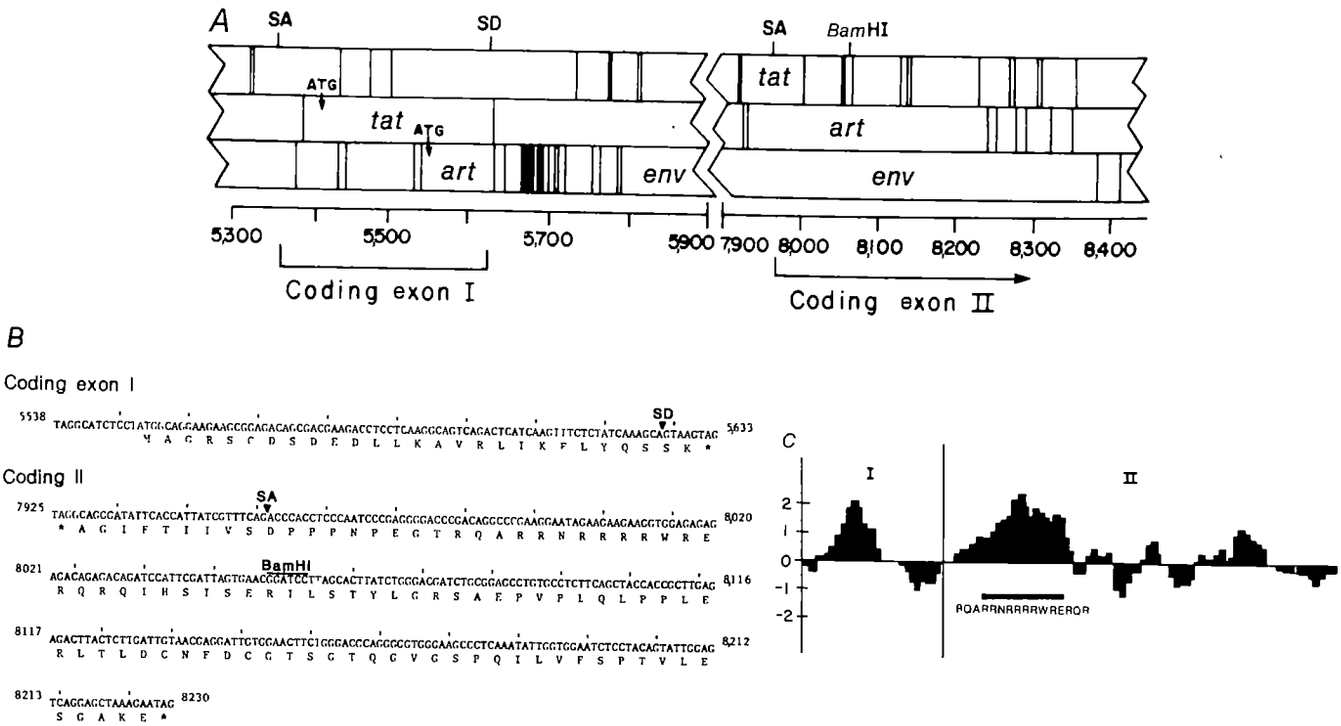

Fig. 3 Structure of the product of the alternative HTLV-III reading frame. The open reading frame in the HTLV-III genome, based on the sequence of Ratner *et al.*[9], is shown in *A*. The vertical lines represent the positions of stop codons. The open reading frames for the *tat*-III, *env* and alternative reading frame (*art*) are indicated. The positions of known splice acceptor (SA) and donor (SD) sites[12] as well as the *Bam*HI site used for mutagenesis (position 8,053) are shown. The putative initiator methionine codons for the *tat*-III and alternative reading-frame products are indicated by arrows labelled ATG. The putative coding exons of the *tat*-III gene and the alternative reading frame are delineated beneath the figure. *B*, DNA sequence of the two open reading frames that constitute the alternative reading frame, with the positions of the probable splice donor (SD) and acceptor (SA) sequences[12] shown. The predicted amino-acid sequence of the potential product of the open reading frame is shown beneath the DNA sequence. If the given splice donor and acceptor sites are used, the amino-acid sequence encoded by the sequence near the splice site would be LYQSNPPPNP. *C*, Hydrophilic (positive)–hydrophobic (negative) profile of the predicted alternative reading-frame product, based on the program of Hopp and Woods[38]. Protein domains specified by the first coding exon (I) are separated by a vertical line from those specified by the second coding exon (II). The amino-acid sequence of a strongly hydrophilic, basic domain is shown beneath the profile.

$pSV_2\beta$-globin[30], which was included in the transfection, was used as an internal standard for RNA synthesis in these experiments. Figure 2 shows that the amount, as well as the size distribution, of the virus-encoded RNA was the same for the pHXBc2 plasmid and for all the mutant HTLV-III proviruses tested, as judged by slot-blot and Northern blot analyses. Evidently the mutations that eliminate the ability of proviruses to produce infectious virus do not affect the synthesis of viral messenger RNA in the Raji cells.

The pattern of HTLV-III proteins produced in the transfected cells differed among the plasmids. Raji cells transfected with the pHXBc2 plasmid expressed HTLV-III-specific proteins of 160K and 120K (the *env* gene products), 55K, 38K, 24K and 17K (the *gag* gene products) and a faint band at 14K (the *tat*-III gene product) (Fig. 2*B*, lane 1). The pHXBc2 provirus used in these studies does not synthesize a complete 27K 3′ *orf* product[20]. Raji cells transfected with HTLV-III provirus containing *tat*-III gene deletions do not express detectable levels of viral protein, as reported previously[24] (Fig. 2*B*, lane 4). To our surprise, Raji cells transfected with pΔ(8053–8474) or pFS8053 failed to express HTLV-III *gag* or *env* gene products, but did synthesize the 14K *tat*-III product in amounts comparable to that seen after transfection with the pHXBc2 plasmid, as judged by radioimmune precipitation (Fig. 2*B*, lanes 2, 3). This observation suggested that mutations at or near position 8,053 attenuate the ability of the provirus to synthesize *gag* and *env* proteins, but do not affect synthesis of the *tat*-III protein.

To determine whether these mutant proviruses produced a functional *tat*-III gene product, the ability of the mutant proviruses to activate the HTLV-III viral LTR in *trans* was measured. Figure 1 shows that the proviruses containing mutations in the 3′ portion of the *env* gene are able to stimulate HTLV-III LTR-directed gene expression to approximately the same extent as is observed for the intact pHXBc2 provirus. We conclude that the mutations that affect *gag* and *env* gene expression do not significantly affect *tat*-III gene expression.

Non-complementation of the defect

Proviruses containing deletions in *tat*-III cannot synthesize detectable levels of viral proteins on transient transfection into cell lines that do not express the *tat*-III product[24]. Therefore, the Jurkat (*tat*-III) cell line was used to test the ability of mutant proviruses to synthesize virion proteins. Immunoprecipitation of Jurkat (*tat*-III) cells 48 h after transfection with the parental pHXBc2 plasmid revealed the presence of *gag* (p55, p38, p24 and p17) and *env* (gp160 and gp120) gene products (Fig. 2*C*, lane 1). HTLV-III *gag* and *env* proteins were also detected after transfection with the plasmids that contained deletions in the 5′ portion of the *tat*-III first coding exon [pΔ(5365–5496) and pΔ(5365–5539) in Fig. 2*C*, lanes 2 and 10, respectively]. By contrast, no *gag* or *env* products were detected in Jurkat (*tat*-III) cells transfected with provirus containing deletions that extend at least 12 nucleotides farther 3′ [pΔ(5365–5551) and pΔ(5365–5702) in Fig. 2*C*, lanes 9 and 3, respectively]. Similarly, none of the proviruses mutated near the *Bam*HI site (position 8,053) that failed to make viral *gag* and *env* proteins in Raji cells yielded detectable levels of these proteins in Jurkat (*tat*-III) cells (Fig. 2*C*, lanes 4, 5). The provirus with a deletion in the

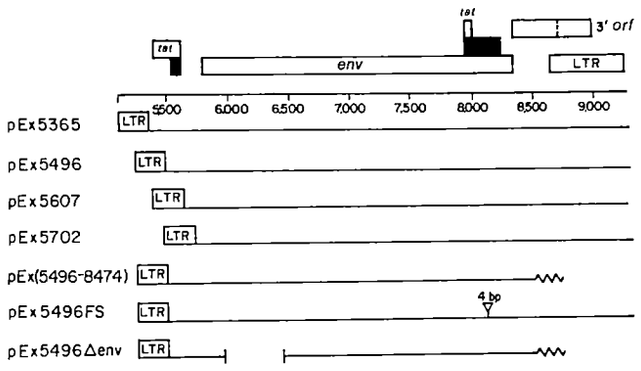

Fig. 4 Structure of plasmids containing the alternative reading frame. The structure of the 3′ half of the HTLV-III genome, based on the sequence of Ratner *et al.*[9], is shown together with the positions of the *env* gene, LTR, 3′ *orf* gene, two *tat*-III coding exons and the putative alternative reading-frame coding exons (here depicted as solid boxes). The position of a stop codon in the 3′ *orf* gene of the parental pHXBc2 plasmid[20,28] used in these studies is denoted by a vertical broken line. In all the plasmids shown, HTLV-III LTR sequences from −167 to +80 are positioned at the nucleotide denoted in the plasmid name. The zig-zag lines represent signals for polyadenylation and splicing derived from the SV40 early region[30]. The 4-bp insertion in plasmid pEx5496FS was constructed as described for plasmid pFS8053 in Fig. 1 legend. pEx5496Δenv was constructed by digesting pEx(5496–8474) with *Stu*I, ligating to 8-bp *Kpn*I linkers, digesting to completion with *Kpn*I, and ligating prior to *E. coli* transfection. All plasmids were constructed using DNA modification and restriction enzymes, by standard procedures.

3′ *orf* gene on plasmid pΔ(8241–8635) synthesized both *gag* and *env* proteins after transfection into Jurkat (*tat*-III) cells (Fig. 1). These experiments suggest that a region having a 5′ boundary between nucleotides 5,539 and 5,551 and a 3′ boundary between 8,053 and 8,241 is necessary for efficient expression of viral *gag* and *env* proteins, even in the presence of a functional *tat*-III product.

A seventh open reading frame

The similarity in the phenotype of mutations located both 5′ to the *env* gene and within the 3′ portion of the *env* gene suggested that these mutations might affect a single gene product. That mutation of the *env* gene product is not alone responsible for the effects observed is demonstrated by the ability of the proviruses on plasmids pΔ(6617–7198) and pΔ(8241–8635) to produce *gag* proteins on transfection into Jurkat (*tat*-III) cells (Figs 1 and 2*C*, lane 8). Plasmid pΔ(6617–7198) contains a deletion-frameshift mutation near the middle of the *env* gene, while plasmid pΔ(8241–8635) contains a deletion involving the 3′ 132 nucleotides of the *env* gene.

We note the existence within the HTLV-III genome of a sequence that could encode a protein and that would be affected by both sets of mutations affecting *gag* and *env* expression. The postulated coding exons of this gene would use alternative reading frames of the first and second coding exons of the *tat*-III gene (Fig. 3). Beginning with a methionine codon at position 5,550, the first coding exon of the putative gene extends to a known splice donor site at position 5,625 (ref. 12). The corresponding splice acceptor, located at nucleotide 7,956, precedes an in-frame open reading frame ending in a stop codon at position 8,227. The splicing events needed to produce this alternative reading-frame product are the same as those used for the *tat*-III gene and are known to occur in the mRNA of HTLV-III-infected cells[12,18,19].

The potential product of the alternative reading frame is 116 amino acids long, and contains stretches of highly basic hydrophilic residues similar to those found in the *tat*-III gene product and in nucleic acid-binding proteins[18,19]. Note that the vectors used for the construction of the Jurkat (*tat*-III) and Raji (*tat*-III) cells are truncated at the *Bam*HI site (position 8,053) and are unable to synthesize the alternative reading-frame product.

A novel *trans*-activator

The hypothesis that a protein encoded by the alternative reading frame described above is necessary, in addition to the *tat*-III product, for efficient HTLV-III *gag* and *env* protein synthesis, would explain the phenotype of the proviral mutants. This hypothesis predicts that plasmids designed to express the alternative reading-frame product should complement the defect of mutants with respect to the synthesis of the *gag* and *env* gene products. To test this prediction, HTLV-III LTR sequences from position −167 to +80 were placed at various positions with respect to the putative initiation codon for the alternative reading frame (Fig. 4). Following co-transfection of these plasmids with plasmids containing mutant proviruses into Jurkat (*tat*-III) cells, viral protein expression was assessed by immunoprecipitation of labelled cell lysates using antiserum from an AIDS patient.

Figure 5 illustrates that placing the HTLV-III LTR 54 nucleotides 5′ to the ATG codon of the alternative reading frame (and downstream of the *tat*-III initiation codon) results in a plasmid (pEx5496) that provides in *trans* a function required for *gag* gene expression by the pFS8053 plasmid (Fig. 5*B*, lane 3 and *C*, lane 4). The *env*-encoded gp160/120 proteins are produced by the pEx5496 plasmid itself on transfection into Jurkat (*tat*-III) cells (Fig. 5*A*, lane 3). The ability of the pEx5496 plasmid to complement the pFS8053 mutation and to synthesize envelope proteins is eliminated by a frameshift mutation within the alternative reading frame (plasmid pEx5496FS; Fig. 5*C*, lane 7 and *D*, lane 3). Plasmids in which the HTLV-III LTR is located 3′ to the ATG codon of the alternative reading frame do not complement the pFS8053 mutation and do not synthesize *env* gene products (plasmids pEx5607 and pEx5702 in Fig. 5*A*, lanes 4, 5 and *B*, lanes 4, 5). By contrast, deletions within the *env* or 3′ *orf* gene of plasmid pEx5496 do not eliminate the ability of the plasmid pFS8053 to activate *gag* gene expression (see plasmids pEx5496Δenv and pEx(5496–8474) in Fig. 5*C*, lanes 5, 6 and *D*, lane 5). HTLV-III *gag* gene expression directed by the plasmid pΔ(8053–8474) can also be activated by pEx5496 (data not shown). We conclude that plasmids capable of producing an alternative reading-frame product can activate, in *trans*, *gag* gene expression by proviruses containing mutations in the alternative reading-frame sequence.

We also note that *gag* gene expression by the plasmid pFS8053 can be activated in Jurkat (*tat*-III) cells by a plasmid that contains the HTLV-III sequences located 5′ to the initiation codon of the *tat*-III gene. The plasmid pEx5365 produces a functional *tat*-III activity as well as providing in *trans* the functions required for *gag* gene expression by plasmid pFS8053 (Fig. 5*B*, lane 2). However, the extent of *gag* gene expression observed in this experiment was less than that observed in the experiments in which pEx5496 was used. pEx5365 does not produce detectable levels of the *env* gene product (Fig. 5*A*, lane 2). One possible explanation for the low level of expression of the complementing activity and of *env* gene products by plasmid pEx5365 is the presence of a strong *tat*-III initiation codon 5 to both genes.

Activation of *env* gene expression

A plasmid designed to express the alternative reading frame but not the *env* gene was tested for the ability to allow *env* gene production by HTLV-III proviruses containing mutations in the alternative reading-frame sequences. The plasmid pEx5496Δenv, which contains a deletion-frameshift mutation in the portion of the *env* gene encoding the exterior glycoprotein gp120, did not yield detectable levels of the *env* protein on transfection into Jurkat (*tat*-III) cells (Fig. 5*D*, lane 2). Co-transfection of this plasmid into Jurkat (*tat*-III) cells with pΔ(5365–5551) allowed the latter plasmid to produce both *gag*

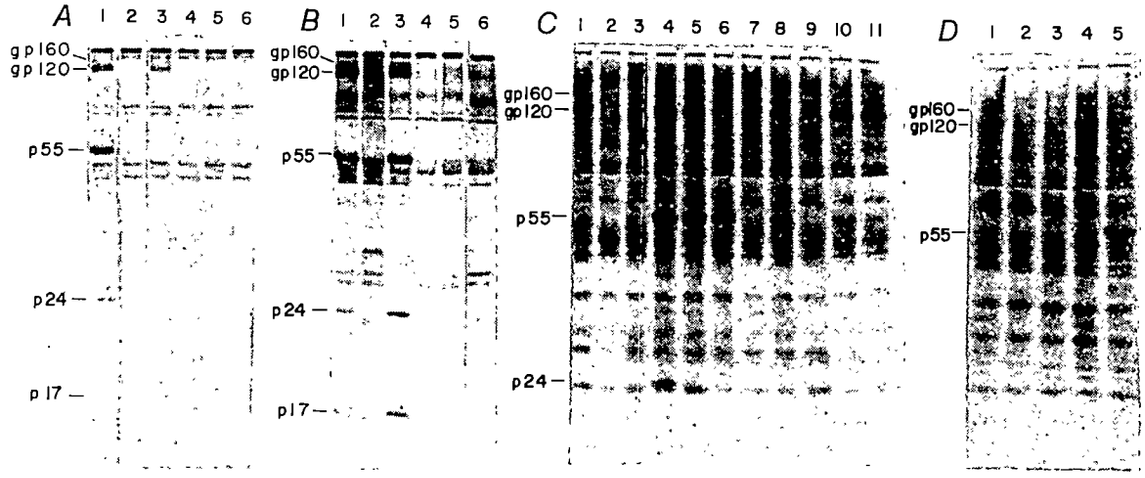

Fig. 5 Complementation of mutations in HTLV-III proviruses by plasmids designed to express the alternative reading-frame product. Jurkat (*tat*-III) cells were transfected by the DEAE-dextran procedure[31] using 10 μg of the proviral mutant to be complemented and 10 μg of the plasmid to be tested for ability to complement the mutation. Forty-eight hours after transfection, cells were labelled with ^{35}S-cysteine and cell lysates were immunoprecipitated using an AIDS patient serum, RV119 (ref. 33). The positions of the gp160 and gp120 *env* proteins and of the p55, p24 and p17 *gag* gene products are indicated. Transfected plasmids in *A* were pΔ(5365–5496) (lane 1), pEx5365 (lane 2), pEx5496 (lane 3), pEx5607 (lane 4), pEx5702 (lane 5) and pIII*β*-globin (lane 6); those in *B* were pΔ(5365–5496) (lane 1), pFS8053 plus pEx5365 (lane 2), pFS8053 plus pEx5496 (lane 3), pFS8053 plus pEx5607 (lane 4), pFS8053 plus pEx5702 (lane 5), and pFS8053 alone (lane 6); and those in *C* were pEx(5496–8474) (lane 1), pEx5496Δenv (lane 2), pEx5496FS (lane 3), pFS8053 plus pEx5496 (lane 4), pFS8053 plus pEx(5496–8474) (lane 5), pFS8053 plus pEx5496Δenv (lane 6), pFS8053 plus pEx5496FS (lane 7), pΔ(5365–5551) plus pEx5496Δenv (lane 8), pΔ(5365–5551) plus pEx5496FS (lane 9), pΔ(5365–5539) plus pEx5496Δenv (lane 10), and pΔ(5365–5539) plus pEx5496FS (lane 11). Transfected plasmids in *D* were pEx(5496–8474) (lane 1), pEx5496Δenv (lane 2), pEx5496FS (lane 3), pEx5496Δenv plus pEx5496FS (lane 4), and pEx5496Δenv plus pFS8053 (lane 5). The predicted *env* gene product synthesized by the pEx5496FS plasmid is 47 amino acids shorter than the wild-type HTLV-III envelope, because of the frameshift mutation.

and *env* proteins (Fig. 5*C*, lane 8). No viral proteins could be detected in Jurkat (*tat*-III) cells transfected either with pΔ(5365–5551) alone (Fig. 2*C*, lane 9) or with plasmids pΔ(5365–5551) and pEx5496FS (Fig. 5*C*, lane 9). pEx5496Δenv also activated the synthesis of the gp160/120 *env* products by plasmids pEx5496FS (Fig. 5*D*, lane 4) and pEx5702 (data not shown). No *env* gene products were detected on transfection of Jurkat (*tat*-III) cells with either pEx5496FS alone (Fig. 5*D*, lane 3) or pEx5702 alone (Fig. 5*A*, lane 5). This result suggests that the inability of these plasmids to synthesize envelope proteins is the result of disruption of the alternative reading-frame sequences rather than of *cis*-acting sequences required to produce envelope proteins.

We conclude that a product encoded by the alternative reading frame can activate, in *trans*, *env* gene expression directed by proviruses mutated in the alternative reading frame.

Discussion

Here we have presented evidence for a novel *trans*-acting function required for efficient synthesis of HTLV-III *gag* and *env*, but not *tat*-III, proteins. In the absence of this second *trans*-acting factor, HTLV-III *gag* and *env* protein synthesis is markedly attenuated, without an apparent change in viral mRNA production. This finding, together with the observation that *tat*-III expression is not dependent on the *trans*-acting function, indicates that the factor exerts its effect at a post-transcriptional level.

The region of the genome required for this second *trans*-acting function is distinct from, but partly overlaps, the *tat*-III and *env* genes. This bipartite region contains an open reading frame that, on splicing, could synthesize a 116-amino-acid, highly basic protein similar to the *tat*-III product. This open reading frame is conserved in all HTLV-III variants sequenced[9–12].

The novel *trans*-acting function defined here activates HTLV-III *gag* and *env* protein expression; this might occur via a positive stimulation of post-transcriptional events affecting utilization of *gag* and *env* mRNA. Alternatively, the second *trans*-acting factor might derepress *cis*-acting negative-regulatory sequences present on viral messages encoding *gag* and *env* products. We favour the latter explanation based on our observations regarding the expression of heterologous genes under the control of the HTLV-III LTR.

We have demonstrated previously that the *tat*-III product alone is sufficient to stimulate HTLV-III LTR sequences (−167 to +80) to direct high-level synthesis of bacterial chloramphenicol acetyltransferase or murine dihydrofolate reductase[24,25]. By contrast, plasmids that contain the same HTLV-III LTR sequences located 5′ to the HTLV-III *env* gene (pEx5486FS or pEx5702) yield no detectable envelope protein in the absence of the alternative reading-frame product, even in the presence of an active *tat*-III gene product. Only after the alternative reading-frame product is supplied in *trans* do the levels of envelope production by these plasmids approximate those of heterologous genes under the control of the HTLV-III LTR in Jurkat (*tat*-III) cells. These observations imply that in the plasmids pEx5496FS and pEx5702 sequences 3′ to +80 inhibit *env* gene expression, and that such inhibition can be relieved by the *trans*-acting function. That the second *trans*-activator is required for *gag* gene expression suggests that *gag* mRNA may contain negative-regulatory sequences in addition to those found in *env* mRNA. We suggest the name *art* (anti-repression *trans*-activator) for the gene that encodes the second *trans*-activator, consistent with the proposed role of this gene in negating the effects of *cis*-acting negative-regulatory sequences present on viral mRNA encoding the HTLV-III structural proteins.

Detectable levels of the *tat*-III gene product but not of the *gag* and *env* gene products are synthesized by proviral mutants defective for the *art* function; therefore whatever inhibits the expression of the *gag* and *env* gene products does not affect *tat*-III gene expression. Sequences encompassing the entire *gag* gene and most of the *env* gene are removed by splicing from the *tat*-III mRNA[12,18,19]. Removal of *art*-responsive *cis*-acting negative-regulatory sequences located in the regions spliced out of *tat*-III messages would explain the independence of *tat*-III expression from the requirement for the *art* product. The *art* product itself should be independent of such negative-regulatory sequences as it should be synthesized from messages that also lack these *gag* and *env* sequences.

The expression of HTLV-III structural genes is governed post-transcriptionally by the *tat*-III product, which acts as a positive regulatory factor[18,19,24], and by the *art* product, which apparently counteracts *cis*-acting negative-regulatory sequences located in or near the *gag* and *env* genes. Two possible roles for this complex regulatory scheme can be considered. HTLV-III is reported to establish a latent state of infection in T cells that are not activated[8]. Lack of *tat*-III or *art* function would lead to a state of infection characterized by accumulation of viral RNA without synthesis of virus structural proteins. Rapid release from such a latent state could be achieved in the absence of new RNA synthesis if the *tat*-III or *art* function were reconstituted. A dependence of *tat*-III and *art* activity on the state of cell differentiation could explain the relationship between HTLV-III latency and T-cell activation.

Alternatively, post-transcriptional regulators may play a part in the lytic cycle of the virus. An early stage of infection characterized by accumulation of viral RNA but not of virion proteins might precede a late phase in which viral proteins toxic to T4 cells are produced. The switch from an early to a late stage of infection would reflect activation of either one or both of the *tat*-III and *art* gene functions. Such an early–late switch would permit accumulation of the mRNAs for toxic virion components before such components themselves are produced. There is some evidence that modulated *tat*-III activity may result in increased production of infectious virus. The yield of virus particles on lytic infection of the Jurkat cell line that constitutively produces high levels of the *tat*-III gene is much lower than that observed on infection of the Jurkat cell line itself, despite the observation that the cytopathic effect of infection is accelerated in the Jurkat (*tat*-III) cells[27]. Premature cell death attributed to high constitutive levels of the *tat*-III gene might explain the decreased virus titres. Temporal regulation of virus gene expression is important in the life cycle of other lytic viruses. The postulated roles of the *tat*-III and *art* genes in the latent and lytic cycles of HTLV-III infection are not necessarily exclusive.

A flexible, multi-tiered regulatory pathway linked to host cell differentiation and proliferation could account for much of the variability observed in victims of AIDS[6]. Similar pathways involving both positive and negative elements may also apply to post-transcriptional regulation of gene expression in the course of normal cellular development. Note also that both the *tat*-III and *art* products provide attractive targets for antiviral agents, as both operate at a post-transcriptional level and are required for viral replication[24,27].

LETTERS TO NATURE

Towards the geometrization of physics

George A. J. Sparling

Department of Mathematics and Statistics, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA

The concept of symmetry breaking may be expressed mathematically by the reduction of a structure group, for example, choosing a point on a sphere reduces its symmetry group from the group of all rotations to the subgroup of rotations fixing that point. A systematic analysis of Penrose's twistor equation[1,2] has revealed that twistor theory embodies a truth of nature: that interactive gravitational field theories in space-time correspond to such a symmetry breakdown—a breakdown that occurs, not in space-time, but in twistor space–the space of null geodesics of space-time. In particular, twistor theory lies at the heart of supergravity.

The Penrose transform[3,4] provides the necessary algorithm linking space-time and twistor concepts. Applied to bundles, it encodes the information of bundles with connection, on space-time, in bundles without connection, on twistor space. This is possible because null geodesics, which are local in twistor space (points), are extended in space-time. The information stored in parallel propagation along geodesics is completely used in building the geometry of the twistor bundle.

Remarkably, one can construct a bundle with connection, in space-time, the bundle of local twistors, such that: (1) the reduction of its structure group, combined with, (2) the simultaneous reduction of the connection, give the relevant field equations. Applying the Penrose transform, the field equations are expressed by a reduction of the structure group, in twistor space: the breakdown of symmetry.

For Dirac spinor fields ω and π, the twistor equation is:

$$\nabla_a \omega - \gamma_a \pi = 0 \qquad (1)$$

Here ∇_a is a spin connection; the indices are abstract; γ_a obeys the Clifford algebra: $\gamma_{(a}\gamma_{b)} = g_{ab}$ (g_{ab} is the metric).

Equation (1) is invariant under the replacements:

$$\nabla_a \to \nabla'_a \equiv \nabla_a + \gamma_a \tau, \quad \omega \to \omega' \equiv \omega, \quad \pi \to \pi' \equiv \pi + \tau\omega$$

This structure creates a short exact sequence of bundles:

$$0 \to \Pi \xrightarrow{i} T \xrightarrow{j} \Omega \to 0 \tag{2}$$

where Π, Ω and T are, in turn, the bundles of spinors π, ω and of local twistors $\binom{\omega}{\pi}$; also $i(\pi) \equiv \binom{0}{\pi}$ and $j\binom{\omega}{\pi} \equiv \omega$.

It is fundamental that the integrability conditions of equation (1) allow one, for space-time dimension $m > 2$, to express the derivative $\nabla_a \pi$ linearly in terms of ω and π: $\nabla_a \pi = T_a \pi + R_a \omega$ (T_a is determined by $\nabla_a \gamma_b$ and by the torsion of ∇_a); in terms of the curvature R_{ab} of ∇_a, R_a is given by:

$$R_{ab} \equiv C_{ab} - \gamma_{[a} R_{b]}, \qquad \gamma^a C_{ab} = 0 \tag{3}$$

Accordingly, one obtains a canonical connection D_a on T:

$$D_a \begin{pmatrix} \omega \\ \pi \end{pmatrix} \equiv \begin{pmatrix} \nabla_a \omega - \gamma_a \pi \\ \nabla_a \pi - T_a \pi - R_a \omega \end{pmatrix} \tag{4}$$

giving a one to one correspondence between solutions of the twistor equation and parallelly propagated local twistors.

Next two maps $t: \Omega \to T$, $p: T \to \Pi$ split the sequence (2) if they obey $jt =$ identity, $pi =$ identity, $pt =$ zero. The connection D_a also splits, inducing connections on Ω and Π, provided the fundamental splitting equation holds:

$$pD_a t = 0 \tag{5}$$

One says that D_a splits directly if the induced connection on Ω is ∇_a. This amounts to the requirement, in equation (4), the twistors of the form $\binom{\omega}{0}$ are preserved by D_a. From equation (4) this is just the equation $R_a = 0$. Let ${}^L\nabla_a$ be the Levi-Civita connection. Then for ∇_a given successively by:

(i) for $m > 2$, $\quad \nabla_a \equiv {}^L\nabla_a$,

(ii) for $m = 4$, $\quad \nabla_a \equiv {}^L\nabla_a - (F_a{}^b \gamma_b - \frac{1}{4}\gamma_a F_{bc}\gamma^b\gamma^c)\gamma_5$,

(iii) for $m = 11$, $\quad \nabla_a \equiv {}^L\nabla_a - F_a{}^{bcd}\gamma_b\gamma_c\gamma_d + \frac{1}{12}\gamma_a F^{bcde}\gamma_b\gamma_c\gamma_d\gamma_e$,

(where F_{ab} and F_{abcd} are completely skew), then the condition of direct splitting of the local twistor connection gives: (i) the Einstein vacuum equations[5]; (ii) the full Einstein-Maxwell equations; (iii) the full equations of classical 11-dimensional supergravity[6].

Example (iii) strongly suggests that there should be a supersymmetric generalization of the above formalism, since after all the construction of the equations of (iii) was first made using supersymmetry. To see how to achieve this, consider the original twistor equation of Penrose, the equation for a Weyl spinor ω^A:

$$\nabla_{A'}{}^{(A}\omega^{B)} = 0 \tag{6}$$

In classical supergravity the derivative $\nabla_{AA'}$ factorizes[7]:

$$\nabla_{AA'} = \bar{\nabla}_A \wedge \nabla_{A'} \equiv \bar{\nabla}_A \nabla_{A'} + \nabla_{A'} \bar{\nabla}_A \tag{7}$$

(Here $\wedge$ is the graded commutator: an anti-commutation for a pair of operators with an odd number of spinor indices; otherwise it is a commutation). Equation (6) now becomes:

$$\nabla_{A'}(\bar{\nabla}^{(A}\omega^{B)}) + \bar{\nabla}^{(A}\nabla_{A'}\omega^{B)} = 0 \tag{8}$$

This immediately suggests that the correct generalization of equation (6) should be the graded twistor equations:

$$\bar{\nabla}^{(A}\omega^{B)} = 0 \tag{9}$$

$$\nabla_{A'}\omega^B = 0 \tag{10}$$

Remarkably, this first guess works. In Table 1, the algebra generated by $\bar{\nabla}_A$ and $\nabla_{A'}$ is given, for the theory of minimal classical supergravity[7]. $\bar{\nabla}_{AB}$ and $\nabla_{A'B'}$ generate the Lorentz algebra. Using Table 1, one now analyses the integrability of equations (9) and (10). First rewrite equation (9):

$$\bar{\nabla}_A \omega^B = \delta_A{}^B \pi, \tag{11}$$

for some π. Define the spinor $\pi_{A'}$ in terms of π: $\pi_{A'} \equiv \nabla_{A'}\pi$. Then it is routine to establish that all derivatives of the *graded twistor* $(\omega^B, \pi_{B'}, \pi)$ may be computed linearly in terms of $(\omega^B, \pi_{B'}, \pi)$. This gives immediately the definition of the *graded twistor connection* on GT, the bundle of graded twistors. The definition is presented in Table 2.

Table 1 The minimal classical supergravity algebra

$$\bar{\nabla}_{AB} \wedge \bar{\nabla}_{CD} = 4\varepsilon_{(A(C}\bar{\nabla}_{D)B)} \qquad \bar{\nabla}_{AB} \wedge \nabla_{C'D'} = 0 \qquad \bar{\nabla}_{AB} = \bar{\nabla}_{BA}$$

$$\bar{\nabla}_{AB} \wedge \nabla_{CC'} = -2\varepsilon_{C(A}\nabla_{B)C'} \qquad \bar{\nabla}_{AB} \wedge \bar{\nabla}_C = -2\varepsilon_{C(A}\bar{\nabla}_{B)} \qquad \bar{\nabla}_{AB} \wedge \nabla_{C'} = 0$$

$$\bar{\nabla}_A \wedge \bar{\nabla}_B = 2Q\bar{\nabla}_{AB} \qquad \bar{\nabla}_A \wedge \nabla_{A'} = \nabla_{AA'}$$

$$\bar{\nabla}_A \wedge \nabla_{BB'} = \varepsilon_{AB} Q_{B'} + R_{ABB'}$$

$$\nabla_{AA'} \wedge \nabla_{BB'} = \varepsilon_{AB} Q_{A'B'} + \varepsilon_{A'B'} \bar{Q}_{AB} + \varepsilon_{AB} R_{A'B'} + \varepsilon_{A'B'} \bar{R}_{AB}$$

$$Q_{B'} \equiv 2Q\nabla_{B'} + Q^B_{B'}\bar{\nabla}_B$$

$$Q_{A'B'} \equiv (\nabla_{(A'}Q^B_{B')})\bar{\nabla}_B + 2Q^{C'}_{A'B'}\nabla_{C'} + 2(\nabla_{(A'}Q)\nabla_{B')} + Q^B_{(A'}\nabla_{B')B}$$

$$R_{ABB'} \equiv -(\nabla_{B'}Q)\bar{\nabla}_{AB} + \varepsilon_{AB}(-\tfrac{1}{2}(\bar{\nabla}^{(C}Q^{D)}_{B'})\bar{\nabla}_{CD} + Q^{C'D'}_{B'}\nabla_{C'D'})$$

$$R_{A'B'} \equiv -\tfrac{1}{2}(\nabla_{(A'}\bar{\nabla}^{(C}Q^{D)}_{B')})\bar{\nabla}_{CD} + (\nabla_{(A'}Q^{C'D'}_{B')})\nabla_{C'D'} - \tfrac{1}{2}(\bar{\nabla}_C\bar{\nabla}^C\bar{Q} - 8Q\bar{Q})\nabla_{A'B'}$$

$$Q_{AA'} + \bar{Q}_{AA'} = 0 \qquad Q_{A'B'C'} = Q_{(A'B'C')} \qquad \bar{\nabla}_A Q_{A'B'C'} = 0$$

$$\bar{\nabla}_A Q = 0 \qquad \bar{\nabla}_A Q^{ABC} = \tfrac{1}{2}\nabla^{(B}_{A'}Q^{C)A'} \qquad \bar{\nabla}_A Q^A_{A'} + 2\nabla_{A'}Q = 0$$

The defining property of the connection is that there be a one-to-one correspondence between solutions of the graded twistor equations and covariantly constant graded twistors. There is now a split exact sequence of graded bundles:

$$0 \to G\Pi \xrightarrow{i} GT \xrightarrow{j} G\Omega \to 0 \tag{12}$$

generalizing equation (2);

$$\text{here} \quad i\begin{pmatrix} \pi_{B'} \\ \pi \end{pmatrix} \equiv \begin{pmatrix} 0 \\ \pi_{B'} \\ \pi \end{pmatrix}, \qquad j\begin{pmatrix} \omega^B \\ \pi_{B'} \\ \pi \end{pmatrix} \equiv \omega^B .$$

The graded analogue of the direct splitting is the condition that the graded twistors $(\omega^B, 0, 0)$ are preserved by the graded connection.

By inspection of Table 2, one immediately finds the equations:

$$Q = 0, \qquad \bar{\nabla}_{(A}Q_{B)B'} = 0 \tag{13}$$

Given equation (13) the induced connection on $G\Pi$ itself splits, preserving spinors of the form $\binom{0}{\pi}$, if and only if the slightly stronger system of equations holds:

$$Q = 0, \qquad Q_{BB'} = 0. \tag{14}$$

Equation (13) gives the standard curvature field equations of classical supergravity. Equation (14), the second level of splitting, gives the standard torsion field equations[7].

Finally, if equation (10) is generalized to the equation:

$$\nabla_{A'}\omega^B = \bar{F}^B\bar{\omega}_{A'} \tag{15}$$

then the two levels of broken symmetry provide the graded version of the Einstein-Maxwell equations[7]:

$$\bar{\nabla}_C\bar{F}^C = 0, \qquad \nabla_{C'}\bar{F}^C = 0, \qquad Q = 0, \qquad Q_{BB'} + \bar{F}_B F_{B'} = 0 \tag{16}$$

Thus, one sees that the graded Penrose transform, first envisaged by Witten[4,8], provides an interpretation of the field equations in terms of the breaking of graded symmetry in graded twistor space. In all existing supergravity theories, it is the torsional constraints that allow for the existence of graded null geodesics and for the construction of the transform.

It is tempting to speculate that the simplest supergravity theory, containing a complete spectrum of helicities, from -2 to 2, derived along the above lines, may be physically viable at

Table 2 The definition of graded twistor transport

$$\bar{D}_A\begin{pmatrix}\omega^B\\ \pi^{B'}\\ \pi\end{pmatrix}\equiv\begin{pmatrix}\bar{\nabla}_A\omega^B-\delta_A{}^B\pi\\ \bar{\nabla}_A\pi_{B'}+Q_{AB'}\pi+(\nabla_{B'}Q)\omega_A+(\bar{\nabla}_{(A}Q_{B)B'})\omega^B\\ -\bar{\nabla}_A\pi+2Q\omega_A\end{pmatrix}$$

$$D_{A'}\begin{pmatrix}\omega^B\\ \pi_{B'}\\ \pi\end{pmatrix}\equiv\begin{pmatrix}\nabla_{A'}\omega^B\\ \nabla_{A'}\pi_{B'}-2\bar{Q}\varepsilon_{A'B'}\pi\\ -\nabla_{A'}\pi+\pi_{A'}\end{pmatrix}$$

$$D_{AA'}\begin{pmatrix}\omega^B\\ \pi_{B'}\\ \pi\end{pmatrix}\equiv\begin{pmatrix}\nabla_{AA'}\omega^B-\delta_A{}^B\pi_{A'}\\ \nabla_{AA'}\pi_{B'}+Q_{AB'}\pi_{A'}+X_{AA'B'}\pi+X_{ABA'B'}\omega^B\\ \nabla_{AA'}\pi+Q_{AA'}\pi-(\nabla_{A'}Q)\omega_A+(\bar{\nabla}_{(A}Q_{B)A'})\omega^B\end{pmatrix}$$

$$X_{AA'B}\equiv\nabla_{(A'}Q_{B')A}-\varepsilon_{A'B'}\bar{\nabla}_AQ$$

$$X_{ABA'B'}\equiv\nabla_{(A'}\bar{\nabla}_{(A}Q_{B)B')}+\tfrac{1}{6}\varepsilon_{A'B'}\nabla_{C'}\bar{\nabla}_{(A}Q_{B)}^{C'}+\varepsilon_{AB}\varepsilon_{A'B'}(4QQ-\tfrac{1}{2}\nabla_{C'}\nabla^{C'}Q)$$

some energy scale. If so, there would be widespread consequences for cosmology.

Finally, a point of philsophy. Local twistors survive in the superstring arena, through the theory of two-surface twistors of Penrose[9]: as the two-surface shrinks to a point, one recovers the local twistor. Is there a place in the superstring theory for a full blown twistor theory? Twistors, being fundamentally spinorial, form a 'square root' for space-time. 'Stringy' twistors ought to provide a square root for superstrings. At the quantum level they should give a 'fermionization' of the superstring theory (the reverse of bosonization)[10,11]. Perhaps the above work should be taken as a small piece of evidence that such a theory exists.

I thank Ted Newman, Roger Penrose and John Porter for their continuing support. Supported in part by grants from the NSF and from the Alfred P. Sloan Memorial Foundation.

Is there a black hole in the sky?

Bohdan Paczyński

Princeton University Observatory, Princeton University, Princeton, New Jersey 08544, USA

The recent discovery[1] that the two quasars, Hazard 1146+111B,C, separated by 157 arc s, are in fact two images of the same quasar raises the question: what massive object is responsible for gravitational lensing? Ultimately, the answer will be provided by observations of a few more pairs of images of other sources when it will be possible to analyse the mass distribution of the lens. One of the imaginable candidates is a supermassive black hole. No observational or theoretical argument can be presented in favour of this possibility at present. Should the future observations point to a compact supermassive lensing object, the presence of a black hole could be established by the unique property that it would appear against the microwave background as a black spot with a diameter of ≳0.1 arc s.

Various candidates for a gravitational lens whose images are split by a few minutes of arc have been proposed[1], including an unusually dense cluster of galaxies, a cosmic string or a black hole. As yet there is no observational evidence for the cluster of galaxies, and it is worthwhile exploring the consequences of the hypothesis that the lensing object is a supermassive black hole.

The angular distance between two objects with redshifts z_1 and z_2 in a universe with dimensionless density $\Omega=1$ and cosmological constant $\Lambda=0$ is given as[2]

$$D_{\rm ang}(z_1,z_2)=\frac{c}{H_0}\frac{2}{1+z_2}[(1+z_1)^{-1/2}-(1+z_2)^{-1/2}] \quad (1)$$

where H_0 is the Hubble constant. This formula may be used to calculate the angular distance between the observer and the deflector, $D_{\rm d}$, between the observer and the source, $D_{\rm s}$, and between the deflector and the source, $D_{\rm ds}$, as well as the effective distance to the lens, $D\equiv D_{\rm d}D_{\rm ds}/D_{\rm s}$. If the source, the point-mass deflector, and the observer are perfectly aligned, then the image forms a ring with radius r_0 in the deflector's plane. This may be calculated from

$$r_0^2=4\,GMD/c^2=2\,r_{\rm g}\,D \quad (2)$$

The angular radius of the ring as seen by the observer would be

$$\alpha_0=r_0/D_{\rm d} \quad (3)$$

If the lensing object is a black hole then it might be seen as a dark spot against a bright background. For a Schwarzschild black hole, the dark spot is a circle with a diameter $3^{3/2}\,r_{\rm g}\simeq 5.196\,r_{\rm g}$. For a Kerr black hole, the dark spot is almost the same size, but it looks like a distorted circle[3]. The angular diameter of the dark circle as seen by the observer is

$$d_{\rm BH}=3^{3/2}\,r_{\rm g}/D_{\rm d} \quad (4)$$

Combining equations (1)-(4), we obtain for the observed diameter of the black hole

$$d_{\rm BH}=\frac{3^{3/2}}{2}\alpha_0^2\frac{D_{\rm s}}{D_{\rm ds}} \quad (5)$$

The angular separation between the two images of a source gravitationally lensed by a point mass is always larger than the diameter of the ring-like image, $2\alpha_0$. However, as the two images of 1146+111 are almost equally bright, the lens and the source may be reasonably well aligned, and I shall adopt $\alpha_0=157$ arc s$/2=3.81\times10^{-4}$ rad. Therefore, the expected diameter of the black spot in the microwave background becomes

$$d_{\rm BH}=0.078\;D_{\rm s}/D_{\rm ds}\;\text{arc s} \quad (6)$$

If the black hole is a relatively nearby object then $D_{\rm s}\approx xD_{\rm ds}$, and $d_{\rm BH}=0.078$ arc s. If the black hole is at a cosmological distance, then $D_{\rm s}>D_{\rm ds}$, and the black spot is larger than 0.078 arc s.

Another interesting quantity is the black hole mass. For a given radius of a circular image, α_0, it may be calculated as follows:

$$r_{\rm g}=\frac{\alpha_0^2\,D_{\rm d}D_{\rm s}}{2D_{\rm ds}} \quad (7a)$$

$$M=2.3\times10^{15}\,M_\odot\,h_{100}^{-1}\frac{[(1+z_{\rm s})^{-1/2}-1][(1+z_{\rm d})^{-1/2}-1]}{(1+z_{\rm d})[(1+z_{\rm s})^{-1/2}-(1+z_{\rm d})^{-1/2}]} \quad (7b)$$

where h_{100} is the Hubble constant in units of 100 km s^{-1} Mpc^{-1}. Note that at a very small observer-deflector distance $D_{\rm d}$, the black hole mass is simply proportional to that distance:

$$M_{\rm BH}=8\times10^5\,M_\odot\times D_{\rm d}/1\;\text{pc} \quad (8)$$

A black hole captures microwave background radiation with a cross-section of $27\pi r_{\rm g}^2$, and therefore it may appear as a 'source' with a negative luminosity

$$L_{\rm BH}=-27\pi r_{\rm g}^2\sigma[2.7\times(1+z)]^4 \quad (9)$$

The redshift of 1146+111 is $z_{\rm s}=1.012$ (ref. 1). The redshift of the lens is not known. The values of the black hole mass, the

Table 1 Variation of the apparent diameter of the black spot, the black hole mass and the negative black hole luminosity as a function of the black hole redshift

z	d (arc s)	log M ($M_\odot$)	log $-L$ ($L_\odot$)

diameter of the black spot and the black hole negative luminosity are given in Table 1 for various assumed values of its redshift, z_d, and for $H_0 = 100$ km s^{-1} Mpc^{-1}.

The only bright background that is present everywhere is the microwave background. The only instrument capable of either resolving the black spot, or at least noticing it as a negative luminosity source is the Very Large Array (VLA). In fact, the black-spot detection might be feasible with the present VLA instrumentation (E. L. Turner, personal communication). It would be very interesting to look for this spot if future analysis indicates the existence of a very compact supermassive object.

I thank Dr E. L. Turner for information about the discovery of the new gravitational lens before publication, and for very many stimulating discussions. Discussions with Dr M. Sikora are also acknowledged. This research was partly supported by NASA grant NAGW-765.

Is QSO1146+111B,C due to lensing by a cosmic string?

J. Richard Gott III

Department of Astrophysical Sciences, Princeton University, Peyton Hall, Princeton, New Jersey 08544, USA

A predicted consequence of cosmic strings is that they should produce equal-brightness double-lens images of distant quasars (QSOs), with separations of up to several minutes of arc (see refs 1, 2). Here I discuss a newly discovered lens candidate[3–6]: QSO1146+111B,C which appears to consist of two images of equal brightness (B is 1.02 times as bright as C, with virtually identical spectra over the observed range) of a quasar at redshift $z = 1.01$, which are separated by 2.6 arc min. If this is produced by a cosmic string, its mass per unit length is $\mu \geq 4.0 \times 10^{23}$ g cm^{-1}, a value large enough to be interesting for string-assisted galaxy formation[7–9] and near the upper limits implied by the isotropy of the cosmic microwave background[2,10] and constraints on gravitational radiation[11]. But note that four other QSOs, also close enough to be double-imaged, have thus far not been detected. Searches for these and for the microwave background temperature shift across the string[2,10] would be useful.

The exact metric for a straight cosmic string has been given elsewhere[2]:

$$ds^2 = -dt^2 + dz^2 + dr^2 + (1-4\mu)^2 r^2 d\phi^2 \quad (1)$$

where μ is the mass per unit length in Planck masses per Planck length, and t, z, r and ϕ are the usual cylindrical coordinates. This is a conical space with angle deficit $D = 8\pi\mu$. Because the space-time is locally flat there is no image magnification. For convenience we adopt a value of $\Omega = 1$ for the cosmic density parameter, and the Hubble constant $H_0 = 50$ km s^{-1} Mpc^{-1}. The low-peculiar-velocity string produces double-lens images of equal brightness with separations[2]:

$$\Delta\theta = D\left[\cos\alpha - \frac{1-(1+z_s)^{-1/2}}{1-(1+z_q)^{-1/2}}\right] \quad (2)$$

where α is the angle between the string and the plane of the sky, z_q is the redshift of the QSO, and z_s is the redshift of the string at its point of closest approach. The formula applies only for those values of α, z_s, z_q which make the term in brackets positive. If 1146+111 is produced by a string, $\Delta\theta = 2.6$ arc min and the minimum value of μ is obtained in the limit $\cos\alpha = 1$, $z_s \ll 1$:

$$\mu \geq 3.0 \times 10^{-5} = 4.0 \times 10^{23} \text{ g cm}^{-1} \quad (3)$$

If this string is moving relativistically with a velocity V_s perpendicular to its own length and to the line of sight, this will produce a temperature shift

$$\Delta T \simeq 2.7\, DV_s/c \text{ K} \simeq 2.0\, V_s/c \text{ mK} \quad (4)$$

in the microwave background across the string[2,10]. A detailed map to look for this effect would be invaluable. This effect will also cause a velocity shift $\Delta V \simeq V_s D$ between the two spectra. The observations[6] indicate $\Delta V \simeq 126 \pm 309$ km s^{-1} in the rest frame of the QSO. A velocity shift $\simeq 120$ km s^{-1} could be produced by a perpendicular string velocity $V_s \simeq 0.5\,c$. The value $\mu \geq 3 \times 10^{-5}$ already pushes the allowed[2,10,11] upper limits so $\cos\alpha$ cannot be small and over the region of $1° \times 1°$ near 1146+111 $\cos\alpha \simeq$ constant. Thus, without loss of generality we shall adopt $\cos\alpha = 1$ in what follows.

Figure 1 shows where we should look for additional multiple QSO images. With a low-peculiar-velocity straight string as the lensing object, any QSO with redshift larger than 1.01 which has an image in the strip between the two horizontal lines must have a second image. The string itself must lie in this strip and any point within the strip must lie within 2.6 arc min of the string. Any QSO lying within 2.6 arc min of the string with $z_q > 1.01$ will be double-lensed (see equation (2)). For $0.2 \leq z_s \leq 0.6$ we would expect four of the other QSOs in the field to be double-lensed. No equal-brightness images of these QSOs have been seen. Thus, if this lensing event is caused by a string, it is surprising that there are no other easily detectable double-lensed QSOs in the field. One reason may be because of time delays between images[2]:

$$t_2 - t_1 = H_0^{-1}(\theta_1 - \theta_2) D[1-(1+z_s)^{-1/2}] \quad (5)$$

where θ_1 and θ_2 are the distances of the two images from the string. If the string passes directly down the middle of the strip then $t_1 - t_2 = 0$ for 1146+111B,C and we are guaranteed seeing them at equal brightness. The time delays for the other pairs of QSO images are, for $z_s = 0.2$ and $z_s = 0.6$ respectively: 190 yr and 6,000 yr for the quasar at $z_q = 2.22$; 240 yr and 3,900 yr for the quasar at $z_q = 2.12$; 450 yr and 1,800 yr for the quasar at $z_q = 1.10$; 300 yr and 6,500 yr for the quasar at $z_q = 1.93$. These delays are sufficient that the quasars could have varied considerably in brightness. Mini-lensing could also affect the brightness of the different images and as most of the string length is in the form of closed loops[8,12] it is always possible that the string is significantly curved, so that it misses making images of some of these other QSOs.

If the lensing object were a black hole or cluster of galaxies (singular isothermal sphere) then the QSOs at $z_q = 2.12$ and $z_q = 1.10$ would be more likely candidates for double imaging than those at $z_q = 2.22$ and $z_q = 1.93$. As B and C are of equal brightness (B is 1.02 times as bright as C in the emission lines

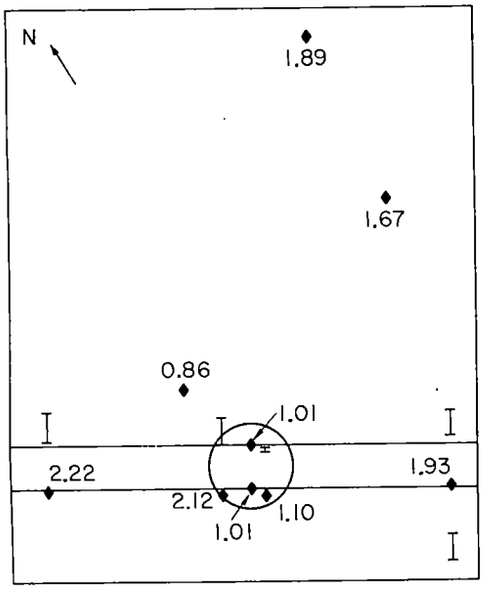

Fig. 1 Map of the known QSO images[4] (with redshifts) in the field of 1146+111B,C. Images B,C are the lower and upper images respectively, with redshifts of 1.01. If the lensing object is a low-peculiar-velocity, straight cosmic string, any QSO image with $z_q > 1.01$ lying in the strip (of width 2.6 arc min) between the two horizontal lines must have an accompanying second image. If $\cos\alpha = 1$ and $0.2 \leq z_s \leq 0.6$, the possible locations for second images of four of the QSOs are shown as vertical bars. The QSO at $z_q = 1.93$ has two sets of second-image locations because the string may pass either above or below it in the figure. If the string moves with a velocity V_s perpendicular to its length and to the line of sight, the two horizontal lines, pivoting on the two QSO images at $z = 1.01$, will be rotated (A. Vilenkin, personal communication) by an angle χ, where $\tan\chi = (v_s/c)\tan\alpha$, so that over some limited ranges of χ it is possible to find solutions which require no additional QSO images. Because, as we have argued, α must be small so that μ is not too large, it is likely that this rotation is relatively small. The lower limit for μ obtained in equation (3) is uncertain (A. Vilenkin, personal communication) by a factor $K = (c - V_{s\parallel})(c^2 - V^2)^{-1/2}$, where V is the velocity of the string and $V_{s\parallel}$ is its velocity parallel to the line of sight,which may be either positive or negative. If the lensing object is a singular isothermal sphere (cluster of glaxies with the requirement that its line-of-sight velocity dispersion $\sigma > 1{,}650\ \mathrm{km\ s^{-1}}$ to produce the observed 2.6 arc min splitting[14]) any QSO image with $z_q > 1.01$ lying inside the circle must have an accompanying second image. If the lensing object is a black hole, any QSO image with $z_q > 1.01$ lying inside the circle must have an accompanying second image at least 1/16th as bright as it is. A failure to find any additional images in this field could be perhaps equally embarrassing for all these lensing scenarios.

which are the most likely to remain constant over a significant period of time) the black hole or singular isothermal sphere cluster must be located approximately midway between the two images, and the critical lensing angle[13,14] is $\beta_{crit} = 1.3$ arc min for a QSO at $z = 1.01$. For quasars at larger redshift β_{crit} will be larger. For the singular isothermal sphere case any QSO image closer than $2\beta_{crit}$ to the centre will have an accompanying secondary image; for the black hole case any QSO image closer than $2\beta_{crit}$ to the centre will have an accompanying secondary image at least 1/16th as bright as itself. (The circle in Fig. 1 for these cases has a radius of $2\beta_{crit} = 2.6$ arc min (refs 13, 14). A supercluster seen edge-on, parallel to the strip and causing some image magnification is another interesting possibility as this might help to account for the unusually large number of QSOs seen[4] in this field.

To differentiate between these lensing models and the possibility that B and C are just too different QSOs, additional spectra of B and C and searches for additional images are essential.

I thank Ed Turner for discussion results before publication. This work was supported by NASA grant NAGW-765.

Relation between solar narrow-band decimetre-wave bursts and associated X-ray bursts

Shinzo Enome* & Larry E. Orwig†

* Toyokawa Observatory, Nagoya University, Toyokawa 442, Japan
† Code 682, NASA Goddard Space Flight Center, Greenbelt, Maryland 20771, USA

Theoretical models have been proposed, stimulated by a successful account of the jovian decametric radiation[1], for a maser mechanism, or a normal relativistic cyclotron resonance mechanism, operating in solar flares, and for transport of energy across magnetic fields to the electron gas by maser-amplified radio waves[2]. Much effort has been directed towards observations of solar-flare radio spike bursts[3–8]. Here we compare solar narrow-band decimetre-wave spike bursts with corresponding X-ray events for 25 solar flares. We find that decimetre spike bursts are 10^2–10^3 times stronger than normal impulsive microwave bursts for the same observed amount of hard X-ray emission. This feature, along with the observation of 100% circular polarization, strongly supports a maser origin for the decimetre spike bursts.

A previous study[8] compared narrow-band decimetre (DCM) bursts with X-ray radiation observed by the hard X-ray (HXM) and soft X-ray (FLM) detectors aboard the spacecraft Hinotori[9,10]. In the work described here, we have taken advantage of the larger data recording capacity of the SMM spacecraft to achieve more homogeneous sampling with respect to flare intensity. We have chosen to compare the hard X-ray data at energies above 30 keV from the SMM hard X-ray burst spectrometer, HXRBS[11], with the radio data from the polarimeters at Toyokawa Observatory[12]. The former provides hard X-ray count rate and 15-channel spectral data in the energy range 30–500 keV with 0.128-s resolution, and the latter provides radio data at four frequencies, 9.4, 3.75, 2 and 1 GHz, at a sampling rate of 0.5 s. The narrow-band DCM events treated here, for which emission is strongly polarized and is seen or strongly enhanced only at 1 GHz, are likely to be a subgroup of the fine-structure radio bursts studied by Droege[3], with additional information on polarization, or part of classical DCM type IV[13], but are probably different from the 2.65-GHz spikes investigated by Slottje[4,5] and from blips[6].

The data sets used in the present analysis were obtained during a period of common observations from 12 to 14 November 1981 during a so-called DCM storm. A portion of this storm is shown in Fig. 1, where the total solar radio emission is plotted against time at four frequencies for 13 November 1981. A typical spike burst is illustrated in Fig. 2, in which the 1-GHz data (*a*) and hard X-ray data above 30 keV (*b*) are plotted against the same timescale for comparison.

For each of the events studied we have obtained the peak intensity of hard X rays above 30 keV and in the radio emission at 1 GHz (Table 1). Figure 3 shows the resulting peak intensity correlation diagram for radio and X-ray events, revealing that

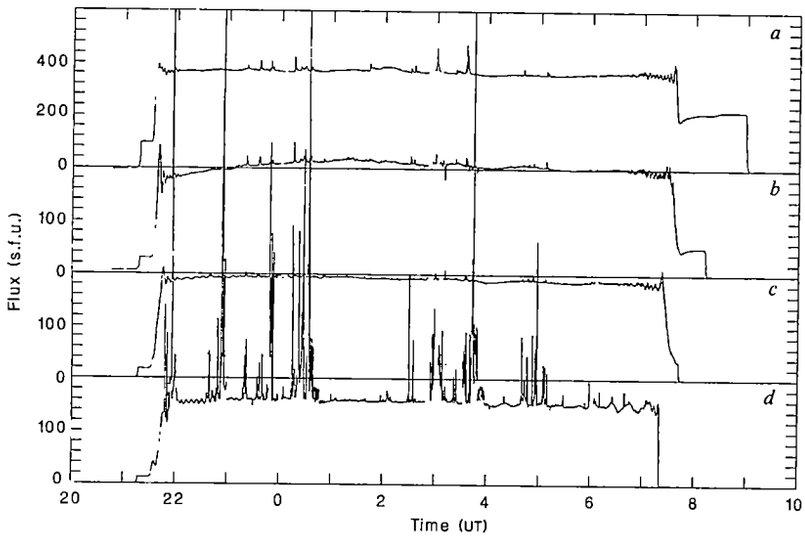

Fig. 1 Time profiles of flux at four frequencies (*a*, 9.4; *b*, 3.75; *c*, 2; and *d*, 1 GHz) observed at Toyokawa on 13 November 1981. Data gaps at 00:00, 03:00, and 06:00 UT (Universal Time) are calibration signals erased.

Events with no entry in the HXR peak rate column (hard X-ray peak rate above background, in the range 30–500 keV) were not observed above instrument background by the HXRBS. s.f.u. are solar flux units.
* Spike burst; † impulsive burst.

there are two distinct classes of events. One is a group of radio events for which there is very weak, if any, hard X-ray emission above 30 keV. In the second group, the radio events are associated with X-ray events of appreciable size. We will call the first group 'coherent' events and the second group 'incoherent' events. The radio bursts of the first group have the following characteristics: (1) all bursts are strongly polarized, ~100% at 1 GHz; (2) all show very spiky structure on timescales of a few seconds or less; (3) all are intense only at 1 GHz; that is, they have a narrow-band spectral character. These characteristics are a common feature of maser-associated phenomena.

The characteristics of incoherent events are almost entirely opposite to those of coherent events. Thus, the spectra of incoherent bursts are not narrow-banded in character, time profiles are less spiky, with typical time constants of ≥10 s, and the degree of polarization is not high. Some incoherent bursts are almost unpolarized, and for those that are polarized the degree of polarization is much less than 100%, even at 1 GHz. It is important to note that for the incoherent events there is a linear relation between the microwave and hard X-ray intensities, reflecting the well-established proportionality between microwaves and hard X rays[14,15]. We should mention that there are three events (18, 19 and 22 in Table 1) which, while being classified as impulsive events, do show a slight mixture of impulsive and spike characteristics.

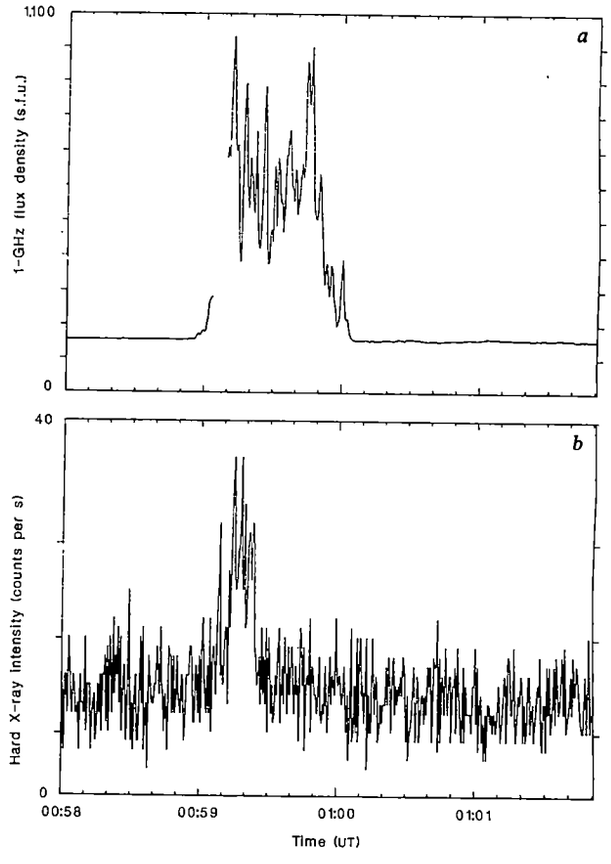

Fig. 2 High-time-resolution profiles of the 1-GHz radio burst (*a*) and X-ray burst (*b*) at 00:59:12 UT on 12 November 1981. The hard X-ray intensity is the raw count rate observed between 30 and 86 keV (including background).

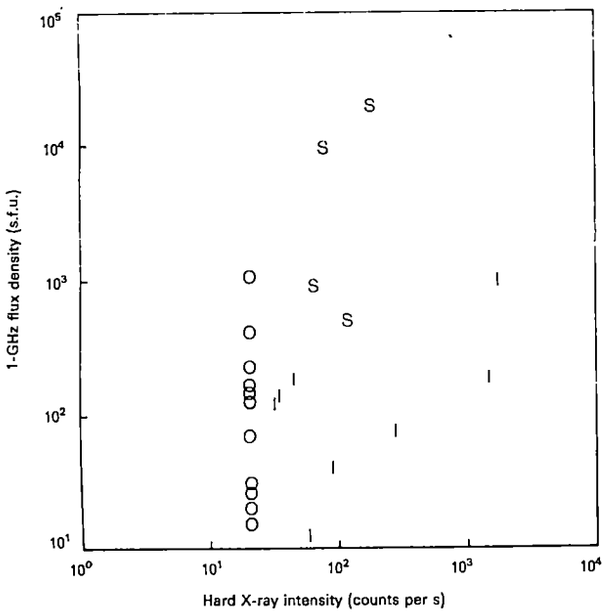

Fig. 3 Correlation diagram between peak flux at 1 GHz and X-ray intensity above 30 keV for the 25 flares studied. 'S' and 'I' indicate spike bursts and impulsive bursts, respectively. Open circles correspond to radio bursts with no observable X-ray enhancement above the background noise, so that the plotted hard X-ray intensity is a 3σ upper limit.

When one considers the above characteristics, the most striking feature of coherent events is the fact that they exhibit unusually weak X-ray emission, almost below the detection limit of the HXRBS. For the events studied here, the ratio of radio to X-ray intensity is larger by a factor of 10^2–10^3 for the coherent events than for the incoherent events. This enhancement factor has thus been determined observationally for the first time, and provides convincing evidence for the existence of a coherent radiation mechanism operating in these events. Its value is indispensable when one considers the saturation mechanism in the maser effect. The factor of 10^2–10^3 should be considered as a lower limit, because the bandwidth and the temporal structure of narrow-band coherent spike bursts might be much smaller and finer than our observational limits of 10 MHz and 0.5 s, respectively. Such bursts, if they exist, could be observed with more sophisticated instruments[3–7,13].

The temporal relation between the two radiations has been examined for both classes of events. Such a comparison is difficult due to the complex structure in both types of radiation. For example, detailed consideration of the event shown in Fig. 2 reveals that the identification of corresponding spikes in each data set for this burst is complicated, and a unique one-to-one correspondence cannot be specified. The results in Table 1 indicate that for those flares for which a comparison can be made there are time delays observed between the main peaks in radio and X-ray emission. In the coherent events the time delays are distributed from −3 to 8 s. Note, however, that radio bursts of the incoherent type are always delayed in time relative to the associated X-ray bursts.

Bottom-current pathways in the Argentine Basin revealed by mean silt particle size

Michael T. Ledbetter

Moss Landing Marine Laboratories, PO Box 450, Moss Landing, California 95039-0450, USA

Regional circulation patterns in the deep sea are very difficult to determine because of time constraints on the acquisition of large physical-oceanographic data sets from abyssal depths; in addition, the large number of long-term (≥1 yr) current-meter arrays needed to delineate bottom-current pathways are extremely costly. An alternative method for inferring benthic flow patterns, described here, is to map the mean size of the silt fraction of sediment on the sea floor. Because of the availability of a large number of core samples in the Argentine Basin, the particle-size approach provides a useful method for determining bottom-current pathways in that deep basin.

The mean particle size of the non-biogenic silt fraction of sediment from seafloor (gravity-core-top) samples has been used to delineate deep western boundary undercurrents (DWBUCs) in the Vema channel[1–3], Amirante Passage[4] and the lower continental rise of eastern North America[5,6]. In those cases, however, the method was used only to identify the depth range of a high-velocity DWBUC and was not applied to an entire basin, which would include areas of low bottom-current velocity. The Argentine Basin in the south-west Atlantic Ocean provides a unique opportunity to test the particle-size technique in a basin where bottom-water velocity ranges from high-velocity DWBUCs to low velocities on the lower flank of the Mid-Atlantic Ridge[7,8]. Another useful factor is the availability of a large number of core-top samples in the region.

The mean silt particle size was determined for the non-biogenic fraction of seafloor samples obtained from gravity core tops deeper than 4,000 m, in which there is no evidence of graded bedding or sedimentary structures indicative of turbidites. The bottom-current velocity inferred from particle-size data is contoured to divide the relative velocity into five divisions, arbitrarily classified from highest to lowest velocity (Fig. 1). The boundary between moderate and high relative velocity was chosen at a mean silt particle size $\phi = 6.0$ (16 μm), the mean size which delineates the top of the DWBUC in both North and South Atlantic studies[1–6]. The contour interval for relative velocity (Fig. 1) represents a difference of 0.2 in silt mean ϕ, which is analysed with a precision of 0.05 (refs 2, 3).

The inferred relative bottom-current velocity in the Argentine Basin reveals a benthic flow pattern which is controlled principally by geostrophy and bathymetry (Fig. 1). Antarctic Bottom Water (AABW) enters the South Sandwich Basin through the newly discovered Bullard Fracture Zone[9], which has served as a bottom-water conduit throughout the Quaternary[10]. On encountering the South Sandwich Ridge, AABW is diverted north, where the main branch flows as a DWBUC into the Georgia Basin while a minor branch flows around the eastern flank of the Islas Orcadas Rise. The two branches rejoin near a gap in the Falkland Fracture Zone[11], where the flow intensifies as it follows approximately the 4,000–5,000-m contour interval through the southwestern and western Argentine Basin.

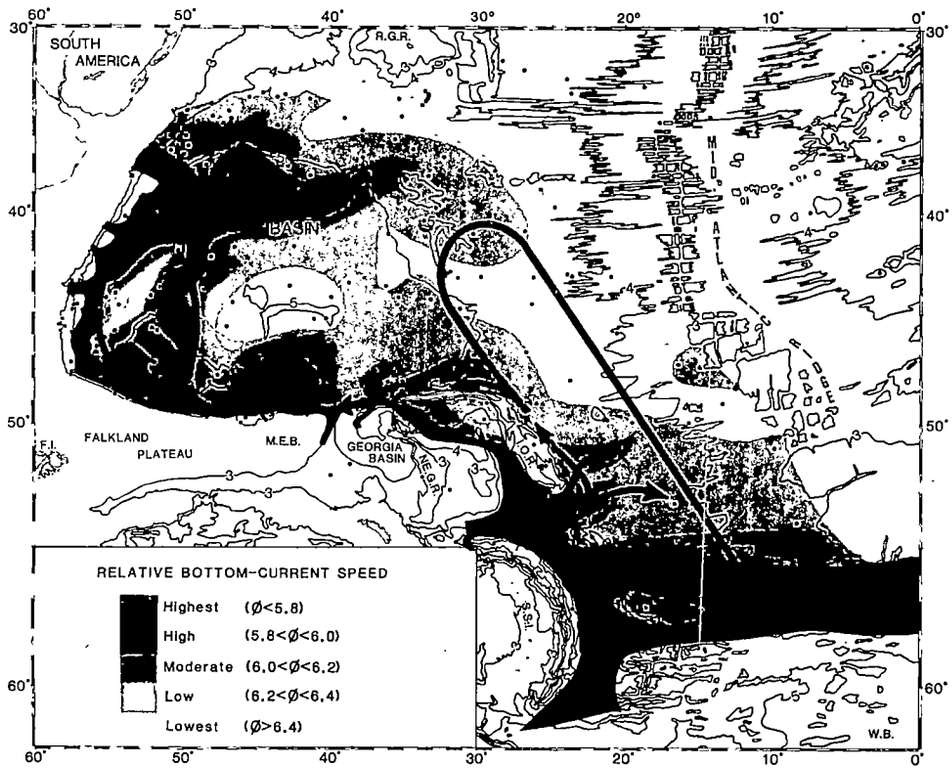

Fig. 1 The relative bottom-current velocity in the Argentine Basin region is inferred from contours of mean silt particle size, $\phi(=-\log_2$ particle size in mm) in gravity core-top samples (dots) deeper than 4,000 m. Benthic oceanography determined from hydrocasts[8] is shown by black arrows (width of arrow volume transport).

Bottom water leaves the Argentine Basin through the Vema and Hunter Channels[12], which have sill depths considerably shallower than the abyssal floor of the basin, with the result that the denser component of AABW, Weddell Sea Bottom Water[7], is diverted east at depths greater than the sill depth of the outlets (Fig. 1). The axis of this flow is at depths slightly greater than 5,000 m, but water as shallow as ~4,500 m is incorporated into a broad return flow which is detectable on the lower flank of the Mid-Atlantic Ridge.

In addition to the main DWBUC flow pattern, the particle-size data reveal several abyssal gyres, or return flows (Fig. 1). A series of small gyres break away from the DWBUC adjacent to rises and ridges in the south-west part of the study area. A large gyre is seen north of the Maurice Ewing Bank and may be controlled by, or be responsible for, the topography of the crescent-shaped Zapiola Ridge[11]. The major return-flow gyre delineated by the particle-size data is found in the western basin to the east of the DWBUC, at a depth of ~5,500 m (Fig. 1). The position of the axis of this return flow corresponds to a zone of eastward-dipping isotherms below 4,000 m which is consistent with a return flow in the hydrographic data[8].

The particle-size data on the South American continental margin have a complex pattern (Fig. 1) resulting from the input of terrigenous material by down-slope processes through the many canyons on the slope. Some of the sources for the input of coarse silt can be seen in the seafloor data map (Fig. 1). It is possible, in principle, to change the particle-size distribution at source or to have different sources of silt particles, so that the regional pattern of particle size represents either source or bottom-current velocity variations, or both. The Argentine Basin is an excellent basin in which to test this hypothesis because of the multiple sources along the Argentine continental margin, the Falkland Plateau, and material transported by deep currents from the Weddell Sea. Despite these numerous sources, the dominant pattern of a high-velocity DWBUC with major return-flow gyres is obvious in the pattern inferred from particle-size data. Therefore, in this basin, the major factor controlling particle-size distribution appears to be the velocity of the current in which the material is deposited.

Because each geological sample represents decades to hundreds of years of sedimentation controlled by flow conditions, the relative bottom-current velocity charted in Fig. 1 represents the long-term bottom-current circulation. It is interesting to note, however, that the bottom-water circulation below 4,000 m determined from hydrocast data[8] on a timescale of years correlates with the long-term geological evidence (decades to hundreds of years) of benthic circulation (Fig. 1). All of the major, high-velocity current patterns are mirrored in the particle-size data, including the small return-flow gyres. The only area of high current velocity which is not predicted by the oceanographic data[8] is the broad eastward-flowing current in the northern basin (Fig. 1), but that study[8] did not extend north of ~40° S and may have missed the eastward-flowing arm of the major gyre in the northern Argentine Basin.

The other disparity between particle-size and hydrographic data lies in the weaker eastern gyre (Fig. 1) predicted from hydrographic data[8]. The particle-size data reveal a large gyre system, with the weakest return flow in the eastern basin, but does not delineate a northern arm of eastward-flowing water in the eastern gyre.

Therefore, the major circulation pattern of long-term bottom-water flow in the Argentine Basin region can be delineated from the particle size of seafloor samples. The pattern revealed by the particle-size approach differs in only one major aspect from that obtained from hydrocast data: the predominant flow pattern includes a basin-wide return-flow gyre to the north and east rather than two separate, smaller gyres[8]. The results are consistent with a major, contour-following DWBUC in the south-western and western Argentine Basin. Because the particle-size method may be applied to existing core-top samples, it should be possible to map the major bottom-current pathways in the abyssal ocean in other areas of dense core coverage. The resulting patterns, when combined with other sediment data, should provide a necessary component for describing the sediment dynamics in areas of current-controlled sedimentation.

Ubiquitous occurrence of 2-nitrofluoranthene and 2-nitropyrene in air

Thomas Ramdahl*, Barbara Zielinska, Janet Arey, Roger Atkinson, Arthur M. Winer & James N. Pitts Jr

Statewide Air Pollution Research Center, University of California, Riverside, California 92521, USA

Several nitrated polycyclic aromatic hydrocarbons (nitro-PAH) are direct-acting mutagens[1,2] and/or carcinogens[2-4], and are important constituents of combustion emissions and ambient air. These nitro-PAH are emitted from various combustion sources including gasoline and diesel engine exhaust[5-8], aluminium smelting effluent[9], coal fly ash[10], wood smoke[6], and cigarette smoke condensates[11]. Of these, diesel engine exhaust is the best characterized[6-8], more than 50 nitrated polycyclic aromatic compounds having been identified by Paputa-Peck *et al.*[8], including 1-nitropyrene (1-NP) as the single most abundant nitro-PAH. However, nitro-PAH may also be formed during source–receptor transport by atmospheric reactions of adsorbed or gas-phase PAH with oxides of nitrogen, nitric acid and other atmospherically important species such as the OH radical[1,12-14]. Evidence for the atmospheric formation of nitro-PAH has come only recently, from observations that 2-nitropyrene (2-NP)[15-17] and 2-nitrofluoranthene (2-NF)[16,17] neither of which has been reported to be emitted from combustion sources, are among the major nitro-PAH present in ambient air. We present here data from several locations which demonstrate that these two atmospherically formed nitro-PAH are ubiquitous in tropospheric ambient air.

Ambient particulate matter was sampled by three different methods. An ultra-high-volume 'mega-sampler'[18], with a 50% cutoff point of 20 μm and typically 6-h sampling periods, was used at Claremont, California, a site ~40 km east of downtown Los Angeles. In Aurskog, Norway, a rural residential area, an electrostatic precipitator (ESP)[19] with an impact stage designed for a 15-μm cutoff was used to collect particulate matter during several weeks in the winter of 1984. The other urban-air particulate matter samples analysed were the US National Bureau of Standards (NBS) Standard Reference Materials (SRMs) No. 1648 and 1649 (refs 20, 21). These samples were collected by means of specially designed filter baghouses over a period of more than a year in St Louis, Missouri (SRM 1648) and Washington DC (SRM 1649).

High-resolution gas chromatography/mass spectrometry (GC/MS) is required to distinguish between 2-NF and the very closely eluting 3-nitrofluoranthene (3-NF) isomer[16,22], as discussed below, because of this near-equality of GC retention times 2-NF has been misidentified as 3-NF in several previous studies[15,23,24]. Our identification of 2-NF is based on the observed GC retention time, along with its characteristically low m/z 217 $[M-NO]^+$ fragment-ion abundance (~4% compared with ~46% relative abundance for this fragment ion in 3-NF)[16,22].

Figure 1 shows that the nitro-PAH fractions of the samples from St Louis, Claremont and Aurskog all contain 2-NF, 1-NP and 2-NP. The concentrations of these three nitro-PAH in the particles analysed from the various locations studied are given in Table 1. Unfortunately, for the NBS SRM baghouse and the Aurskog ESP samples, the actual ambient air concentrations cannot be determined because the sample air volumes are unknown. However, from our present measurements at Claremont and earlier measurements[15,16], these nitro-PAH are typically present in the low pg m^{-3} range. In all of the samples analysed, 2-NF was the most abundant nitro-PAH, with 1-NP and 2-NP being present in lesser amounts.

Due to the small difference in the GC retention times for 2-NF and 3-NF, the 2-NF present in SRM 1648 and in samples from Philadelphia, Pennsylvania, and a rural site in Denmark in winter were originally reported as 3-NF in refs 23, 24 and 15, respectively. These samples have since been re-analysed, with the result that 2-NF, and not 3-NF, has been shown to be present in all cases[17,25,26]. These and our present observations show conclusively that 2-NF and 2-NP are ubiquitous in ambient particulate organic matter (POM). Although Jäger[27] reported the presence of 3-NF in ambient air in Prague, Czeckoslovakia, it is possible that the nitrofluoranthene isomer identified from the thin-layer chromatography–fluorescence quenching measurements was actually 2-NF, as it is not clear that this method[27] could distinguish between 2-NF and 3-NF. Additionally, Morita *et al.*[28] have reported an unidentified nitrofluoranthene or nitropyrene isomer more abundant than 1-NP in an urban air sample in Japan; this could also be 2-NF.

Table 1 Concentrations of nitro-PAH and BeP (μg g^{-1}) in air particulate matter samples at different locations in the USA and Norway

Compound	Claremont*	St Louis†	Washington‡	Aurskog§
2-NF	2.8	0.56	0.60	0.56
1-NP	0.36	0.16	0.20	0.15
2-NP	0.08	0.06	0.05	0.17
BeP	3.4	5.2‖	4.6	44
Concentration ratios				
2-NF/BeP	0.8	0.1	0.1	0.01
2-NP/BeP	0.02	0.01	0.01	0.004

* Combined sample from four 6-h sampling periods from 14 to 15 September 1985.

‡ NBS SRM 1649.
§ Sampled during February and March 1984.
‖ From ref. 24.

Indeed, the only well-documented report of the presence of 3-NF in ambient air is that of Pitts *et al.*[16], in which a small amount of 3-NF, together with a much greater amount of 2-NF, was detected in one sample collected during morning hours in Riverside, California. Based on literature data, the 1-NP and 3-NF observed in ambient POM probably originate from combustion sources[5-11], atmospheric transformations[1,12,13] and/or reactions during collection[1,29]. However, 2-NF and 2-NP have not been observed in combustion emissions, nor from any nitration reactions of adsorbed fluoranthene or pyrene in the dark[1,29-31], although Wu and Niki[32] have recently tentatively identified 2-NP as a product of the reaction of NO_2 with monodisperse pyrene on silica particles in nitrogen in the presence of light.

* Current address: Norsk Hydro A.S., PO Box 4313, S013 Nygaardstangen, Norway.

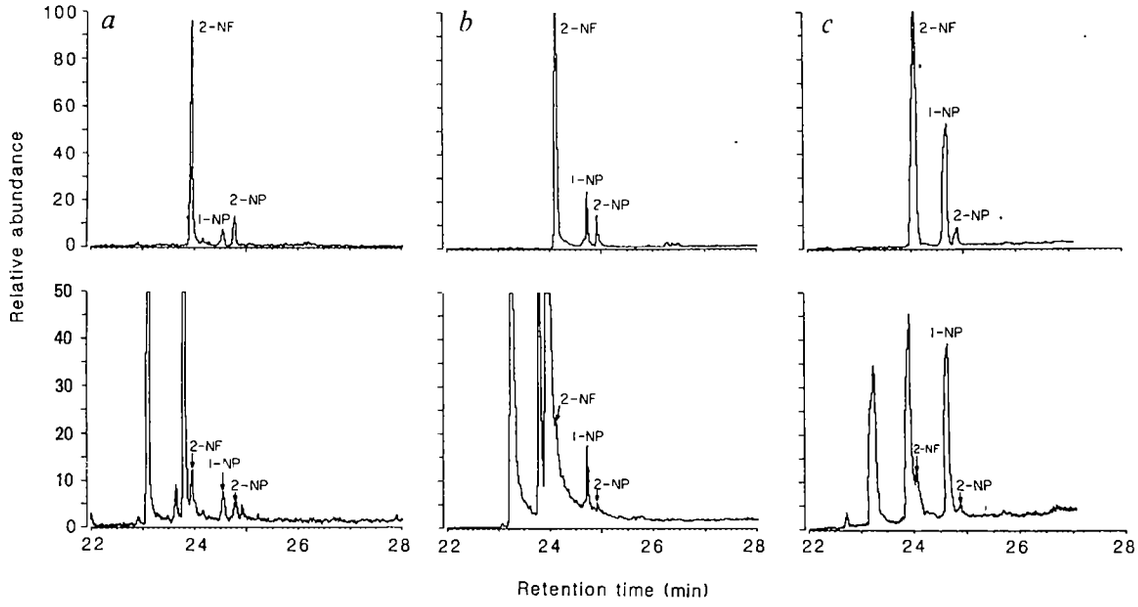

Fig. 1 GC/MS multiple ion detection (MID) mass chromatograms (top, molecular ion M^+; bottom, fragment ion $[M-NO]^+$) of enriched nitro-PAH fractions of extracts of air particulate matter from: *a*, Aurskog, Norway; *b*, St Louis, Missouri and *c*, Claremont, California (see Table 1). Note the characteristically low $[M-NO]^+$ fragment-ion relative abundances for 2-nitrofluoranthene (2-NF, 4%) and 2-nitropyrene (2-NP, 8%), in comparison with that of 1-nitropyrene (1-NP, 39%)[16,22]. The samples were Soxhlet-extracted for 18 h with dichloromethane. 2-Nitrofluoranthene-d_9 and 1-nitropyrene-d_9 were added to the extracts as internal standards. The extracts were pre-cleaned by open-column silica (5% H_2O) chromatography to remove aliphatic hydrocarbons and polar material. The fractions of interest were further fractionated by normal-phase high-performance liquid chromatography (HPLC) using a semi-preparative silica column. The HPLC fractions containing nitro-PAH were analysed by GC/MS MID using a Finnigan model 3200 mass spectrometer operating in the electron impact mode. The samples were chromatographed on a 30-m DB-5 fused silica capillary column (J&W Scientific), directly eluting into the ion source. On-column injection was made at 50 °C, followed by a temperature program at 8 °C min^{-1} to 350 °C. The data were calibrated by comparing the ratios of the areas of the molecular ion (m/z 247) peaks to those of the deuterated internal standards (m/z 256)[16].

Thus, 2-NF and 2-NP observed in ambient POM seem to be formed from their parent PAH during atmospheric transport[15,16]. Table 1 lists the concentrations of 2-NF and 2-NP relative to that of benzo[*e*]pyrene (B*e*P), a fairly non-reactive[33] PAH of similar volatility. Although the same nitro-PAH are observed at all of the locations studied, the extent of the formation of 2-NF and 2-NP from the parent PAH varies (assuming that the ratios of emitted fluoranthene and pyrene to B*e*P are similar at all locations), with that for 2-NF varying much more (by a factor of ~80) than that for 2-NP (a factor of ~5). This suggests that different reaction pathways may be responsible for the formation of 2-NF and 2-NP. Table 1 also shows that the ratios 2-NF/B*e*P and 2-NP/B*e*P exhibit the same trend as the ambient temperatures; that is, Claremont > St Louis ≃ Washington > Aurskog, consistent with the occurrence of gas-phase reactions as formation pathways for these nitro-PAH. Indeed, 2-NF is formed from the gas-phase reaction of fluoranthene with N_2O_5 (ref. 17), and this may be one reaction pathway under atmospheric conditions. Other reaction pathways which could form 2-NF and 2-NP include OH-radical-initiated reactions[15,16] and, for 2-NP, photoinduced reactions with NO_2 (ref. 32).

Summer conditions are not necessary for the formation of 2-NF and 2-NP, as these nitroarenes are present in the winter air samples from Aurskog and Denmark[15,26]. Indeed, the Aurskog sample contains the highest absolute amount (wt/wt particles) of 2-NP of all the samples for which data are given in Table 1. The main sources of PAH in this area of Norway are emissions from residential heating by wood and kerosene, which results in high atmospheric levels of PAH in winter (stagnant air) conditions[34], and as expected (Table 1), the ambient air at this location contains ~10 times more PAH (as indicated by the concentration of benzo[*e*]pyrene) than do the other samples analysed.

Thus, atmospherically formed 2-NF and 2-NP are observed in conditions ranging from Claremont in summer (high temperature, high radiation flux) to Aurskog in winter (low temperature, low radiation flux). Of the known reactions of PAH under atmospheric conditions[17,35,36], the gas-phase reactions with N_2O_5 and/or with OH radicals followed by NO_2 addition are candidates for the formation of these NO_2-PAH. Laboratory and ambient atmospheric measurements intended to resolve these questions are in progress.

We thank the California Air Resources Board (contract no. A4-081-32; Dr Jack K. Suder, project monitor) for financial support. The collection of the Aurskog sample was made possible by support from the Nordic Council of Ministers, through the MIL-2 project. The technical assistance of Mr Travis M. Dinoff (SAPRC) and Mr Adler Mikalsen (Norwegian Institute for Air Research, Aurskog particulate sampling) is acknowledged. T.R. thanks the Royal Norwegian Council for Scientific and Industrial Research for a 1985 Research Fellowship.

Influence of Saharan dust on the rain acidity and atmospheric input to the Mediterranean

M. D. Loÿe-Pilot, J. M. Martin & J. Morelli

Institut de Biogéochimie Marine, UA CNRS 386, Ecole Normale Supérieure, 46 rue d'Ulm, 75230 Paris Cedex 05, France

It has long been recognized that Saharan dust may be transported a long way from its sources, particularly over the ocean[1], and especially over the tropical North Atlantic, as far as the Caribbean[2–7], and over various areas of the Mediterranean[8–10]. The eolian transport of desertic aerosols is a major contribution to oceanic sedimentation[11–13] and may have important climatic implications[14]. This phenomenon is responsible for episodes of so-called 'red rain' or 'red snow' which have been identified in various areas of the European continent[15–17]. Numerous red rains and red dust falls have been observed in Corsica. From 1984 data on the chemistry of precipitation collected in South Corsica, we show here that due to its $CaCO_3$ content, Saharan dust significantly increases the *p*H of rain water. This may counteract the effects of acidic rain. An assessment of African dust deposition indicates that, compared with the sediments discharged by the Rhône river, atmospheric input to the northwestern Mediterranean contributes significantly to sedimentation in that region.

Data were taken from our sampling station located in a clean area near the Bavella Pass (41°50′ N, 9°10′ E), at 1,200 m above sea level. Systematic observations on rain chemistry have been made since 1980 at this station, using a plastic gauge of 400 cm^2 aperture. According to the intensity of precipitation, its frequencies, duration and the accessibility of the site in winter, the sampling times ranged from several hours to one week. Generally, samples represent bulk deposition (wet plus dry), although some samples were taken within precipitation episodes and were thus not mixed with dry deposition. More rarely, in some periods without rain, dry deposition was collected separately, by rinsing the plastic gauge with distilled water. The liquid samples, which were sometimes produced from melting snow, were filtered indoors close to the field, using 0.4-μm Nuclepore filters, to evaluate the particulate matter content. The *p*H was measured using a potentiometric method; Na^+, K^+, Ca^+ and Mg^{2+} by atomic absorption spectrometry; and Cl^-, SO_4^{2-}, NO_3^- and NH_4^+ by a colorimetric method.

Only 1984 data will be discussed here, attention being focused on the magnitude of the load of red dust in rainwater samples and its influence on dissolved calcium enrichment and *p*H. Indeed, it is only the latter two parameters that are systematically affected by the incorporation of red dust in rain water. Figure 1 concerns 60 successive rain samples of 1984, including 19 'red rains'. The represented weights of solid matter relate only to 'red rains', the other values being generally <2 mg per filter. The calcium enrichment, which can be considered as an index of non-marine calcium sources, is defined by the relation E_{Ca} = (Ca/Na) rain water/(Ca/Na) sea water.

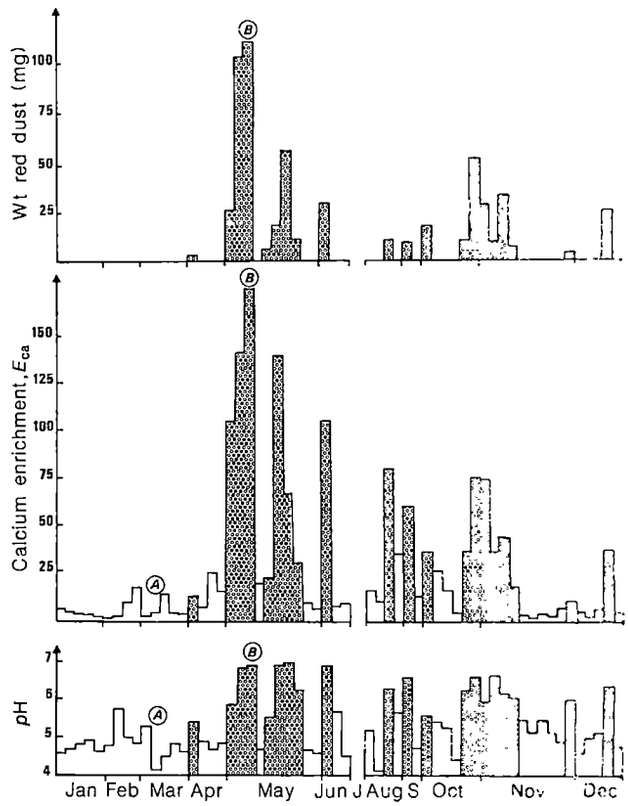

Fig. 1 Simultaneous variations in the red dust content of rainwater samples, their calcium enrichment and their *p*H during 1984. A and B refer to episodes for which air-mass trajectories are given in Fig. 2.

Figure 1 reveals seasonal variations of the input of red dust, with sporadic episodes. A maximum is observed in spring, for example, in May when seven rainfalls account for ~60% of the annual deposition of red particulate matter, with a contribution of 40% for the two events of 5 and 10 May only. Moreover, the two observed episodes of red dust dry fallout occurred in May and June; they account for 10 and 33 mg of red dust and contribute to 8% of the bulk annual red dust input. Compared with the annual total deposition of solid particulate matter, red dust represents 84% of this flux.

Careful study of the back trajectories of the 700- and 850-mbar air masses arriving on the sampling zone confirms that this red dust originates from arid regions in the north of Africa. The incorporation into rain of desert particulate matter is accompanied by a strong increase in the dissolved calcium content. This agrees with the similar evolution of the collected load of red dust and calcium enrichment in rainwater samples. E_{Ca} is maximal and higher than 100 for some May episodes and reflects the strong influence of continental sources. Mineralogical analysis by X-ray diffraction shows that the incoming Saharan dust contains 5–30% of calcite and sometimes gypsum, although this is generally <2%. These $CaCO_3$ contents fit the composition of wind-blown Saharan dust collected in various regions[18–21]. The partial dissolution of this component accounts for a significant increase in rainwater *p*H. During situations without input of Saharan dust, the *p*H varies from 4.1 to 5.6, corresponding to E_{Ca} of often lower than 10 and rarely higher than 20. Such calcium enrichments can be related to the influence of the European continental environment but it is difficult to specify whether they are due to natural sources (soils) or to industrial

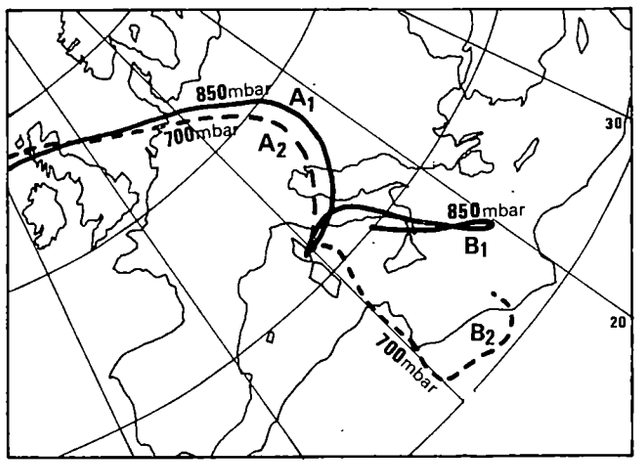

Fig. 2 Back trajectories (4 days) of air masses arriving in the sampling zone for an acidic episode (trajectories A_1 and A_2 correspond to 8 March 1984 at 18.00 UT) and for an episode with a maximal input of Saharan dust (trajectories B_1 and B_2 correspond to 10 May 1984 at 06.00 UT).

emissions (such as cement works). The influence of a residual Saharan aerosol background cannot be excluded.

The *p*H values increase to 6 or 7 during 13 of the 19 Saharan dust episodes. In considering the origin of the more acidic values, we must remember that rain water may be naturally acidic[24]. In the Mediterranean Basin, the Italian volcanoes represent a major natural source of atmospheric sulphuric acidity, especially the SO_2 emissions of Etna, which constitute 1,000–2,000 tonnes day^{-1} on average[25–28]. Nevertheless, for the lower *p*H values, black particulate matter is often recovered after rain filtration. This is in agreement with the relatively high sulphate content of rain water: 5–10 mg l^{-1} after correction of marine sulphate from bursting bubbles. According to the origin of incoming air masses, such a result could be explained by the spreading of atmospheric pollution over the northwestern Mediterranean.

The antagonistic effects of Saharan dust and other natural and industrial sources of aerosols on the acidity of the collected rain samples is supported by the data in Fig. 2. For example, we show back trajectories of 700- and 850-mbar air masses for two well-differentiated kinds of meteorological situations. The first corresponds to an episode of relatively acidic rain with a *p*H of 4.1 (trajectories A, 8 March), the second to a *p*H of 6.8 observed for the maximal input of Saharan dust (trajectories B, 10 May). Taking into account the possible atmospheric impact of long-range transport of pollutants,[29–31], the acid episode could be related to emissions from various European industrial regions and where there is no atmospheric mixing with African aerosols. In this case, the neutralization of rain acidity by incoming Saharan dust must occur later, after deposition, and this may have pedological and ecological implications. On 10 May, there is a more complex situation with the superposition of air masses, which could have passed over volcanic and industrial Italian regions, with air masses of African origin. Thus, the collected rain scavenged atmospheric components of different origins, and the acidity might have been neutralized within cloud and rain.

Finally, we shall consider the geochemical consequence of atmospheric deposition of Saharan material in the Mediterranean environment. If the contribution from dry fallout is included, results from 1984 at Bavella Pass indicate a red dust flux of 14 tonnes $km^{-2}\,y^{-1}$, which represents an annual deposit of ~10 μm assuming a density of 1.25–1.65[32]. This value accounts for about 10% of the Western Mediterranean pelagic sedimentation: 100 μm yr^{-1} [33], which could be greatly influenced by marine biogenic material. How representative this flux is when evaluating atmospheric input into the Mediterranean is questionable, in that rainfall is relatively high in the mountainous areas of Corsica. With respect to the complex removal processes of aerosols[34–35], this effect of relief may enhance the scavenging of atmospheric particulate matter and consequently its deposition rate compared with the corresponding flux for marine-adjacent regions. However, in the case of red dust, we observed that the first rain droplets contributed to the major part of its deposition. Moreover, data from Bavella Pass (1,200 m) and the neighbouring station of Arza (700 m) show similar values for red dust deposition, collected simultaneously for 11 of the 19 red rains of 1984. For these episodes, which represent 80% of the annual red dust wet fallout in Bavella station, the input was 11% higher in Arza where the rainfall was 17% lower. Thus, the altitude effect does not seem to be very important for the removal of airborne desert material. It is, therefore, not unrealistic to extrapolate the above red dust deposition rate to sea level for the northwestern Mediterranean Basin, that is, 277,000 km^2. This leads to an input of 3.9×10^6 tonnes yr^{-1}, which is of the same order as the average annual downstream flow of solids in the Rhône (4.3×10^6 tonnes; ref. 36). A more precise evaluation would have to take into account regional geographical variability in the atmospheric deposition of Saharan dust. Despite the inaccuracy of the present assessment, it appears that this phenomenon must play an important part in the geochemistry and sedimentology of the marine zone considered.

This work was carried with the financial support of the CNRS Land–Sea Interactions Coordinated Group (GRECO–ICO) and ATP Aerosols désertiques and of ENSJF, Biologie-Géologie Laboratory. Air-mass trajectories were established by Météorologie Nationale. We thank Dr R. Chester for useful comments and J. A. Lefèvre and N. Kielbasa for technical assistance.

Amino-acid sequence of the β-subunit of the $(Na^+ + K^+)$ATPase deduced from a cDNA

Gary E. Shull*, Lois K. Lane† & Jerry B. Lingrel*

Departments of * Microbiology and Molecular Genetics and of † Pharmacology and Cell Biophysics, University of Cincinnati College of Medicine, 231 Bethesda Avenue, Cincinnati, Ohio 45267-0524, USA

The sodium/potassium-dependent ATPase [$(Na^+ + K^+)$ATPase], which establishes and maintains the Na^+ and K^+ gradients across the plasma membrane of animal cells, consists of two subunits, α and β. Complementary DNA clones encoding the catalytic (α) subunit of sheep kidney[1] and *Torpedo californica* electroplax[2] enzymes have previously been isolated and characterized. However, there is little information concerning the primary structure of the β-subunit, a glycoprotein of unknown function and relative molecular mass (M_r) ~55,000 (ref. 3). Here we describe the isolation and characterization of a cDNA clone containing the entire coding region of the β-subunit of the sheep kidney $(Na^+ + K^+)$ATPase. We also discuss structural aspects of the protein and present evidence for a possible evolutionary relationship with the KdpC subunit of the *Escherichia coli* K^+-ATPase[4].

Tryptic peptides of the β-subunit of the sheep kidney $(Na^+ + K^+)$ATPase were isolated and the amino-acid sequences of three peptides determined (Table 1). The N-terminal amino-acid sequences of both sheep[5] and dog[6] kidney β-subunits are included in Table 1. A 26-base oligonucleotide probe, derived from the 9-amino-acid N-terminal sequence shared by the sheep and dog enzymes, was used to screen a sheep kidney cDNA library (see Fig. 1 legend). Eight cDNAs, with inserts ranging in size from 1.8 to 2.6 kilobases (kb), were isolated. Restriction endonuclease mapping and blot hybridization analysis demonstrated that all eight cDNAs were related (data not shown). The identity of these cDNAs was confirmed by analysis of the nucleotide sequence in the region containing homology to the oligonucleotide probe. The N-terminal sequence of the sheep enzyme was identified, and of the 26 amino acids determined for the N-terminus of the dog enzyme, there was only a single mismatch, at residue 28.

The nucleotide sequence of the largest clone, pβNKA1, was determined and the amino-acid sequence of the β-subunit deduced (Fig. 1). The cDNA consists of a 528-base-pair (bp) 5′-untranslated region, a 909-bp open reading frame and a 1,142-bp 3′-untranslated sequence. There is no polyadenylation signal[7] or poly(A)$^+$ tract at the 3′ end of the cDNA; however, restriction analysis of the other cDNAs suggests that pβNKA1 lacks approximately 50 bp at its 3′ end. Three potential polyadenylation signals (AATAAA) occur earlier in the 3′-untranslated sequence (at residues 1,888, 2,408 and 2,433), and restriction endonuclease mapping suggests that two of the cDNAs are polyadenylated following the site at residue 1,888. The 5′-untranslated region, like that of the α-subunit mRNA[1], is G+C-rich (75%). The initiation methionine codon, located at residue 529, is the first ATG triplet in the cDNA, lies in a perfect 9-bp consensus sequence for the initiation of translation[8], and is preceded by an in-frame stop codon at residue 517. The initiation methionine is immediately followed by the N-terminal sequence of the mature sheep β-subunit[5]. Therefore, the β-subunit, like the α-subunit[1], does not contain a hydrophobic N-terminal signal peptide. The amino-acid sequences determined for the three tryptic peptides are located at residues 3–17, 71–90 and 150–156, respectively. The mature protein consists of 302 amino acids and has a M_r (minus the carbohydrate groups) of 34, 937.

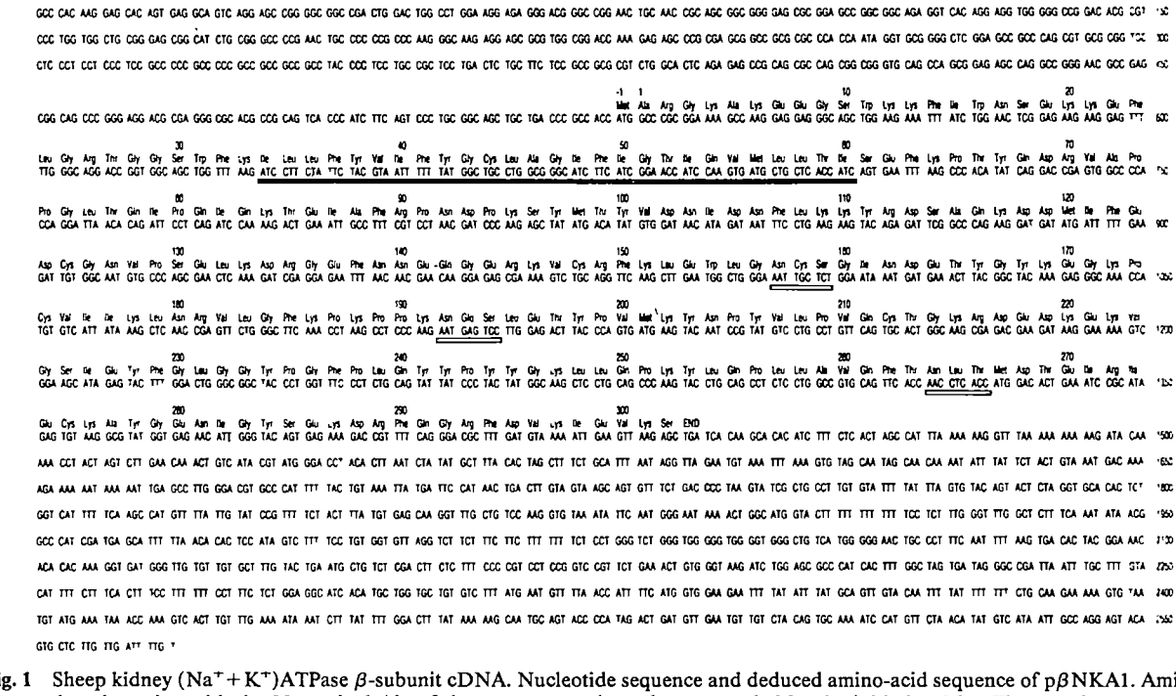

Fig. 1 Sheep kidney $(Na^+ + K^+)$ATPase β-subunit cDNA. Nucleotide sequence and deduced amino-acid sequence of pβNKA1. Amino acids are numbered starting with the N-terminal Ala of the mature protein and are preceded by the initiation Met. The putative transmembrane domain is indicated by the black bar and potential *N*-linked glycosylation sites by open bars.

Methods. A 50,000-colony sheep kidney cDNA library was constructed in the vector pBR322 using size-selected cDNA (800–3,500 bp) as described previously[1]. A 26-base deoxyinosine-containing oligonucleotide probe[24], 5′-GC(I,C)(C,A)G(I,C)GG(I,C)AAIGC(I,C)-AAIGAIGAIGG-3′, was derived from the 9-amino-acid N-terminal peptide (Table 1) and the library was screened as described earlier[1]. Plasmid DNA was isolated from 26 colonies that gave strong hybridization signals and analysed by restriction mapping and blot hybridization analysis. During blot hybridization, high-stringency washes were performed in the presence of tetramethylammonium chloride[25]. Under these conditions eight related cDNAs, including pβNKA1, retained their hybridization signals. DNA sequence analysis of both strands was performed using the Maxam–Gilbert procedure[26].

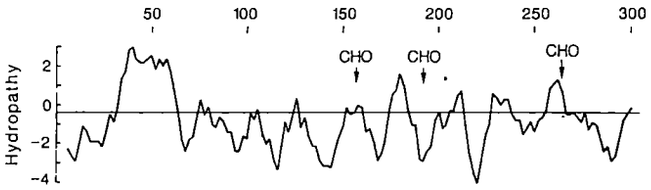

Fig. 2 Hydropathy plot of the $(Na^+ + K^+)$ATPase β-subunit. Nine-residue averages have been plotted using a hydropathy program based on the procedure of Kyte and Doolittle[12]. The locations of potential *N*-linked glycosylation sites (CHO) are indicated.

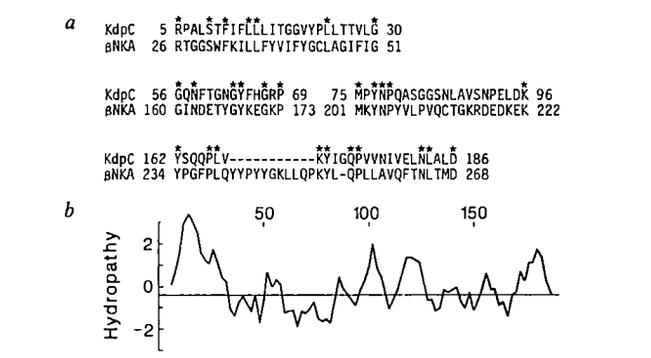

Fig. 3 Similarity between the KdpC subunit of the *E. coli* K^+-ATPase[4] and the $(Na^+ + K^+)$ATPase β-subunit. *a*, Amino-acid homology between KdpC and the β-subunit (βNKA). Homologous residues are indicated by an asterisk; gaps have been added to maximize homology. *b*, Hydropathy plot of KdpC using a 9-amino-acid window as in Fig. 2.

Photochemical labelling[9,10] and immunochemical[11] procedures have led to the suggestion that the β-subunit has one or more transmembrane domains. Hydropathy analysis[12] (Fig. 2) of the deduced amino-acid sequence indicates that the protein has one transmembrane domain (residues 34–60; see Fig. 1), located near the N-terminus. Electron microscopy[13] studies suggest that a large proportion of the β-subunit is located on the extracellular side of the membrane and Geering *et al.*[14] have demonstrated that only a small cytoplasmic domain of ~2,000 daltons is removed by trypsin. Thus, the hydrophilic N-terminal domain (residues 1–33) would appear to be located on the cytoplasmic side of the membrane whereas residues 60–302 probably lie on the extracellular side. Following limited papain digestion of the dog kidney enzyme, Chin[6] determined the partial sequence of a peptide located on the extracellular side of the membrane and approximately 9,000 daltons from the N-terminus. This sequence, Ile-?-Phe-Ile-Pro-?-?-?-Ile, shares partial homology with the sheep sequence beginning with Ile 87, which we have assigned to the extracellular side.

The presence of three *N*-linked oligosaccharide chains has been indicated by studies on the biosynthesis of chicken skeletal muscle $(Na^+ + K^+)$ATPase[15] and by endoglycosidase F treatment[16] of rat kidney and axolemma $(Na^+ + K^+)$ATPase. The deduced primary structure contains three potential *N*-linked glycosylation sites[17] (Asn-X-Ser/Thr), all located in the predicted extracellular regions of the protein (Asn residues 157, 192 and 264). The sequence of tryptic peptide T3 (Table 1), which begins at residue 150, could not be determined beyond residue 156 even though the quantities of the preceding amino acids in the sample being analysed were well above the limit of detection. Asparagine 157 was apparently blocked, as would be expected if it were a site for carbohydrate attachment.

It is of interest to know which transmembrane domains of the α-subunit are in contact with that of the β-subunit. Electron microscopy studies of two-dimensional crystals[18] suggest that

$(Na^+ + K^+)$ATPase was purified from the outer medulla of frozen lamb kidneys as described previously[22]. The enzyme (68 mg) was solubilized in 7% SDS, 1% 2-mercaptoethanol and two 34-mg aliquots were applied to a Bio-Gel A-5m column (2.5 × 190 cm) and eluted with 25 mM Tris-HCl *p*H 7.5, 0.1% SDS, 0.02% NaN_3 and 1 mM 2-mercaptoethanol. The β-subunit peaks of the two column runs were pooled and lyophilized. The β-subunit (~10 mg) was dissolved in H_2O and passed through a Sephadex-G 25 column (1.5 × 90 cm) in 10 mM sodium phosphate *p*H 7.5, 0.1% SDS. The void volume fractions containing the β-subunit were adjusted to 5 M urea and 144 mg of solid succinic anhydride was added slowly while maintaining the *p*H at 7.5 ± 0.5. After 30 min the total reaction volume was applied to a Sephadex-G25 column and eluted with 50 mM NH_4HCO_3. Fractions containing succinylated β-subunit were pooled, adjusted to 2 M urea and concentrated by ultrafiltration to ~1 mg ml^{-1}. TPCK-treated trypsin (255 μg; Cooper Biomedical) was added to 4 mg of succinylated β-subunit, incubated for 2 h at room temperature and lyophilized. Aliquots (2 mg) of the digest were dissolved in 0.3 ml of 1 mM dithiothreitol in HPLC grade H_2O and after 15 min adjusted to 0.1% trifluoroacetic acid (TFA) in a final volume of 0.5 ml and injected onto the HPLC system described previously[23]. Peptide peaks detected by absorbance at 280 nm were partially purified on a 15-cm Vydac C_{18} column with monitoring at 220 nm and then purified on a 15-cm Vydac C_4 column using the same solvent system (0.1% TFA in H_2O/0.1% TFA in acetonitrile). The tryptic peptides were sequenced, without prior amino-acid analysis, using an Applied Biosystems 470A gas phase sequencer; phenylthiohydantoin-amino acids were analysed on a Waters Nova-PAK C_{18} HPLC column. Lysine was identified as succinylated lysine. The N-terminal sequences of three tryptic peptides of the β-subunit are shown. Sheep kidney N-terminal peptide data are from ref. 5, dog kidney data from ref. 6.

cleavage of the α-subunit at trypsin site 3 (see ref. 19) removes a substantial portion of the protein which is located well away from the β-subunit. The location of trypsin site 3 at Arg 262 of the α-subunit has been confirmed by amino-acid sequence analysis (L.K.L., unpublished observations). As the first and second hydrophobic domains of the α-subunit occur in the peptide that is removed, they cannot be associated with the β-subunit. It also seems unlikely that the third and fourth hydrophobic domains (H3 and H4) are in contact with the β-subunit; H3 is in close proximity to Arg 262[1] and, because of its length, H4 is likely to be located inside the transmembrane shaft and cytoplasmic stalk. Therefore, one or more of the C-terminal hydrophobic domains of the α-subunit, which begin at residue 780, are likely to be in contact with the β-subunit.

As an evolutionary relationship between the α-subunit of the $(Na^+ + K^+)$ATPase and the KdpB protein of the *E. coli* K^+-ATPase has been clearly demonstrated[1,2,4], we compared the amino-acid sequence and hydropathy plot of the β-subunit with those of the KdpC protein, a 190-amino-acid subunit of the K^+-ATPase[4]. (An additional subunit, KdpA, is exceptionally hydrophobic and is clearly unrelated to the β-subunit.) The results suggest a possible relationship between the two proteins, although this is by no means as clear as that between the α-subunit and KdpB protein. Although there are four blocks of amino-acid homology between the two proteins (Fig. 3*a*), the homology is not extensive and in order to align these sequences it is necessary to postulate a number of large insertions

or deletions. Although this is reasonable considering the evolutionary time separating the two ATPases, such a procedure could also produce an apparent relationship between unrelated proteins (see ref. 20). There are also similarities between the hydropathy profile of KdpC (Fig. 3*b*) and that of the β-subunit (Fig. 2). KdpC has a hydrophobic domain near its N-terminal end which is likely to be a transmembrane domain, and the remainder of the protein lacks any obvious transmembrane domains. Thus, it is possible that the orientation of the KdpC protein in the membrane is the same as that of the β-subunit. Although there is insufficient evidence to conclude that these proteins have evolved from a common ancestor, the similarities suggest such a possibility. This may have important implications for other cation transport ATPases, particularly the $(H^+ + K^+)$ATPase[21] of the gastric mucosa which, like the $(Na^+ + K^+)$ATPase and the K^+-ATPase, transports K^+.

We thank Dr Terence Kirley and Greg Kelso of the Peptide/Protein Chemistry Core Facility of the University of Cincinnati for analysis of peptide sequences, Jeannette Greeb and Kelly Coyne for technical assistance, Michael Hughes for synthesis of the oligonucleotide probe, Greg Wernke for DNA sequence analysis, and Gwen Kraft for preparing the illustrations. This work was supported by NIH grants PO1 HL22619 (Mission I and core 2), RO1 HL25545 and NSF Instrument Grant DMB 8414251.

The antigen receptor on human T lymphocytes consists of two variable immunoglobulin-like glycoproteins, α and β, which occur in association with three invariable T3 membrane proteins[1-3]. In humans two of these proteins, T3-γ and T3-δ, are glycoproteins of relative molecular mass (M_r) 25,000 (25K) and 20,000 (20K), respectively, while the third, T3-ε, is a 20K non-glycosylated protein[4-6]. On the surface of murine T cells, a non-glycosylated protein dimer composed of 17K subunits (T3-ζ) is found associated with the T-cell receptor α and β chains and the three T3-like polypeptide chains[7,8]. It is generally accepted that major histocompatibility complex-restricted antigen recognition is a function of the α–β heterodimer. This has led to the postulation that the proteins of the T3 complex are involved in the signal transduction that immediately follows antigen recognition via the antigen receptor[9]. Events believed to be involved in early T-cell activation, such as rapid increases in phosphatidylinositol turnover and free intracellular calcium[9,10], can be triggered by antibodies directed against either the T3 complex or the clonotypic receptor. We have previously reported our findings on the cloning of the complementary DNA and genomic structure encoding both the human and murine 20K glycoprotein, T3-δ (refs 11–13). We now present our results on the cloning of the cDNA encoding the human 20K non-glycosylated chain, T3-ε.

Complementary DNAs encoding the non-glycosylated T3-ε chain were isolated using a high-titre rabbit antiserum, I3, directed against both T3-δ and T3-ε proteins. A λgt11 library constructed from poly(A)$^+$ RNA derived from pokeweed mitogen-activated peripheral blood T lymphocytes was screened for the presence of bacteriophages synthesizing β-galactosidase fusion proteins immunoreactive with I3. From the $\sim 1 \times 10^6$ plaques screened, 4 were isolated which remained positive in their reactivity with I3 throughout all further purifications.

To eliminate potential bacteriophages encoding T3-δ, DNA was isolated from the four purified plaques and analysed on a Southern blot. All four inserts were of identical size on *Eco*RI digestion and gel electrophoresis (~1.0 kilobase (kb)), and all hybridized with relatively equal intensity to a ^{32}P-labelled probe prepared from one of them (data not shown). Significantly, the T3-δ cDNA insert of clone pPGBC-9 (ref. 11) showed no hybridization with this probe. We therefore concluded that these four isolates were related clones, and since none coded for T3-δ, it was likely that they encoded T3-ε.

To confirm that the isolates were coding for the T3-ε protein, the β-galactosidase-containing fusion protein was analysed by Western blotting using monoclonal antibodies specific for T3-δ or T3-ε[14]. The results (Fig. 1) demonstrated that bacteria containing DNA from one of the four isolates, 5a.2, synthesize a protein slightly larger than β-galactosidase which reacts only with the T3-ε-specific monoclonal antibody and not with the T3-δ-specific antibody. Hence, the cloned cDNA insert contained nucleotide sequences that coded for (part of) the T3-ε polypeptide chain.

A series of immunohistological and immunochemical analyses have led to the conclusion that the T3-ε polypeptide chain is expressed exclusively in T lymphocytes[14]. As judged by Northern blot analyses (Fig. 2*a*), a 1.4-kb messenger RNA hybridizes to the *Eco*RI insert of 5a.2 (subcloned into pBR322, pDJ1) only in human cells of T-cell lineage. Recent data suggest that proteins analogous to the human T3 polypeptides are associated with the murine T-cell receptor α- and β-chains[7,8]. Figure 2*b* demonstrates that murine T3-ε mRNA, ~1.5 kb in size, was also found exclusively in cells of T-cell lineage. Moreover, mRNA hybridizing with the T3-ε cDNA has been found in all T-cell leukaemias tested so far[15,16].

The nucleotide sequence of pDJ1 was determined by the dideoxy chain termination inhibition method of Sanger *et al.*[32].

Fig. 1 Immunoblot analysis of human T3-ε β-galactosidase fusion protein. A λgt11 bacteriophage isolate, 5a.2, containing a putative T3-ε coding region, was selected using a rabbit anti-T3-δ and -T3-ε antiserum. An SDS extract of 5a.2-infected *Escherichia coli* strain Y1089, synthesizing a human T3-ε β-galactosidase fusion protein (lane 1), and immunopurified T3 proteins (lane 2) were separated by SDS-PAGE under reducing conditions on a 7.5% gel. The proteins were transferred to nitrocellulose[25]. The strips were first blocked with 1.5% gelatin followed by either monoclonal anti-human T3-δ antibody SP64 (left panel) or monoclonal anti-human T3-ε antibodies SP6 and SP10 (ref. 14) (right panel). Nitrocellulose strips were developed with ^{125}I-labelled sheep F(ab')$_2$ anti-mouse immunoglobulin (Amersham) followed by autoradiography. 'M' denotes radioactive M_r markers whose sizes are indicated ($\times 10^{-3}$). Lower arrows indicate positive reactivity of both anti-T3-δ and anti-T3-ε antibody populations with purified T3 proteins. The upper arrow indicates the presence of a T3-ε fusion protein slightly larger than the 116K β-galactosidase marker which was detected only by the anti-T3-ε antibodies.

Methods. The λgt11 cDNA isolates were obtained as follows. The cells used for isolation of RNA were normal human peripheral blood lymphocytes that had been cultured with pokeweed mitogen for 5 days. At this time the cells were >90% T3$^+$ as judged by immunofluorescence[26]. Total mRNA was extracted in guanidine hydrochloride[27] and poly(A)$^+$ RNA was isolated by selective retention to oligo(dT)-cellulose. Synthesis of cDNA and addition of *Eco*RI linkers for cloning into the *Eco*RI site of the β-galactosidase-encoding *lacZ* gene of λgt11 was performed as described elsewhere[28,29]. Before ligation into λgt11, the cDNA was digested with *Eco*RI and fragments >800 bases were isolated from low-gelling agarose. A total of 1.2×10^6 recombinants were obtained. After amplification in *E. coli* strain Y1088, the library was grown up in *E. coli* strain Y1090 for screening with antibody. For isolation of human T3-ε cDNAs, an antiserum, I3, was prepared in rabbits that had been immunized with both T3-δ and T3-ε proteins purified as described previously[20]. Antibody screening was performed essentially as described in ref. 29. Nitrocellulose filters were blocked in 1.5% gelatin and then incubated with the I3 rabbit anti-T3-δ and -T3-ε antiserum. The filters were developed with ^{125}I-labelled donkey F(ab')$_2$ anti-rabbit immunoglobulin (Amersham). Four positive bacteriophages were plaque-purified and the DNA was isolated[30]. To produce stable β-galactosidase fusion proteins, bacteriophage particles from one of the four λgt11 isolates, 5a.2, were used to infect *E. coli* strain Y1089 at a multiplicity of infection of 5. Infected bacteria were grown at 30 °C on nitrocellulose filters and replicate filters were prepared[30]. The filters were baked for 2 h at 80 °C, prehybridized and hybridized in 50% formamide, 5×SSC, 50 mM sodium phosphate *p*H 6.5, 250 μg ml^{-1} sonicated salmon sperm DNA, 0.1% bovine serum albumin, 0.1% Ficoll, 0.1% polyvinylpyrrolidone, and 0.1% SDS. The *Eco*RI insert of isolate 5a.2 was ^{32}P-labelled to a specific activity $>10^8$ c.p.m. μg^{-1} by the random hexadeoxyribonucleotide priming method[31] and used to probe the filters. The filters were hybridized at 42 °C overnight, then washed several times in 2×SSC, 0.1% SDS at room temperature followed by two successive washes in 0.2×SSC, 0.1% SDS at 65 °C. Filters were exposed to Kodak XAR-5 film at −70 °C using an intensifying screen. Positive colonies were selected and grown at 32 °C. Induction of the *lacZ* fusion products with isopropyl β-D-thiogalactopyranoside was performed as described by Huynh *et al.*[29].

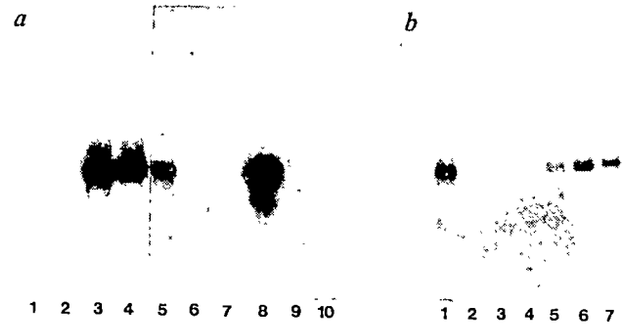

Fig. 2 Northern blotting analysis of human and murine mRNA. Total cellular RNA from the following sources was analysed by Northern blotting to determine the tissue distribution of T3-ε mRNA: *a*, lane 1, human umbilical vein endothelium; lane 2, human B-lymphoblastoid line BL; lane 3, human T-leukaemic cell line HPB-ALL; lane 4, human T-leukaemic cell line Jurkat; lane 5, a human T4$^-$T8$^+$ cell line; lane 6, a human Epstein–Barr virus-transformed B-cell line; lane 7, normal human bone marrow; lane 8, T-leukaemic cells from a Sézary syndrome patient (T3$^+$, T4$^+$, T8$^-$); lane 9, human promyelocytic leukaemic line HL60; lane 10, human fetal brain. *b*, Lane 1, human T-leukaemic cell line HPB-ALL; lane 2, normal murine brain; lane 3, murine Ltk$^-$ fibroblasts; lane 4, murine B-lymphoma cell line A20; lane 5, murine T–T hybridoma (T-helper cell) B8C3; lane 6, normal murine lymph node cells; lane 7, murine thymoma line BW5147.

Methods. Total mRNA was extracted from cells in guanidine hydrochloride[27]. mRNA (20 μg total) was denatured by heating to 65 °C in 50% formamide and separated by electrophoresis in a 1% agarose formaldehyde gel. The RNA was transferred to Biodyne filters (ICN) and the filters were baked for 2 h at 80 °C. Prehybridization, hybridization and washing steps were done exactly as described for Fig. 1 using the ^{32}P-labelled *Eco*RI insert from pDJ1 as probe.

Clone pDJ1 consisted of an insert of 995 base pairs (bp) with an open reading frame of 554 bp. As this clone was not full length, a second library which had been prepared from mRNA of a human T4$^+$T8$^-$ T-cell clone according to the method described by Okayama and Berg[17,18] was screened using the insert from pDJ1 as a probe. From this library, pDJ4 containing an insert of ~1.4 kb, was selected for sequencing.

Figure 3*b* shows the complete nucleotide sequence of the T3-ε cDNAs. The first in-frame AUG was found at position 55 of the nucleotide sequence. There was only one long open reading frame which continued until a termination signal at position 754. A consensus poly(A) addition site, AATAAA, was found at position 1,294 followed by a poly(A) tail 14 nucleotides downstream. The relative molecular mass of T3-ε predicted from the protein sequence in Fig. 3*b* is 23,153. A hydropathicity plot of the coding segment (Fig. 3*c*) predicted the presence of a putative N-terminal signal peptide containing an 11-amino-acid hydrophobic core[19]. This signal peptide is followed by a hydrophilic domain 104 amino acids long. A 26-amino-acid hydrophobic segment, beginning at position 105, delineated a putative hydrophobic transmembrane region. The segment between residues 131 and 190 is hydrophilic, whereas the C-terminus (191–211) is uncharged. The absence of potential sites for *N*-linked glycosylation in the translated amino-acid sequence was consistent with our observation that T3-ε contains no *N*-linked oligosaccharides[5,20].

To compare the amino-acid sequence predicted from the nucleotide sequence with that of the mature T3-ε protein, we performed partial N-terminal radiosequencing of purified T3-ε tryptic fragments. As this protein has the same M_r and almost the same isoelectric point as T3-δ, classic protein separation techniques failed to yield pure T3-ε. Because T3-δ is a glycoprotein and T3-ε is not, treatment with endoglycosidase F followed by preparative SDS-polyacrylamide gel electrophoresis (PAGE) had been used to obtain pure T3-δ[5,20]. Since Endo-F treatment does not always result in complete deglycosylation, the material that remained after digestion is often impure and can give rise to incorrect amino-acid sequences. In these experiments, therefore, we have used a different approach to obtain

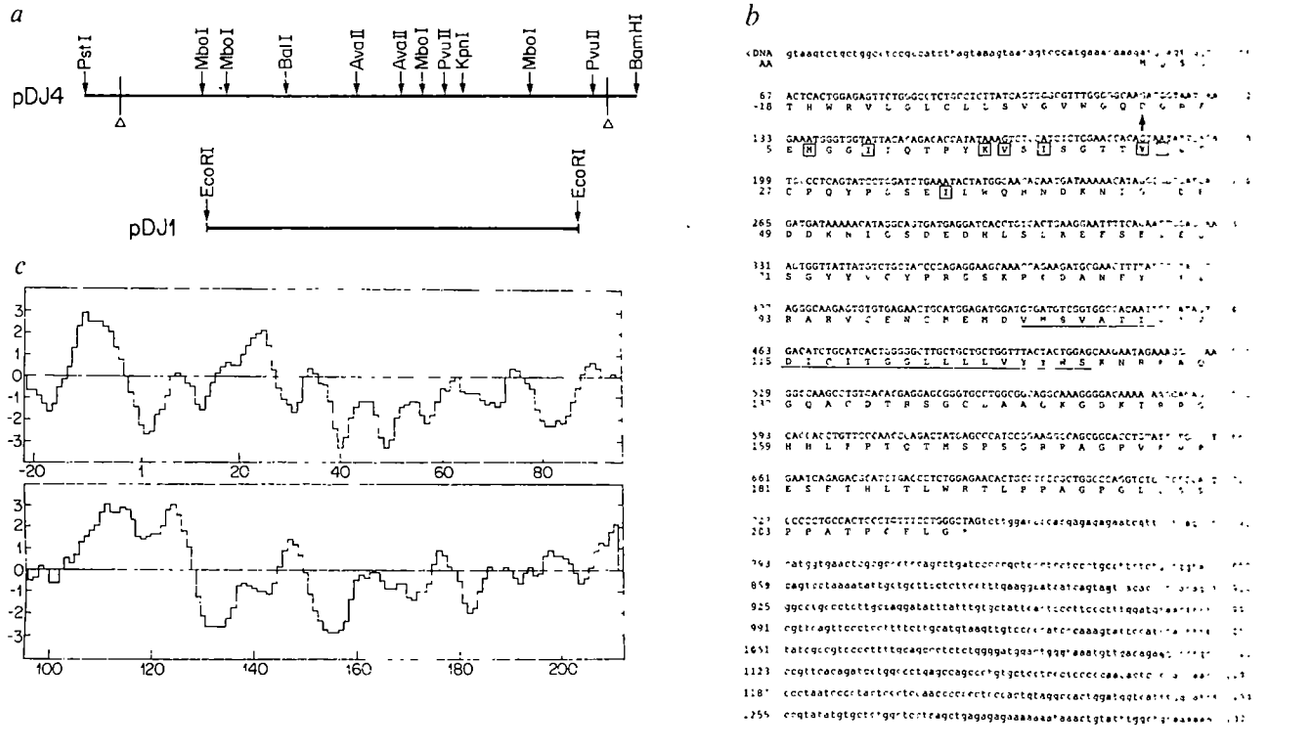

Fig. 3 Analysis of the nucleotide sequence of the human T3-ϵ chain. *a*, Partial restriction map of T3-ϵ cDNA pDJ4 containing restriction endonuclease sites used to determine nucleotide sequences. The open triangles beneath pDJ4 represent the insert boundaries. The 5′ *Pst*I and 3′ *Bam*HI sites are derived from the cloning vector. The *Eco*RI sites in pDJ1 are derived from linkers added during cDNA synthesis. *b*, The combined nucleotide sequence of pDJ1 and pDJ4 was determined by the dideoxy chain termination method of Sanger[32] using bacteriophage M13 mp18 or mp19 (ref. 33). Isolated restriction fragments were either ligated directly into the appropriate M13 vector restriction site or made blunt-ended by treatment with the large fragment of *E. coli* DNA polymerase I before ligation into the *Sma*I site of the appropriate M13 vector. The deduced amino-acid sequence of the only long open reading frame is shown below the nucleotide sequence, beginning with the initiation methionine at position −22. The arrow indicates amino acid 1 of the mature protein. Boxed amino-acid residues 6, 9, 15, 16, 18, 23, 24 and 35 correspond to those residues determined by amino-acid sequencing (see Fig. 4*c*). *c*, Plot of the relative hydropathicity of T3-ϵ. The hydropathicity values of each amino acid have been determined using the weight system of Kyte and Doolittle[34]. The average hydropathicity value at residue i is calculated across 6 residues from $i-3$ through to and including $i+2$. Positive values indicate hydrophobic regions and negative values represent hydrophilic segments.

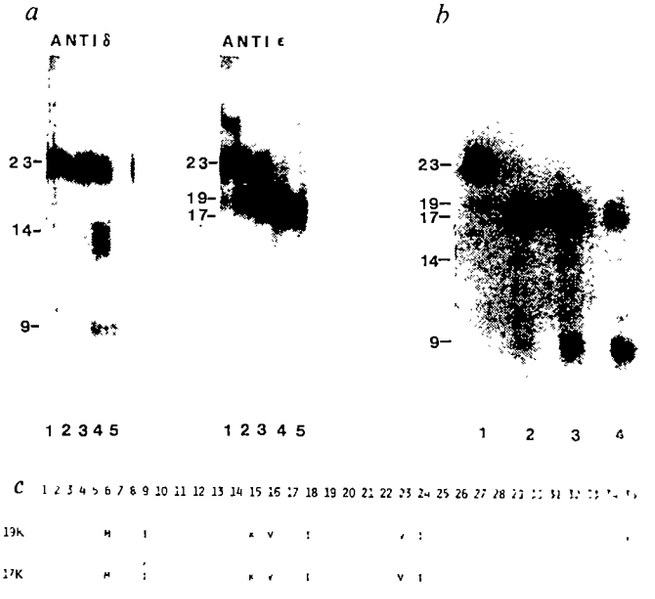

Fig. 4 Isolation and partial amino-acid sequences of the large tryptic fragments of the T3-ϵ protein. *a*, Western blot analyses of the trypsinization products of purified T3-δ and T3-ϵ proteins using monoclonal anti-T3-δ antibodies (left panel) or monoclonal anti-T3-ϵ antibodies (right panel). Lanes 1–5 represent titration of trypsin: lane 1, no trypsin; lane 2, 0.0015 μg ml^{-1}; lane 3, 0.0060 μg ml^{-1}; lane 4, 0.03 μg ml^{-1}; lane 5, 0.15 μg ml^{-1}. *b*, Analysis of ^{35}S-cysteine and ^{35}S-methionine metabolically labelled trypsinization products of T3-δ and T3-ϵ proteins. Lane 1, no trypsin; lane 2, 0.0015 μg ml^{-1}; lane 3, 0.0060 μg ml^{-1}; lane 4, 0.03 μg ml^{-1}. *c*, N-terminal amino-acid assignments for the 19K and 17K tryptic fragments of T3-ϵ.

Methods. Isolation of purified T3-δ and T3-ϵ proteins was as described previously[20]. For metabolic labelling, ^{35}S-cysteine, ^{35}S-methionine and ^{3}H-isoleucine, ^{3}H-lysine or ^{3}H-valine were used. Trypsinization of samples at the appropriate trypsin concentration was carried out at 37 °C for 4 h in the presence of 20 μg sperm whale apomyoglobin (Beckman). Trypsinization was terminated by the addition of trichloroacetic acid to a final concentration of 10%. For Western blot analysis, proteolytic fragments were separated by SDS-PAGE under reducing conditions on a 15% gel. Conditions for Western blotting were exactly as for Fig. 1. For radiosequencing, proteolytic fragments were separated by SDS-PAGE under reducing conditions on a 14–20% gradient gel. The 19K and 17K bands were eluted[35] and radiosequenced on a Beckman protein sequenator with a cold trap modification using the Beckman 0.1 M Quadrol program 121078. Identification of the phenylthiohydantoin-amino acids was as described by Coligan *et al.*[36].

T3-ϵ amino-acid sequences and we believe this explains the differences between the sequence we now report and the earlier published sequence[20]. First, both 20K T3 proteins (T3-δ and T3-ϵ) were isolated after immunoadsorbent column chromatography and SDS-PAGE. The mixture of these two proteins was subjected to limited trypsinization and large tryptic fragments (9K, 14K, 17K and 19K) were separated by SDS-PAGE. Using anti-T3-δ and T3-ϵ monoclonal antibodies in a Western blotting experiment, we determined that the two larger fragments were derived from T3-ϵ and the smaller ones from T3-δ (Fig. 4*a*). The 17K and 19K fragments isolated from metabolically labelled HPB-ALL cells (Fig. 4*b*) had identical N-terminal amino-acid sequences (Fig. 4*c*). As shown in Fig. 3*b*, the predicted amino-acid sequence agrees with the assignment of residues 6, 9, 15, 16, 18, 23, 24 and 35 of the tryptic fragments. Therefore, the cDNA pDJ4 must encode the complete T3-ϵ protein. Since it

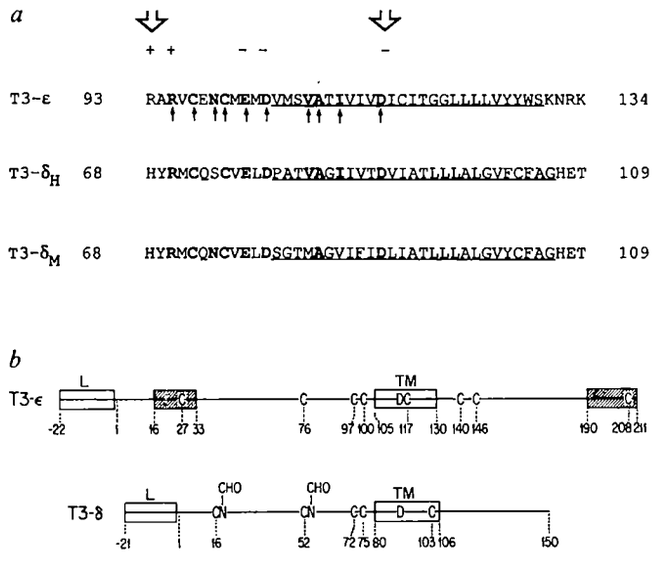

Fig. 5 Comparison of the T3-δ and T3-ε polypeptide chains. *a*, Homology region (see text) of T3-ε, including the entire transmembrane domain, compared with the human (T3-δ_H) and murine (T3-δ_M) T3-δ chains. Residues shared between T3-ε and human or murine T3-δ are shown in bold type and denoted by solid arrows. Boundaries of the homology region are indicated by open arrows. The transmembrane region of each chain is underlined. *b*, General features of the organization of the human T3-ε and T3-δ chains. L, leader sequence; TM, transmembrane region; C, cysteine; N, asparagine; CHO, *N*-linked glycosylation sites. The shaded areas in T3-ε denote the N-terminal and C-terminal uncharged regions. Numbering refers to the relative position of residues in the mature protein.

is unlikely that trypsin would have cleaved a Gln–Asp peptide bond (residues −1, 1; Fig. 3*b*), this sequence must represent the N-terminus of the mature T3-ε protein. We therefore conclude that the 17K and 19K tryptic fragments contain the N-terminus of the mature T3-ε protein and that amino acids −22 to −1 predicted from the cDNA sequences of pDJ4 represent the T3-ε signal peptide.

A search of the Los Alamos National Laboratory DNA database and the National Biomedical Research Foundation (NBRF) protein database using the NUCALN and PRTALN programs revealed no strong homologies between the T3-ε sequences and any other sequence. Although no strong overall homology existed between T3-ε and T3-δ, an interesting feature was noted. As was observed in the case of the T3-δ chain[11], the T3-ε protein contains an Asp residue in the transmembrane region at position 115. Starting from this transmembrane Asp residue in T3-ε and going towards the N-terminus, there is a stretch of 23 amino acids which contains 6 charged residues. Nine of the 23 amino-acid residues are shared between T3-ε and T3-δ, while the remaining 14 residues contain mostly conservative changes. In addition, 5 of the 6 charged residues as well as the 2 Cys residues are shared between T3-ε and both the human and murine[12] T3-δ chains. In particular, the negatively charged Asp residue in the transmembrane region is of great interest because of the association of the T3 proteins with the T-cell receptor heterodimer. Both the α and β chains of the T-cell receptor contain a Lys in their respective transmembrane regions[21–24]. The negatively charged Asp residues in T3-ε and T3-δ could form salt bridges with these charged residues of the heterodimer α and β chains, and such an interaction is likely to be significant because of the hydrophobic milieu of the plasma membrane. The 23-amino-acid homology region of T3-δ and T3-ε may also be important for the interaction with the α and β chains.

Based on the homology between T3-δ and T3-ε, we postulate that the region between residues 105 and 130 is a transmembrane segment and thus that the T3-ε protein is oriented in a fashion similar to the T3-δ chain, that is, the N-terminal domain is extracellular and the C-terminal domain cytoplasmic. Note that there are two relatively long uncharged regions, residues 16–33 and 191–211 (see Figs 3*c*, 5*b*). Although these regions neither form an α-helix nor consist of a strongly hydrophobic nucleus, they may be inserted in the plasma membrane. Further protein chemical studies will clarify this issue. Because the T3-ε cytoplasmic domain is considerably larger than that of the previously described α, β and δ chains, we predict that the ε protein must be involved in some signal transduction property of the T3 complex which is activated on engagement of the associated T-cell receptor heterodimer.

We thank Dr Ken-Ichi Arai (DNAX) for making available to us the cDNA library used to isolate pDJ4, Drs Peter van den Elsen and David Ucker for advice throughout this study, Drs C. T. Caskey and G. Rovera for help in cDNA library synthesis and screening, Sharon McGrath for preparation of this manuscript, and the DFCI/Harvard School of Public Health NIH-supported Molecular Biology Research Resource for assistance with computer analysis. This work was supported by NIH grants AI-15066 and AI-17651. D.P.G. was supported by a fellowship from the Cancer Research Institute/Eleanor Naylor Dana Charitable Trust. J.M.P. was supported by a Physician Scientist Award.HD00657-01. C.L.P. is a Fellow and C.P.T. is a Scholar of the Leukemia Society of America.

Acquired immune deficiency syndrome (AIDS) has become a worldwide epidemic[1–6], so the development of vaccines and antiviral agents effective against the causative agent, human T-lymphotropic virus type III (HTLV-III), is vital. This work would be greatly simplified if a suitable animal model could be developed. Here we report the isolation of an HTLV-III-related retrovirus, STLV-III/Delta, from rhesus macaques (*Macaca mulatta*) with transmissible simian AIDS (SAIDS) and from asymptomatic sooty mangabeys (*Cercocebus atys*). SAIDS was initially diagnosed in several macaques previously inoculated with tissue homogenates of mangabey origin. Western blot analysis of both the mangabey and macaque sera demonstrated the presence of antibody cross-reactive primarily with the HTLV-III proteins p24 and p61. In a related experiment, analysis of these same sera revealed simian antibody to STLV-III/Delta proteins similar, but not identical, to those of HTLV-III with estimated relative molecular masses (M_rs) of 16,000 (16K), 26K, 35K, 45K, 60K and 110K. Infection of the mangabey, an African primate, with an HTLV-III-related virus may provide a clue to the origin of HTLV-III in humans. The apparent difference in susceptibility to SAIDS-like disease between infected macaques and mangabeys suggests that these species may respond differently to STLV-III infection.

Beginning with four macaques which had been inoculated with homogenates of a cutaneous lepromatous leprosy lesion from a sooty mangabey[7], we have transmitted SAIDS and/or lymphoma by inoculation of tissue homogenates in 11 of 14 recipient macaques[8]. Co-culture of lymphoid tissue from six of these animals with the human H9 cell line led to the isolation of a retrovirus morphologically similar to HTLV-III (Fig. 1*a*). This retrovirus, STLV-III/Delta, induced the formation of syncytia in H9 cells and displayed a Mg^{2+}-dependent reverse transcriptase activity.

STLV-III/Delta and HTLV-III are also related antigenically. An enzyme-linked immunosorbent assay (ELISA) for HTLV-III antibodies performed longitudinally on sera from the four inoculated macaques revealed a rise in antibody titre for three of the monkeys (Fig. 2). The rise in antibody titre after inoculation suggests that these macaques may have acquired STLV-III/Delta from the mangabey. Antibody cross-reactive with HTLV-III was detected by ELISA in sera from 3 of 39 mangabeys (Fig. 3). In addition, STLV-III/Delta was isolated from several mangabeys by co-culture of peripheral lymphocytes with H9 cells (Fig. 1*b*).

Western blot analysis of simian antisera using detergent-disrupted HTLV-III virions confirmed the presence of HTLV-III-cross-reactive antibody in all ELISA-positive samples. Antibody specific for STLV-III/Delta was also detected in the serum of 2 macaques and 10 mangabeys that were ELISA-negative. In total, anti-STLV-III/Delta antibody was detected in sera from 5 of 11 macaques from the SAIDS transmission study and in 13 of 44 mangabeys.

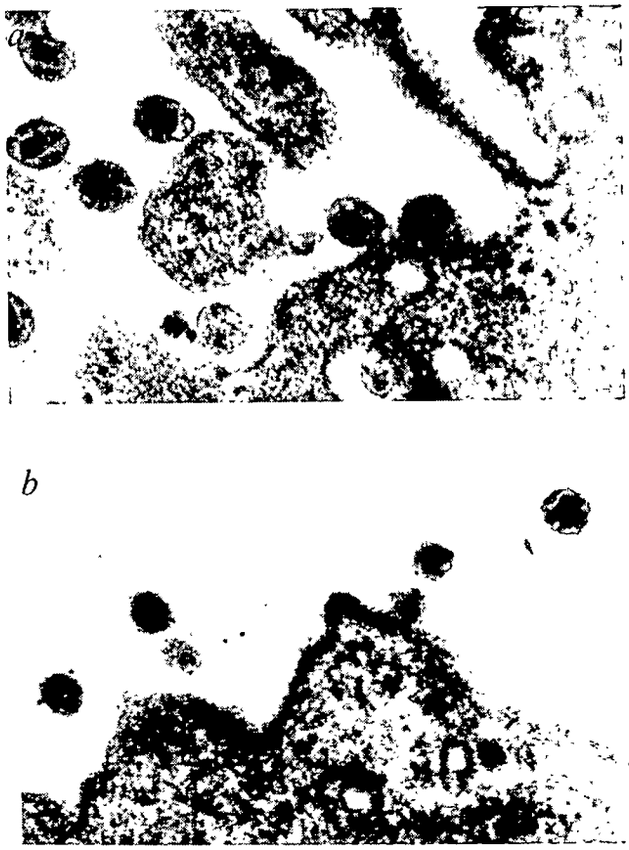

Fig. 1 Electron micrographs of the H9 human T-cell line infected with STLV-III/Delta cultured from a macaque with SAIDS (*a*) and from an asymptomatic mangabey (*b*). Ficoll gradient-purified peripheral lymphocytes from macaque B670 (*a*) and mangabey E038 (*b*) were cultured at 5×10^6 cells ml^{-1} in 7% CO_2 with 10 μg ml^{-1} phytohaemagglutinin (PHA) for 72 h in RPMI-1640 medium supplemented with 15% fetal calf serum (FCS). The PHA was subsequently removed by washing and culturing was continued in RPMI-1640 supplemented with 15% FCS and 10 half-maximal units per ml of human interleukin-2. At 3- and 7-day intervals, H9 cells (5×10^4 ml^{-1}) were added to duplicate cultures and the cells were monitored for syncytia formation. STLV-III infectivity was verified by fixed-cell indirect immunofluorescence using rhesus reference serum and electron microscopy. Infected cells were fixed in glutaraldehyde, embedded in Epoxy resin, and sectioned. Tissue sections were stained with uranyl acetate and lead citrate and photographed in a Siemens transmission electron microscope. Final magnification: *a*, ×83,000; *b*, ×45,000.

Figure 4 shows Western blot results for representative sera. The predominant immunoreactive HTLV-III proteins recognized by sera from both macaque (lanes *d, f*) and mangabey (lanes *h, j, l*) were the p24 core protein and a larger protein of $M_r\sim61$K. Additional proteins ranging in size from 35K to 50K were also variably recognized by these sera. Simian sera reacted with STLV-III/Delta proteins which were of similar, but not identical, M_rs to those of HTLV-III (Fig. 4, lanes *c, e, g, i, k*). The STLV-III/Delta proteins most commonly recognized by both macaque and mangabey sera were of M_r 110K and 26K; these probably correspond to the 120K *env* and 24K *gag*-related proteins of HTLV-III. Additional proteins of estimated M_r 60K, 45K, 35K and 16K also were variably recognized by the different antisera tested. Sera obtained from 50 healthy macaques and from 31 of 44 mangabeys from the Delta Regional Primate Research Center (DRPRC) colony, however, did not react with protein determinants of either virus.

The cross-reactivity of these simian antisera with both STLV-III/Delta and HTLV-III virion preparations suggests that these

two viruses have common immunoreactive epitopes. This observation was confirmed by the ability of STLV-III/Delta virions to adsorb HTLV-III-cross-reactive antibody (data not shown). STLV-III/Delta and HTLV-III are distinct, however, since in the reciprocal Western blot, a pool of human AIDS sera did not react with any of the simian virion proteins (Fig. 4, lanes *m*, *n*). In addition, Southern blot analysis of STLV-III-infected H9 cell DNA using radiolabelled sequences complementary to HTLV-III[9] failed to reveal genetic homology between the two viruses, even under conditions of low stringency (data not shown).

STLV-III/Delta is antigenically distinct from the HTLV-I-related simian virus STLV-I[10]. Analysis of mangabeys for anti-HTLV-I antibodies by ELISA specific for the viral p24 core protein detected significant antibody in 14 of 32 monkeys tested (Fig. 3), whereas sera from sick macaques were uniformly negative for anti-HTLV-I antibody (data not shown). Antibody cross-reactive with HTLV-III was detected in several healthy mangabeys as well as in sick macaques. However, there was individual variation, with several mangabeys being seropositive for a single virus. Thus, Western blot analysis of serum from mangabey A015, which is seropositive for HTLV-I but seronegative for HTLV-III by ELISA, did not detect antibody to STLV-III/Delta viral proteins (data not shown).

A macaque retrovirus similar to STLV-III/Delta, STLV-III_{Mac}, has been identified in association with experimentally induced SAIDS at the New England Regional Primate Research Center (NEPRC)[11,12]. The putative *env*- and *gag*-related proteins of this virus, however, have identical M_rs to those of HTLV-III; antibody cross-reactive with the NEPRC virus was also detected in human AIDS serum. The disparity in cross-reactivity observed between that study and our own may reflect differences in the techniques used. The difference observed in the M_rs of the putative core proteins, however, may be significant, particularly as in both studies the simian viral proteins were normalized to those of HTLV-III. In our hands, Western blot analysis also detected other STLV-III/Delta proteins which

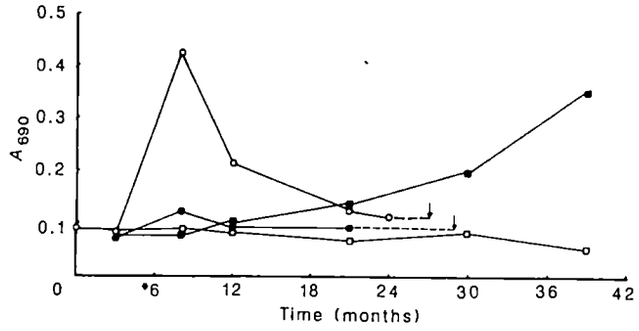

Fig. 2 Presence of HTLV-III-cross-reactive antibody in macaques inoculated with lepromatous mangabey tissue homogenates. Four macaques were inoculated as described elsewhere[15] with tissue homogenates prepared from lepromatous leprosy lesions at the time designated by the asterisk. Serum was obtained from these animals at various times post-inoculation and assayed for HTLV-III-cross-reactive antibody by ELISA using the manufacturer's instructions (Litton Bionetics). The arrows mark the time of death due to SAIDS of two of the animals; two animals remained alive at this time. Monkeys are designated as follows: ○, B988; ●, 8664; ■, B845; □, 745.

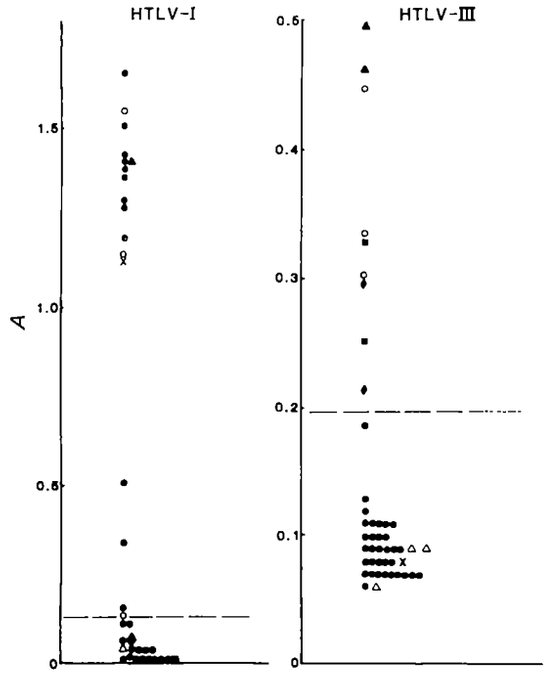

Fig. 3 Prevalence of HTLV-I- or HTLV-III-cross-reactive antibody in the DRPRC mangabey monkey colony. Random sera obtained from mangabey monkeys at the DRPRC were assayed by ELISA (Litton Bionetics) for antibodies to either HTLV-I or HTLV-III. The dashed lines designate the cut-off point for significant positive values calculated for human samples as described in the assay. Individual samples of interest are designated as follows: ○, positive human control sera; △, negative human control sera; ●, representative mangabey sera. The rest are sera obtained at various time intervals from mangabey monkeys A015 (×), D089 (▲), E038 (■) and D178 (◆).

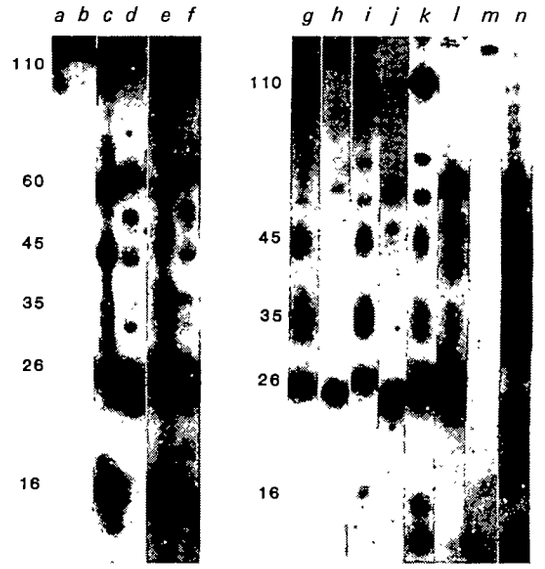

Fig. 4 Western blot analysis of the reaction of primate antisera with detergent-disrupted STLV-III/Delta and HTLV-III virion proteins. STLV-III/Delta virions were purified from infected H9 cell culture supernatants as described elsewhere[16-18]. HTLV-III virions were obtained on a contractual basis from the NIH. STLV-III/Delta (lanes *a*, *c*, *e*, *g*, *i*, *k*, *m*) and HTLV-III (lanes *b*, *d*, *h*, *j*, *l*, *n*) virions were treated with SDS and 2-mercaptoethanol, boiled briefly and subjected to electrophoresis through a 10% polyacrylamide gel containing SDS as described elsewhere[18]. Size-fractionated proteins were electroblotted onto nitrocellulose and the transferred immunoreactive proteins detected by incubation with primate antiserum. Antigen-antibody complexes were detected by subsequent incubation with ^{125}I-labelled *Staphylococcus* protein A, followed by autoradiography. Lanes *a*, *b*, an over-exposure of normal rhesus control sera; lanes *c*, *d*, rhesus B988 serum; *e*, *f*, rhesus B845 serum; *g*, *h*, mangabey E038 serum; *i*, *j*, mangabey D178 serum; *k*, *l*, mangabey D089 serum; *m*, *n*, pool of human AIDS sera.

had similar, but not identical M_rs to those of HTLV-III. Taken together, these data suggest that STLV-III/Delta is related to, but distinct from, STLV-III_{Mac}. Resolution of this discrepancy will require a direct comparison of the two viruses.

An HTLV-related virus endemic in our mangabey colony in the apparent absence of SAIDS is notable. SAIDS at DRPRC has been confined to a single series of transmissions which originated with a mangabey tissue inoculum. This fact, coupled with the prevalence of the virus in mangabeys, suggests that STLV-III/Delta in our macaques with SAIDS is of mangabey origin. Although STLV-III appears to be endemic in our mangabey colony, the characteristic SAIDS pathology has not been observed among these animals. These observations suggest that virus transfer from an African (mangabey) to an Asian (macaque) species may result in significant differences in pathogenicity. A comparison of host responses to infection in the two species may prove useful in understanding the pathogenesis of human AIDS.

STLV-III has also been reported in the African green monkey[13,14]. The presence of HTLV-III-related retroviruses in at least two African primates, the African green monkey and the mangabey, is consistent with the hypothesis that HTLV-III emerged in humans as a result of an early trans-species transfer in Africa.

Mechanism of activation of *HuBlym*-1 gene unresolved

Joan M. Devine*

Dana Farber Cancer Institute, 44 Binney Street, Boston, Massachusetts 02115, USA

The *HuBlym*-1 gene has been isolated from Burkitt's lymphoma DNA on the basis of its reported ability to produce foci of cells when NIH 3T3 cells are transfected with it[1,2]. The sequence of *HuBlym*-1 has been reported[1] but it has not been established whether the sequence of the transforming gene differs from that of the gene in normal tissue, as might be expected from the common observation of mutational activation of proto-oncogenes into oncogenes. I report here that there are no differences between the sequences of three recombinant DNA clones that were isolated from Burkitt's cell lines and that cross-hybridize to *HuBlym*-1 but do not induce foci when transfected into NIH 3T3 cells, and the reported sequence of Burkitt's lymphoma *Blym*[3]. Also there is no obvious or consistent increase in the transcription of the *HuBlym*-1 gene in Burkitt's lymphoma cell lines of the type that might otherwise have accounted for its transforming activity even in the absence of a mutation. How the *HuBlym*-1 gene is activated therefore remains a mystery.

Total genomic DNAs isolated from six Burkitt's lymphoma cell lines have been reported to induce foci with an efficiency of between 0.1 and 1.0 transformants per μg DNA when transfected into NIH 3T3 cells[2]. The gene responsible for this transforming ability, *HuBlym*-1, has been cloned from the Burkitt's lymphoma cell line CW678 (ref. 2). This cloned gene transforms NIH 3T3 cells with high efficiency and has the same pattern of restriction enzyme sensitivity in a transfection assay[2,4] as the genomic DNA from all six Burkitt's lymphoma cell lines[2]. The biologically active transforming gene is contained within a 1.0-kilobase(kb)*Eco*RI fragment of the clone[2]. This fragment has been subcloned into a plasmid, pHuBlym-1, and its nucleotide sequence determined[3]. The gene is 600–700 nucleotides long and is apparently interrupted by a single intervening sequence, yielding a predicted polypeptide of 58 amino acids[3]. Previous, though not extensive, studies indicate that the *HuBlym*-1 gene is neither amplified nor rearranged in Burkitt's cell lines[3], therefore other possible mechanisms of activation of the *HuBlym*-1 gene have to be considered. It is known that *ras* genes can be activated to a transforming phenotype by a single base mutation at position 12 or 61 (refs 5, 6), or by coupling to a viral long terminal repeat (LTR) which gives enhanced transcription of the gene[7,8]. Thus, two possible mechanisms for the activation of the *HuBlym*-1 gene are changes in its nucleotide sequence and changes in the level of transcription of the gene.

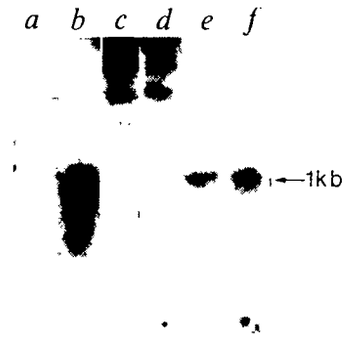

Fig. 1 Southern transfer of DNA clones isolated from λ clones and probed with *HuBlym*-1. *a*, The λ marker, which does not hybridize to the probe. *b*, λHuBlym-1 DNA digested with *Eco*RI. A 1-kb fragment hybridizes to the 1-kb probe which is its exact homologue. *c–f*, *Eco*RI-digested DNAs from clones isolated from the λ libraries constructed in EMBL3: *c*, *d*, DNAs from the EW36 λ library. The DNA in *c* did not transform NIH 3T3 cells whereas that in *d* did. *e*, *f*, DNA from Raji λ library. The DNA in *e* did not transform NIH 3T3 cells; that in *f* did. DNAs were isolated, digested with *Eco*RI, run on a 0.3% agarose gel and then transferred to nitrocellulose. The filter was probed with the ^{32}P-labelled 1-kb *Eco*RI fragment from pHuBlym-1. The 1-kb fragments in *c–f* were subcloned into pBR322 and their nucleotide sequences determined.

During the original isolation of λHuBlym-1, a number of other clones were isolated which hybridized to the *ChBlym*-1 probe[2,9]; these clones were screened together with λHuBlym-1 in a transfection assay. λHuBlym-1 was selected because it transformed NIH 3T3 cells whereas 14 other clones did not (A. Diamond, personal communication). As these other clones could contain the non-transforming counterpart of the *HuBlym*-1, they have now been analysed by digestion with *Eco*RI, gel electrophoresis and Southern blotting to identify those that contain a DNA insert similar to that in λHuBlym-1.

DNAs from six of the clones showed restriction enzyme digestion patterns similar to that of λHuBlym-1, including the presence of a 1.0-kb *Eco*RI fragment which in λHuBlym-1 contains the active transforming HuBlym-1 gene[2] (Fig. 1*b*). The 1.0-kb fragment from one of the clones was subcloned in pBR322 and the nucleotide sequence of both strands was determined, using a combination of the dideoxy chain termination method[10]

* Present address: Celltech Ltd, 250 Bath Road, Slough SL1 4EN, Berkshire, UK.

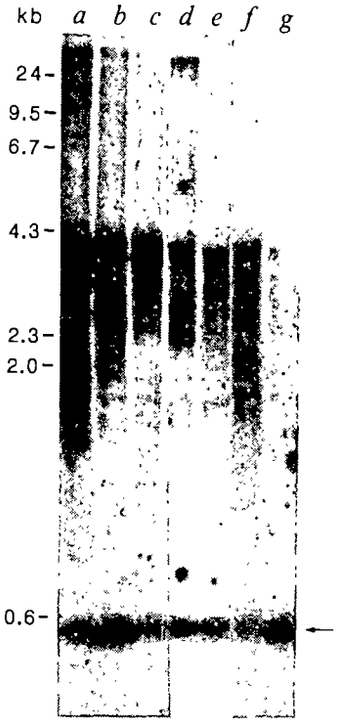

Fig. 2 Hybridization of *HuBlym*-1 probe to poly(A)$^+$ RNA. *a–c*, RNAs isolated from Burkitt's lymphoma cell lines CW678, EW36 and Raji, respectively. *d*, *e*, RNAs isolated from the EBV-immortalized cell lines LAZ φ156 and LAZ 388. *f*, RNA from a pre-B-cell line; *g*, RNA from a myeloma cell line. The size markers shown are λ DNAs digested with *Hin*dIII. The arrow indicates the *Blym* band at ~600 bases. Total RNA was isolated, poly(A)$^+$ RNA selected and samples (10 μg) of poly(A)$^+$ RNA run on a 1.5% formaldehyde gel. The RNA was then transferred to a nitrocellulose filter, which was hybridized to ^{32}P-labelled plasmid pHuBlym-1.

and chemical sequencing[11]. The nucleotide sequence observed was exactly the same as that already determined for *HuBlym*-1. This result was completely unexpected. In order to confirm it, recombinant DNA libraries were constructed from the DNAs of two other Burkitt's cell lines: EW36, an American Epstein-Barr virus (EBV)-negative line[12], and Raji, an African EBV-positive line[13]. These lines were chosen as they represent both associated and non-associated EBV lines[14] and because they are clearly of different origin. Both have been shown to transform NIH 3T3 cells[2]. The DNAs of these cells were partially digested with *Mbo*I, size-fractionated and ligated into the *Bam*HI site of the λ vector EMBL4. After *in vitro* packaging, the library was screened with the 1.0-kb *Eco*RI fragment from pHuBlym-1 and plaques hybridizing to this probe were selected. Both intact phage and DNA were separately used to transfect NIH 3T3 cells. Two subsets of clones were picked from each of the libraries: those that induced transformation of NIH 3T3 cells and those that did not. DNAs from the two groups were then screened for the presence of a 1.0-kb *Eco*RI fragment (Fig. 1*c–f*). Four clones which contained a 1.0-kb *Eco*RI fragment were selected: one from each of the two Burkitt's libraries that transformed NIH 3T3 cells and one from each of the two that did not transform NIH 3T3 cells. The 1.0-kb fragment from each clone was subcloned into pBR322. In this case also, the nucleotide sequence of the two transforming and one of the two non-transforming clones were shown to be identical to the sequence of the original transforming *HuBlym*-1 (approximately 60% of the other non-transforming gene was sequenced and found to be identical).

All the genes described and sequenced so far in this paper were isolated from DNA obtained from Burkitt's lymphoma cell lines. It was therefore important to clone and isolate the corresponding DNA sequence from a recombinant DNA library prepared from a non-Burkitt's lymphoma cell line. DNA was therefore isolated from the IMR 90 cell line[15], which is a human embryo fibroblast line that is not immortalized but which grows well for 20–30 passages[15]. The recombinant DNA library was prepared and screened as above except that the lambda vector used was λ47.1. Two clones homologous to the 1.0-kb *Eco*RI fragment probe isolated from pHuBlym were selected, their 1.0-kb *Eco*RI fragments were subcloned and the nucleotide sequences of both strands determined for one of the subclones. Again, the sequences were identical to that of *HuBlym*-1.

The level of transcription of *HuBlym* in several Burkitt's lymphoma cell lines and in several other human cell lines was investigated by Northern transfer analysis (Fig. 2). In all the lines examined, a messenger RNA of ~600 bases was detected at a similar level, indicating that the induction of foci by DNA from Burkitt's lymphoma cell lines is not a consequence of increased transcription of the *HuBlym*-1 gene.

The nucleotide sequences of the three non-transforming alleles of *HuBlym*-1 described here are identical to the sequence reported for the allele that induced focus formation in NIH 3T3 cells[3]. The results of the mRNA analysis demonstrate that increased levels of *HuBlym* mRNA are not detected in Burkitt's lymphoma cell lines, however there is always a problem in knowing what to use to make a proper comparison. The way in which the *HuBlym*-1 gene is activated therefore remains an open question.

I thank Dr Geoffrey Cooper for his hospitality during this work and for his willingness to read the assays for focus formation that were part of these experiments. I also thank Dr John Cairns for stimulating discussions and helpful comments on the manuscript. J.M.D. was supported by a Travelling Fellowship from the ICRF, London and by a special Fellowship from the Leukaemia Society of America.

COOPER AND DIAMOND REPLY—The work reported by Dr Devine was in part performed in this laboratory and was to have been completed here following her departure in October 1984. At that time, transfection experiments were to be performed on the clones isolated from normal human DNA and the sequence of the clone from normal human DNA required completion to resolve several existing ambiguities and gaps. However, we found that all of the clones from the Raji and EW36 Burkitt's lymphoma libraries used by Devine contained cellular inserts whose restriction endonuclease cleavage patterns were indistinguishable from each other and from the original isolate of λ HuBlym-1. Since these clones were isolated from libraries constructed with DNAs partially digested with *Mbo*I, these results strongly indicated the possibility of contamination of Devine's isolates with the original transforming clone. In addition, transfection assays performed and read by Devine before she left the laboratory indicated that the clones designated by her as "non-transforming" from the CW678 and EW36 Burkitt's lymphoma libraries induced transformation with efficiencies comparable to the clones designated "transforming". Restriction digests of the clones isolated from a random library of normal human DNA were also found to be identical to the original λ HuBlym-1 isolate, again raising concerns about contamination. We therefore concluded that a bona fide normal copy of the gene had to be isolated and analysed in order to exclude the possibility of contamination of the clones on which Devine has reported.

A clone of the 5-kilobase (kb) *Hin*dIII fragment containing *Blym*-1 was therefore reisolated from normal human DNA. The restriction map of this clone is different from other *Blym*-1

clones in the laboratory, ruling out the possibility of cross-contamination. The 1-kb *Eco*RI fragment of this clone induces transformation of NIH 3T3 cells with efficiencies comparable to that of the 1-kb *Eco*RI fragment of the original λ HuBlym-1 clone. Both of these clones have also displayed comparable activities in assays of transformation of primary human foreskin fibroblasts to anchorage independence and transformation of BALB.3T3 cells to platelet-derived growth factor-independent growth. Further, the nucleotide sequences of the 1-kb *Eco*RI fragments of the normal and Burkitt's lymphoma clones are identical.

We therefore conclude that activation of transforming potential does not require a mutation within the minimal 1-kb transforming region of *Blym*-1. These results suggest the hypothesis that flanking sequences may regulate transforming activity and experiments are now in progress to test this possibility. The notion that regulatory changes may be involved in activating transforming genes is not inconsistent with the fact that there are no significant increases in the total level of expression of *Blym*-1 in Burkitt's lymphomas compared with Epstein-Barr virus-immortalized cell lines. In fact this situation is similar to that observed with *myc*, where its activation by translocation appears to result in de-regulation of gene expression rather than in a significant increase in *myc* RNA levels in most Burkitt's lymphomas and plasmacytomas[1-4].

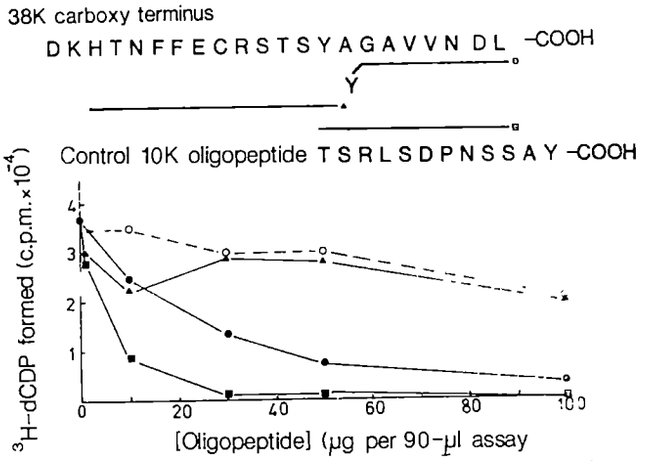

Fig. 1 Effect of synthetic oligopeptides on ribonucleotide reductase activity in an extract of HSV-1-infected baby hamster kidney (BHK) cells. The figure shows the effects of increasing concentrations of peptides 1-4 (●, ○, ■ and ▲, respectively). DK···DL—COOH represents the 22 amino acid sequence of the 38K carboxy terminus. Horizontal lines indicate the amino acid sequences of peptides 1, 3 and 4.

Methods. Synthetic oligopeptides were obtained from Cambridge Research Biochemicals (Cambridge, UK) and Peptide and Protein Research Consultants (Windsor, UK). Crude extracts were obtained from virus-infected cells as described elsewhere[6] and partially purified by precipitation with 45% ammonium sulphate. Ribonucleotide reductase was assayed by determining the amount of cytidine diphosphate (CDP) converted to deoxycytidine diphosphate (dCDP) in a 90-μl reaction (for 1 h at 31 °C) containing 100 μg partially purified extract, 200 mM HEPES *p*H 8.2, 10 mM dithiothreitol (DTT), 100 μM CDP and 1 μCi ^{3}H-CDP (10-30 Ci mmol^{-1}). The nucleotides were converted to the corresponding nucleosides by digestion with snake venom phosphodiesterase and the resulting cytidine and deoxycytidine separated by reverse-phase HPLC (B.M.D., in preparation). In the conditions of this assay, the host cell enzyme is inactive and only the viral enzyme contributes to the measured activity.

Specific inhibition of herpesvirus ribonucleotide reductase by synthetic peptides

Bernadette M. Dutia*, Margaret C. Frame, John H. Subak-Sharpe, William N. Clark & Howard S. Marsden†

MRC Virology Unit, Institute of Virology, University of Glasgow, Church Street, Glasgow G11 5JR, UK

Ribonucleotide reductase is an essential enzyme for DNA synthesis in all prokaryotic and eukaryotic cells; it catalyses the reductive conversion of ribonucleotides to deoxyribonucleotides. Several herpesviruses including herpes simplex virus type 1 (HSV-1)[1], HSV-2[2], pseudorabies virus (PRV)[3], equine herpesvirus type 1 (EHV-1)[4] and Epstein-Barr virus (EBV)[5] have been found to induce novel ribonucleotide reductase activities. There is evidence that the HSV-1 ribonucleotide reductase activity is virus-encoded[6] and essential for virus replication[7]. This makes herpesvirus ribonucleotide reductases potential targets for antiviral chemotherapy. The HSV-1-encoded enzyme consists of two subunits[8,9,18]: V136, the large subunit of relative molecular mass (M_r) 136,000 (136K) (RR_1), which has been shown to be essential for enzyme activity[7], and V38, the small subunit (RR_2) which forms a complex with the large subunit and is also likely to be essential for enzyme activity[9]. Two particular features of the enzyme make it an attractive antiviral target. First, there is evidence for a common, highly conserved herpesvirus ribonucleotide reductase and second, the interaction between the large and small subunits may itself be exploitable. Here we identify a synthetic peptide which specifically inhibits the activity of virus-induced enzyme. We deduce that the mechanism of inhibition involves interference with the normal interaction between the two types of subunit.

The discovery of an oligopeptide which inhibits ribonucleotide reductase activity arose from experiments designed to show that both RR_1 and RR_2 were necessary for enzyme activity. To this end, RR_2 was removed from an enzyme extract of HSV-1-infected cells by immunoaffinity chromatography using IgG from serum raised against the synthetic octapeptide NH_2-Tyr-Gly-Ala-Val-Val-Asn-Asp-Leu-COOH (YGAVVNDL, using the one-letter code). This peptide corresponds to the carboxy-terminal seven amino acids of RR_2 plus an amino-terminal tyrosine added to facilitate linkage to a carrier protein[9]. Immunoaffinity chromatography was performed by first adsorbing the enzyme extract with immune anti-peptide IgG immobilized on Sepharose 4B. After stringent washing, bound RR_2 was eluted with the synthetic peptide. However, attempts to reconstitute the enzyme activity by adding back purified RR_2 were unsuccessful at least because the synthetic peptide necessarily present with eluted RR_2 inhibits enzyme activity (see below). Frame *et al.*[9] had previously obtained indirect evidence that the carboxy terminus of RR_2 is masked by the large subunit; this suggested that the synthetic peptide might correspond to a region

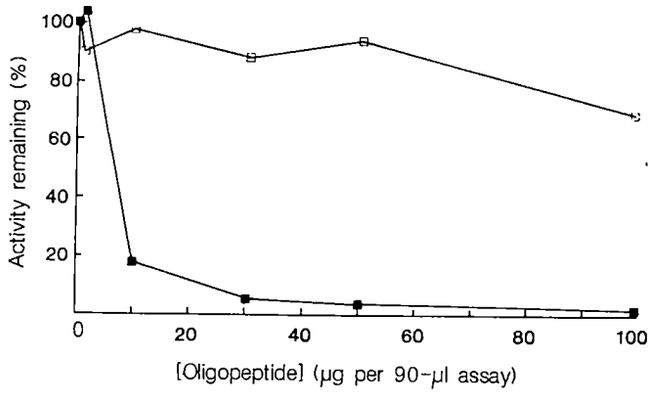

Fig. 2 Inhibition by the synthetic peptide 3 (see Fig. 1 and text) is specific for the viral and not the cellular ribonucleotide reductase. Partially purified extracts were obtained from either HSV-1-infected (■) or uninfected (□) BHK cells, and HSV-1-infected ribonucleotide reductase activity was assayed as described in Fig. 1 legend. The assay was modified to measure mammalian enzyme activity and contained 100 mM HEPES *p*H 7.6, 2.7 mM ATP, 2.7 mM magnesium acetate, 10 mM DTT, 55 μM CDP and 1 μCi ^{3}H-CDP (10–30 Ci mmol^{-1}). The enzyme activity is expressed as a percentage of that found in the absence of oligopeptide. The 100% values correspond to 51,806 and 17,064 c.p.m. of ^{3}H-dCDP formed by the infected and uninfected cell extracts, respectively.

of the small subunit involved in interacting with the large subunit. We suspected that the synthetic peptide might compete for a site on the large subunit and displace the small subunit.

Ribonucleotide reductase activity in extracts of HSV-1-infected and mock-infected cells was assayed in the presence of various concentrations of the synthetic oligopeptide YGAVVNDL (peptide 1). The results show that peptide 1 inhibits virus-specific activity (Fig. 1). Peptide 2 (NH_2-Thr-Ser-Arg-Leu-Ser-Asp-Pro-Asn-Ser-Ser-Ala-Tyr-COOH, TSRLSDPNSSAY), which corresponds to the amino-terminal sequence of the 10K protein product of the HSV-1 gene US9 (ref. 10), was included in the experiment as a control and did not inhibit activity.

A comparison of the predicted amino-acid sequences of ribonucleotide reductases from HSV-1, HSV-2, EBV, *Escherichia coli*, clam and sea urchin[11–15] and varicella zoster virus (VZV)[16] shows that the tyrosine residue at position 9 from the carboxy-terminal end of the herpesvirus RR_2 is conserved in all species[17]; this led us to speculate that this tyrosine was particularly important for enzyme function. We therefore tested two further oligopeptides, one corresponding to the carboxy-terminal nonapeptide NH_2-Tyr-Ala-Gly-Ala-Val-Val-Asn-Asp-Leu-COOH (YAGAVVNDL, peptide 3) and differing from peptide 1 by the inclusion of an alanine residue between the tyrosine and glycine residues, and the other a tridecapeptide NH_2-Ser-His-Thr-Asn-Phe-Phe-Glu-Cys-Arg-Ser-Thr-Ser-Tyr-COOH (HTNFFECRS-TSY, peptide 4), which corresponds to the conserved tyrosine residue and the adjoining 12 amino acids on the amino-terminal side. Figure 1 shows that peptide 3 is a more effective inhibitor than peptide 1 whereas peptide 4 is at best only marginally inhibitory. In this experiment the concentration of peptide giving 50% inhibition of enzyme activity was 4.5 μg per assay for peptide 3 and 21 μg per assay for peptide 1, which shows that peptide 3 is approximately five times more inhibitory than peptide 1.

To test whether the inhibition of ribonucleotide reductase activity by peptide 3 was specific for the virus-induced enzyme, we investigated the effect of the peptide on the viral and cellular enzymes. Figure 2 shows that the inhibition is specific for the virus-induced enzyme and has little effect on the cellular enzyme.

The highly conserved carboxy-terminal amino-acid sequence of HSV-1 and HSV-2 (refs 12, 13), EBV[15] and VZV[16] led us to test whether the antigenic domain(s) recognized by the anti-peptide 1 serum described above is also conserved in other herpesviruses. Extracts from cells infected with HSV-1, HSV-2, VZV, PRV and EHV-1 were made and immunoprecipitations performed as described elsewhere[9]. In those experiments no immunoprecipitation of any cellular proteins was observed. Figure 3 shows that RR_2 is specifically immunoprecipitated from extracts of cells infected with any of these herpesviruses and that RR_1 is co-precipitated from cells infected with HSV-1, HSV-2 and PRV but not VZV and EHV-1. This result suggests that PRV, like HSV-1 and HSV-2, has two types of interacting ribonucleotide reductase subunits and that their site of interaction is likely to be a common target for the inhibitory oligopep-

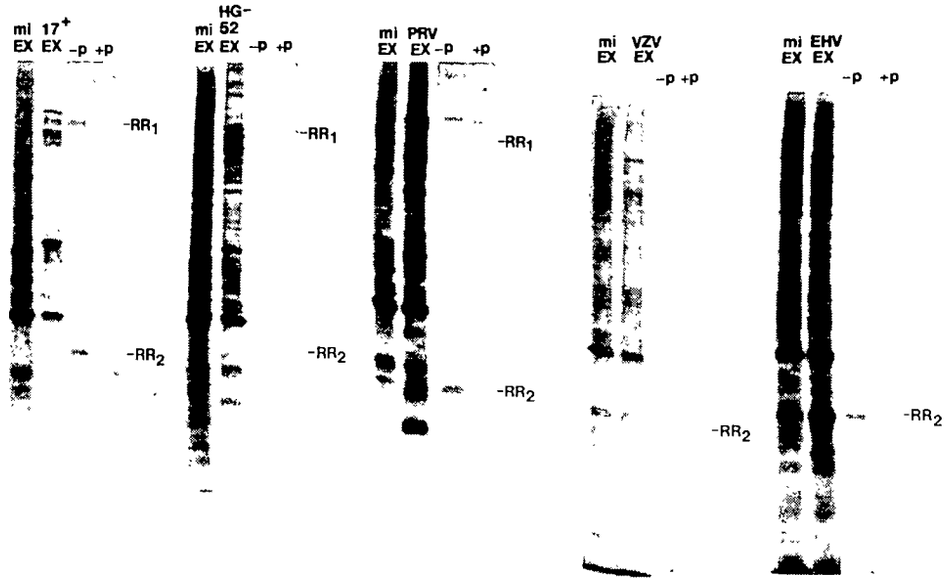

Fig. 3 Immunoprecipitation of polypeptides from extracts of cells infected with herpesviruses HSV-1 (strain 17 syn$^+$), HSV-2 (strain HG52), PRV, VZV and EHV-1, using IgG purified from an antiserum (14119) raised against the carboxy-terminal seven amino acids of the small ribonucleotide reductase subunit (RR_2) of HSV-1 and HSV-2. ^{35}S-methionine-labelled extracts of BHK cells infected with HSV-1, HSV-2 and PRV were prepared as described elsewhere[9]. Rabbit kidney (RK) cells were infected with EHV-1 in a similar manner. HFL cells were infected with VZV by co-culturing confluent monolayers with VZV-infected HFL cells. Immunoprecipitations were carried out as described elsewhere[9] in extraction buffer containing 0.5% SDS. IgG was purified from antiserum 14119 by ion-exchange chromatography and used in immunoprecipitations with (+p) and without (−p) 100 μg of the synthetic peptide 1, against which the antiserum was raised[9]. Lanes designated mi EX, 17$^+$ EX, HG52 EX, PRV EX, VZV EX and EHV EX show ^{35}S-methionine-labelled polypeptide profiles for mock-infected, HSV-1 (strain 17 syn$^+$), HSV-2 (strain HG52), PRV, VZV and EHV-infected cell extracts, respectively. RR_1 and RR_2 are, respectively, the large and small herpesvirus ribonucleotide reductase subunits.

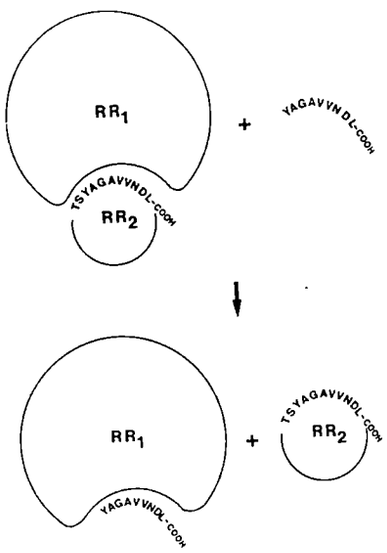

Fig. 4 Possible mechanism for inhibition of the herpes virus ribonucleotide reductase by the synthetic peptide 3.

tides. For EHV-1 and VZV the situation is less clear—different conditions may well be necessary to co-precipitate RR_1 with RR_2 from cells infected with these viruses.

Figure 4 presents a model to explain the inhibition of enzyme activity based on evidence indicating that the two subunits interact via the carboxy terminus of RR_2 (ref. 9). The model proposes that the inhibitory nonapeptide prevents the association of the two subunits by competing for the subunit binding site on RR_1, displacing RR_2. The model is not intended to imply that only one large and one small subunit combine to form the active enzyme, or that the carboxy-terminal region is the only site involved in the interaction between the small and large subunits.

The potential therapeutic implications of specific inhibition of the subunit interaction are being investigated. Exposure of infected cell monolayers to various concentrations of the nonapeptide (peptide 3) did not reduce the yield of infectious virus; this is probably because the peptide is too large to enter the cell unaided. Present efforts are directed towards identification of smaller peptides which specifically inhibit ribonucleotide reductase activity both *in vitro* and *in vivo*.

We thank Mrs M. Murphy, Mrs A. Orr and Mr G. Hope for technical assistance; Dr J. B. Clements, Dr A. J. Davison and Dr J. McLauchlan for helpful discussions; and Ms A. Cullinane for providing the stock of EHV. We also thank Miss F. Conway and Mrs A. Simpson for typing the manuscript.

Ribonucleotide reductase, an essential enzyme for the synthesis of deoxyribonucleotides, is formed by the association of two non-identical subunits in almost all prokaryotic and eukaryotic cells[1]. The same model probably holds for the herpes simplex virus (HSV)-encoded ribonucleotide reductase[2–6]; two polypeptides of relative molecular mass 136,000 (136K; H1) and 40K (H2) (referred to elsewhere as RR_1 and RR_2; see for example, Dutia *et al.*[26]) have been associated with the viral enzyme by both genetic[7,8] and immunological[9–11] studies. Furthermore, DNA sequence analyses have shown significant stretches of amino-acid homology between these viral polypeptides and those of, respectively, subunit 1 (ref. 12) and subunit 2 (ref. 13) of the *Escherichia coli* and mammalian enzymes. To assess the involvement of the 40K polypeptide in reductase activity, we synthesized a nonapeptide corresponding to the sequence of its carboxy terminus with the intention of raising neutralizing antibodies specific for the viral activity (E.A.C. *et al.*, in preparation). We report here the unexpected finding that the nonapeptide itself specifically inhibits the HSV ribonucleotide reductase activity in a reversible, non-competitive manner, and we suggest that it does this by impairment of the correct association of the two subunits. This phenomenon emphasizes the potential usefulness of synthetic peptides in probing critical sites involved in macromolecular interactions.

The nonapeptide NH_2-Tyr-Ala-Gly-Ala-Val-Val-Asn-Asp-Leu-COOH, corresponding to the carboxy-terminal nine amino acids of the HSV type 1 (HSV-1) 40K and HSV-2 38K polypeptides (as predicted from the DNA sequences[14,15]), was synthesized by the solid-phase technique of Merrifield[16] and its primary structure verified by quantitative amino-acid analysis after acid hydrolysis and digestion with leucine aminopeptidase. The preparation was 99% pure as determined by HPLC. HSV-1 or HSV-2 ribonucleotide reductase was partially purified from quiescent BHK-21/C13 cells infected respectively with strain F and strain HG-52 at 20 plaque-forming units (PFU) per cell, whereas the cellular enzyme was obtained from exponentially growing BHK-21/C13 cells or hydroxyurea-resistant 96-V-2(600) cells. The latter cells exhibit high ribonucleotide reductase specific activity owing to overproduction of the two enzyme subunits (ref. 17 and our unpublished observations for subunit 1).

Figure 1 shows the effect of the synthetic peptide on the HSV-1 enzyme: 50% inhibition was observed with 22 μM nonapeptide and total inhibition was obtained with a concentration of 400 μM. The curve obtained for the HSV-2 enzyme was almost identical (data not shown). The cellular enzyme extracted from 96-V-2(600) (Fig. 1) or BHK-21/C13 cells (data not shown) was completely insensitive to the presence of the peptide in the assay up to a concentration of 1 mM. To show that this specific effect was due to the nonapeptide rather than attributable to some trace contaminants, we used an anti-nonapeptide rabbit serum with specific neutralizing activity against the HSV ribonucleotide reductase activity (E.A.C. *et al.*, in preparation). Purified IgG (5 μg, which gave 60% neutralization in the absence of peptide) was pre-adsorbed with increasing concentrations of nonapeptide

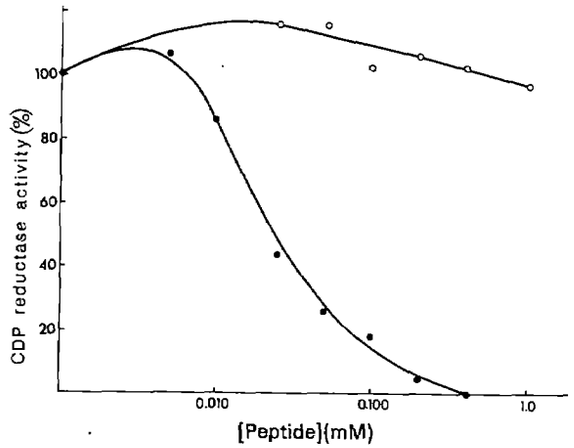

Fig. 1 Effect of the synthetic nonapeptide on viral (●) and cellular (○) ribonucleotide reductase activities. One unit (U) of ribonucleotide reductase activity is defined as the amount of enzyme generating 1 nmol of dCDP per h under the standard assay conditions. The results are expressed as a percentage of the activity obtained in the controls without nonapeptide.

Methods. Viral and cellular ribonucleotide reductases were, respectively, partially purified from HSV-1 (strain F)-infected confluent BHK-21/C13 cells and exponentially growing 96-V-2(600) cells by precipitation of the cell extract with ammonium sulphate as described elsewhere[6]. Aliquots of the viral (50 μg; specific activity 30 U mg^{-1}) or cellular (40 μg; specific activity 34 U mg^{-1}) enzyme preparation were mixed with increasing concentrations of nonapeptide, and ribonucleotide reductase activity was assayed by monitoring the reduction of CDP as described previously[6]. Briefly, the standard reaction mixture, in a final volume of 60 μl, contained: 50 mM HEPES *p*H 7.8, 4 mM $MgCl_2$, 4 mM ATP, 4 mM NaF, 6 mM DTT, 54 μM CDP and 0.25 μCi ^{3}H-CDP. For the viral activity, $MgCl_2$ and ATP (which are non-essential for this activity) were usually omitted and 20 mM DTT was used instead. These changes did not affect the inhibition by the nonapeptide. After 30 min of incubation at 37 °C, the reaction was stopped by immersing the tube in boiling water for 4 min and the precipitate removed by centrifugation. Nucleotides in the supernatant were converted to nucleosides by enzymatic hydrolysis. The deoxyribonucleosides were subsequently separated from the ribonucleosides by ascending polyethyleneimine-cellulose chromatography.

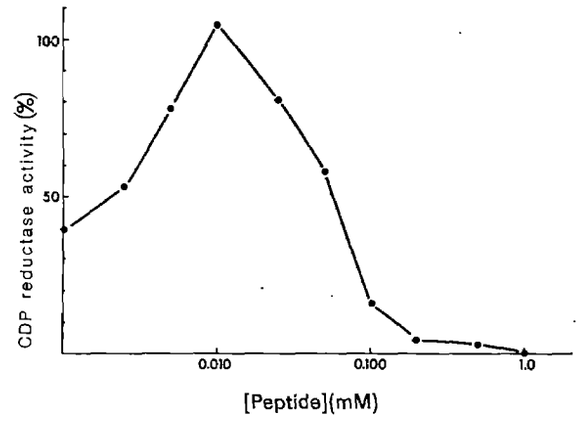

Fig. 2 Effect of the nonapeptide on the neutralizing activity of an anti-nonapeptide antiserum. The anti-nonapeptide antiserum (P9) was obtained by immunizing a rabbit with the nonapeptide conjugated to methylated bovine serum albumin, as described elsewhere[25]. IgGs were purified from the P9 serum by adsorption to a column of protein A-Sepharose CL-4B (Pharmacia), followed by elution with 0.1 M glycine *p*H 2.5. After incubation of 5 μg of P9 IgGs with increasing concentrations of nonapeptide for 30 min at 20 °C, 50 μg of partially purified HSV-1 ribonucleotide reductase (specific activity 30 U mg^{-1}) was added to each sample. After a second incubation of 30 min at 20 °C, ribonucleotide reductase activity was assayed as outlined in Fig. 1 legend.

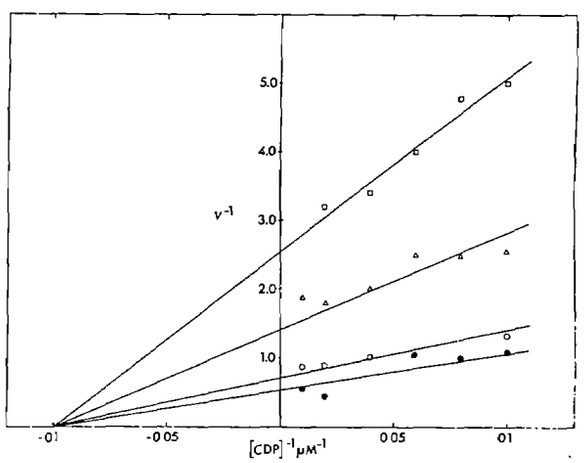

Fig. 3 Double-reciprocal plot of velocity (v) versus CDP concentrations at different nonapeptide concentrations. Aliquots of partially purified HSV-1 enzyme preparation were mixed with the following nonapeptide concentrations: 0 μM (●), 15 μM (○), 25 μM (△), 50 μM (□), and assayed using the standard reaction mixture as described in Fig. 1 legend, except that CDP was added at the appropriate concentrations.

and preincubated with 50 μg of viral enzyme before the ribonucleotide reductase assay. At low nonapeptide concentrations, the ability of the IgG to neutralize the enzyme activity was progressively eliminated until equivalence was reached at 10 μM (see Fig. 2). Subsequently, the activity was inhibited but the curve was displaced to the right relative to that in Fig. 1, as expected if the nonapeptide is responsible for the inhibition.

As further controls for the specificity of the inhibition, we also examined the effect of the nonapeptide on other HSV-encoded enzymatic activities involved in DNA metabolism: thymidine kinase, DNA polymerase and DNase. These viral enzymes were specifically measured respectively by phosphorylation of ^{3}H-bromodeoxycytidine[18], ^{3}H-dGTP incorporation in activated DNA in the presence of 150 mM ammonium sulphate[19], and solubilization of ^{3}H-thymidine from *in vivo* labelled DNA assayed at *p*H 9.0 (ref. 20). None of these enzymatic activities was affected by the presence of 1 mM of the nonapeptide (data not shown), indicating that the action of the inhibitor was specific to the HSV ribonucleotide reductase activity.

We next investigated the mechanism of action of this inhibitor. As HSV ribonucleotide reductase activity could be completely restored when the nonapeptide was removed by dialysis from a preparation of enzyme preincubated with 1 mM nonapeptide, we concluded that the inhibition was reversible. Preincubation of the peptide with the viral enzyme did not change the degree of inhibition observed at given peptide concentrations. Measurement of the initial rate of product formation in the presence of inhibitor revealed that the change in the velocity (v) of the reaction was very rapid, being already established after 2 min. These results suggested that the peptide did not need any modification by a factor present in the extract to become active. The nature of the inhibition was determined by varying the CDP concentration at several fixed concentrations of nonapeptide. By means of a double reciprocal plot, we demonstrated that the nonapeptide behaved as a non-competitive inhibitor with respect to CDP (Fig. 3). The K_i, calculated by re-plotting $1/v$ against the inhibitor concentration, gave a value of 15 μM. By using the same type of analysis, we determined that this inhibitor also does not compete with the reducing agent dithiothreitol (DTT).

To explain the unexpected inhibitory activity of the nonapeptide, we hypothesize that the carboxy terminus of the presumptive subunit 2 (H2) of the HSV ribonucleotide reductase

is directly involved in binding with subunit 1 (H1). Thus, the carboxy-terminal nonapeptide would compete with H2 for some critical binding site and effectively prevent the formation of the active holoenzyme; this notion is supported by the observed specificity of the inhibition for the viral enzyme, as the nonapeptide does not share significant amino-acid homology with subunit 2 of the cellular enzyme[13] and thus presumably does not interact with the cellular subunit 1. Our findings that the inhibition is reversible and non-competitive with respect to the substrate and the reducing agent are also in agreement with this hypothesis. However, at present we cannot exclude other possibilities such as the inhibition by the nonapeptide of some essential interaction between viral subunit 2 and other cellular protein(s) or constituent(s). These hypotheses should be testable by crosslinking studies using radiolabelled nonapeptide.

Here we report that a synthetic peptide derived from the amino-acid sequence of an enzyme behaves as a specific inhibitor of the enzyme, adding another area of research in which synthetic peptides have proved useful. Synthetic peptides have been used largely to examine the interactions between proteins and receptors[21-24]. We predict that the use of such synthetic peptides, derived from amino-acid sequences implicated in the association of proteins with receptors, membranes, DNA, RNA or enzyme subunits, will be of prime importance in elucidating macromolecular interactions. Moreover, it is tempting to speculate that synthetic peptides could have potential in antiviral chemotherapy. In this respect, we are testing the effect of our nonapeptide on replication of HSV.

We thank Claire Guilbault for technical assistance and Lucille Beaudet for the assays of HSV thymidine kinase, DNA polymerase and DNase. We also thank W. H. Lewis for his gift of the 96-V-2(600) cell line and V. Bibor-Hardy and W. E. C. Bradley for critical reading of the manuscript. This work was supported by grants from NCI (Canada) to Y.L. and from MRC (Canada) to P.B. E.A.C. is the recipient of a studentship from La Société de Recherche sur le Cancer and P.G. of a postdoctoral fellowship from FRSQ (Québec).

Re-routing of a secretory protein by fusion with human growth hormone sequences

Hsiao-ping H. Moore* & Regis B. Kelly†

* Department of Physiology-Anatomy, University of California, Berkeley, California 94720, USA
† Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, USA

Cells with electron-dense secretory vesicles use them to store only specialized secretory products such as peptide hormones; other types of secreted proteins are externalized by an alternative, constitutive route[1]. One possible mechanism for such segregation is that proteins destined for dense secretory vesicles contain unique 'sorting domains'[2] that allow for selective targeting. Here, we set out to determine whether a constitutively secreted protein could be diverted to the dense secretory vesicles by attachment to a peptide hormone sequence. We made use of the ability of the mouse pituitary tumour cell line, AtT-20, to correctly sort exogenous secretory proteins introduced into them by DNA transfection[3]. We constructed a plasmid encoding a hybrid protein in which a constitutively secreted viral protein was fused to the carboxy terminus of human growth hormone (hGH). Cells expressing the hybrid protein were found to target it to dense secretory vesicles with an efficiency close to that observed for the parental hGH. These results support the hypothesis that sorting domains on peptide hormones direct their packaging into dense secretory vesicles. The results also suggest that proteins secreted by the constitutive pathway either do not contain any sorting domain, or their sorting signals can be overridden by those which direct peptide hormones.

Generation of fusion proteins is a useful means of studying the targeting of nuclear, mitochondrial, vacuolar and membrane proteins to their correct destinations[4-9]. To construct a hybrid between a constitutively secreted protein and a protein destined for dense secretory vesicles (that is, destined for the regulated pathway), we fused the hGH sequence to the truncated vesicular stomatitis virus (VSV) G sequence (Fig. 1*a*). The truncated G protein (designated TG) contains an intact 432-amino-acid luminal region of the G protein but lacks the entire membrane-spanning and cytoplasmic domains (79 amino acids from the carboxy terminus)[10]. When transfected separately into AtT-20 cells, hGH was found to be transported to the regulated pathway while TG was exported efficiently by the constitutive pathway[3]. Figure 1*b* illustrates the strategy for constructing a precise in-frame fusion between the two coding sequences. An hGH complementary DNA including 35 bases of the 5'-untranslated sequence[11] was first inserted in the appropriate orientation between the Rous sarcoma virus (RSV) long terminal repeat (LTR) promoter and the TG coding sequences in an expression vector (step 1 in Fig. 1*b*). A fragment containing the hGH-TG sequences was subcloned into an M13 vector, and a 200-base pair (bp) sequence at the junction of hGH and TG was deleted by oligonucleotide-directed mutagenesis (steps 2, 3 in Fig. 1*b*). As shown in Fig. 1*a*, the resulting sequences encode a hybrid protein in which the last amino acid of hGH is joined directly to the first amino acid of the mature TG protein, which lacks its signal peptide. We found that ~2% of the M13 phage plaques had incorporated the desired mutation. To ensure that no other mutations had been introduced during the mutagenesis procedure, we sequenced the entire insert, including regions outside the mutated area, before cloning it back into the RSV-LTR expression vector (step 4 in Fig. 1*b*).

Figure 2 shows immunoprecipitation analyses of cellular and secreted proteins from an AtT-20 cell line that had been stably transformed with the chimaeric plasmid described above. As neither hGH nor TG is normally processed from larger precursor propeptides, it was predicted that the fusion protein would be a single polypeptide with a relative molecular mass (M_r) equal to the sum of those of hGH (22,000; SSK) and TG (54-56K). The transformed cells synthesized a protein with an apparent

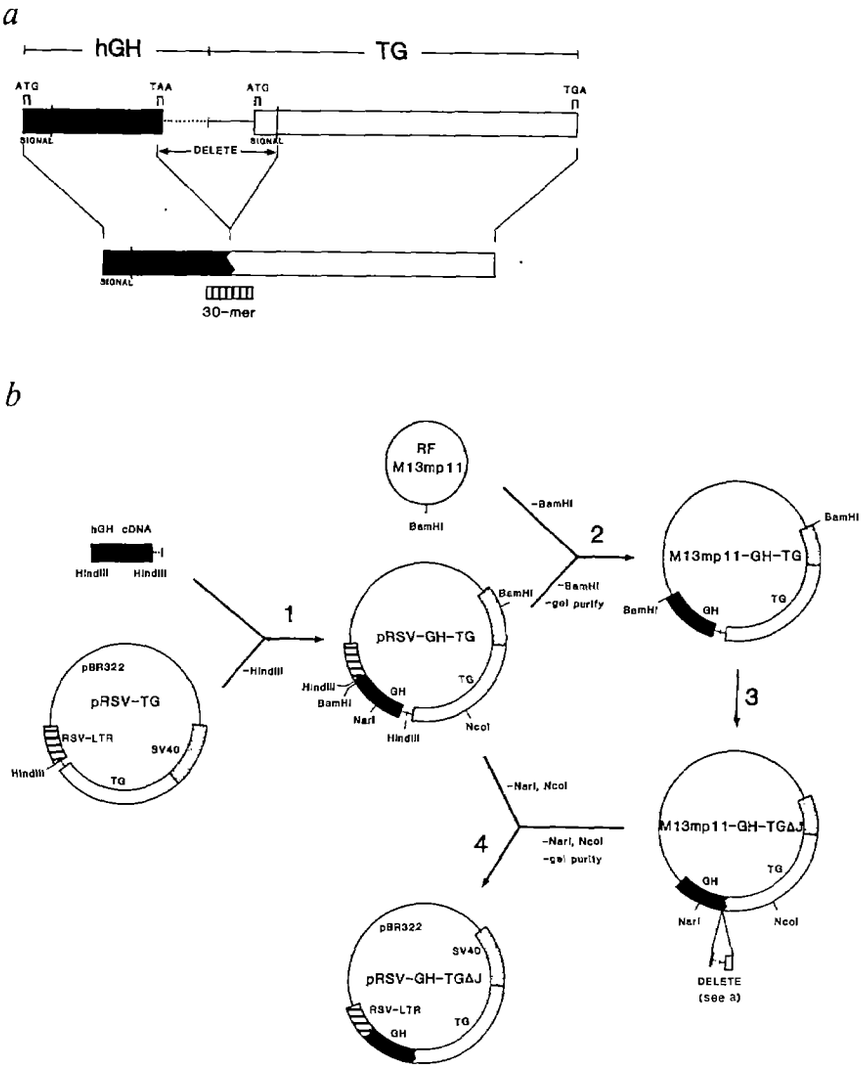

Fig. 1 *a*, Structure of a hGH-TG hybrid created by oligonucleotide-directed mutagenesis. A 30-mer mutagenic primer was used to delete the hGH-TG junctional region, including the stop codon and the 3′-untranslated sequences of hGH, and the 5′-untranslated sequences and the 16-amino-acid signal peptide of the truncated G protein. Half of the primer is complementary to the 15-base sequence immediately downstream from the signal peptide of TG; the other half is complementary to the last 15 bases of the mature hGH coding sequences. *b*, Construction of an expression vector containing the hGH-TG hybrid. The full-length hGH cDNA, carried on a *Hin*dIII fragment (chGH800/pBR322; ref. 11), was inserted in the *Hin*dIII site of pRSV-TG, the plasmid vector used previously to express a truncated VSV G protein in AtT-20 cells[3] (step 1). A 3.0-kilobase (kb) *Bam*HI fragment spanning the entire hGH and truncated G sequences was then subcloned into M13mp11 (step 2). The fusion junction was modified by site-directed mutagenesis using the single-stranded M13 DNA as a template (step 3; see *a*). An 814-base pair (bp) fragment emcompassing the modified fusion junction was then cloned back into the expression vector pRSV-hGH-TG as a *Nar*I/*Nco*I fragment (step 4). ▨, RSV LTR; ■, hGH sequences; □, TG sequences; ▩, simian virus 40 splice junction and polyadenylation site; —, pBR322 sequences; ▥, mutagenic primer.

Methods. pRSV-TG (100 ng) was digested with *Hin*dIII, treated with phosphatase and then ligated to 100 ng of an 803-bp *Hin*dIII fragment which had been excised from chGH800 and purified on agarose gels. Plasmids with the hGH sequences inserted in the same orientation as TG were isolated and digested with *Bam*HI. The 3.0-kb fragment was purified on agarose gels, ligated to *Bam*HI-digested, phosphatase-treated M13mp11 vector, and used to transform *Escherichia coli* JM101. Single-stranded phage DNA was prepared and sequenced by the dideoxy method[18] to ensure the correct orientation of the insert. One pmol of the single-stranded template was annealed simultaneously to 20 pmol of 5′ phosphorylated mutagenic primer and 20 pmol of a second, 15-base primer. The latter anneals to sequences 180 bp away from the mutagenic primer, in the TG coding region. After *in vitro* synthesis in the presence of DNA polymerase large fragment (Klenow) and T_4 ligase, the reaction mixture was used to transform *E. coli* JM101. Phage plaques carrying the desired mutation were identified by hybridization to [5′-^{32}P]-labelled mutagenic primer, followed by washing under conditions of appropriate stringency. DNA from the purified plaque was sequenced by dideoxy sequencing to confirm the mutation. The *Nar*I/*Nco*I fragment was then excised from the M13 vector, gel-purified, and ligated to pRSV-GH-TG, which had been digested with *Nco*I and *Nar*I and treated with phosphatase.

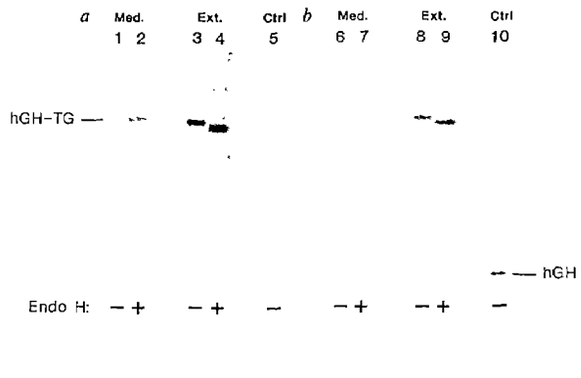

Fig. 2 Transformed AtT-20 cells synthesize and secrete a glycosylated hGH-TG hybrid protein. An AtT-20 cell line stably transformed with the plasmid pRSV-GH-TGΔJ was radiolabelled with ^{35}S-methionine for 13 h. Cellular and secreted proteins were then analysed by immunoprecipitation with anti-VSV (*a*) or anti-hGH (*b*) antisera, followed by SDS-polyacrylamide gel electrophoresis (SDS-PAGE). Lanes 1, 2, 6 and 7 are autoradiograms of immunoprecipitates from samples of medium, and lanes 3, 4, 8 and 9 are from cell extracts. As a control, samples of medium from cells expressing hGH protein not fused to TG were analysed in parallel (lanes 5, 10). Samples in lanes 2, 4, 7 and 9 were digested with Endo H before electrophoresis.

Methods. A 10-cm dish of AtT-20 cells was transfected with 120 μg of pRSV-GH-TGΔJ and 24 μg of pSV2-neo by the calcium phosphate procedure[3]. Clones surviving the G-418 selection were picked and screened by hGH radioimmunoassay (Hybritech). Cells from a positive clone, I17, were labelled, and medium and extract samples were prepared and analysed according to published procedures[3].

M_r of ~72–75K that could be precipitated by both anti-VSV (Fig. 2, lane 3) and anti-hGH (Fig. 2, lane 8) antisera. The specificity of the immunoprecipitation reaction was demonstrated by the fact that authentic hGH could be precipitated only by the anti-hGH (Fig. 2, lane 10), not the anti-VSV (lane 5) antiserum. The fusion polypeptide was secreted into the culture medium by the transformed cells (Fig. 2, lanes 1, 6), and the secreted form exhibited similar immunoreactivity with both antisera. The fusion protein could also be detected by a hGH radioimmunoassay (Hybritech, La Jolla, California) (data not shown); by this assay, the rate of synthesis of the hybrid protein was estimated to be 0.3 pmol per h per mg cell protein. As this is much less than the level of the endogenous hormone, adrenocorticotropic hormone (ACTH; 18 pmol per h per mg cell protein), it is unlikely to perturb the sorting machinery.

The glycosylation pattern of the fusion protein suggests that it traverses the normal secretory compartments before secretion. VSV G has two *N*-linked oligosaccharide addition sites whereas hGH is not glycosylated. The fusion protein acquires post-translational glycosylation similar to that of the truncated G protein. The predominant intracellular form of the fusion protein bears oligosaccharides of the high mannose type and is sensitive to endoglycosidase H (Endo H) digestion (Fig. 2, lanes 3,4 and 8, 9). A minor band with a slightly slower mobility, not apparent in the exposure of Fig. 2, was also detected in the cell extracts, especially after 1–2 h of chase (not shown); this form bears oligosaccharides of the complex type and is resistant to Endo H digestion. In contrast, the secreted fusion protein is exclusively Endo H-resistant (Fig. 2, lanes 1, 2 and 6, 7). Almost identical patterns were also found for ACTH (not shown).

The above results suggest that the conformation of the two parent proteins has not been drastically altered in the hybrid protein. First, the hGH moiety of the hybrid preserved sufficient antigenicity for measurement by radioimmunoassay and immunoprecipitation (note that a monoclonal antibody and two different polyclonal antibodies were used). Similarly, the TG portion retained sufficient antigenicity to be recognized by an anti-VSV-specific antiserum. Furthermore, the glycosylation sites on TG were still available.

To determine whether the hGH sequences could divert TG to the dense secretory vesicles, we examined the effects of secretagogues on the secretion of the hybrid protein. As we have shown previously, secretagogues stimulate the secretion of only those proteins that are packaged in dense secretory vesicles[12], thereby providing a simple test for the secretory pathway taken by the hybrid protein. Cells were labelled with ^{35}S-methionine for 16 h and then chased for 6 h to reduce the background contributed by constitutive secretion[3]. We then determined the effect of the secretagogue 8-bromocyclic AMP (8-Br-cAMP) on the rate of secretion. We have demonstrated previously that secretagogue-stimulated cells show enhanced secretion of hGH but not of TG, indicating that only the former is packaged into the regulated secretory vesicles. Those results were confirmed here (Fig. 3*b*). Under the same conditions, secretion of the hGH–TG fusion protein was clearly stimulated (Fig. 3*a* (lanes 3, 4) and *b*). To quantitate the extent to which the hybrid protein is sorted into the regulated pathway, we calculated the increase in the amount of secretion induced by 8-Br-cAMP and normalized it to the steady-state rate of secretion. The 'sorting indices' obtained by such quantitation (described in detail in ref. 3) indicate that the hGH–TG hybrid enters the regulated secretory vesicles with ~50% the efficiency of hGH (0.43 for hGH compared with 0.22 for hGH–TG; see legend to Fig. 3*b*). This extent of sorting is at least comparable to, if not better than, that of the endogenous hormone ACTH (0.14; see Fig. 3*b*). Thus, because of the attachment of hGH sequences, the truncated G protein has acquired the ability to be packaged into regulated secretory vesicles.

Conceivably, sorting of proteins into the two pathways could be achieved by means of sorting domains present on either the

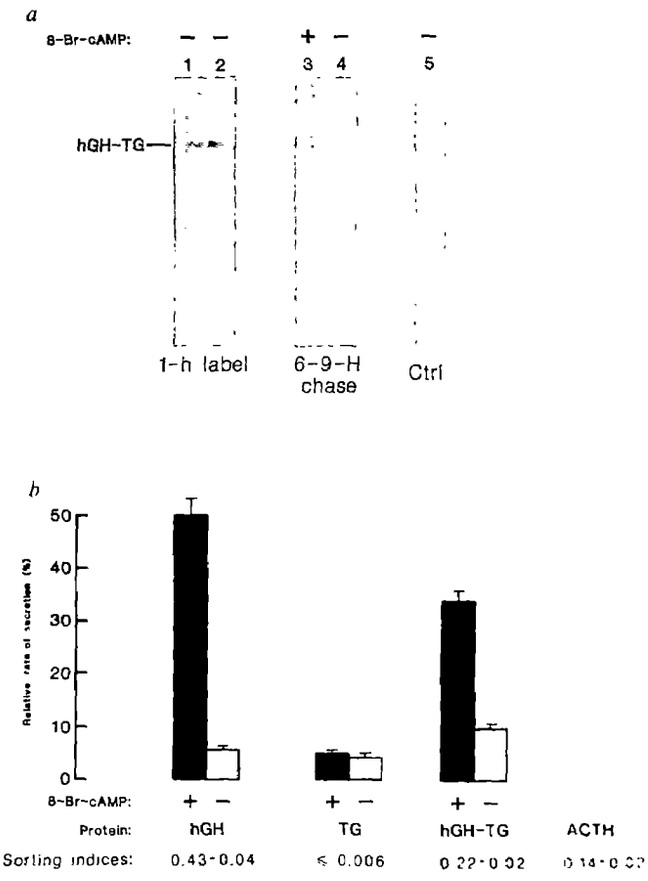

Fig. 3 The hGH–TG hybrid protein is secreted by a secretagogue-dependent, regulated pathway. *a*, Lanes 1 and 2, secretion of ^{35}S-methionine-labelled hybrid proteins from two identical dishes before stimulation. The amount represents total secretion during 1 h of continuous labelling. Lanes 3 and 4, secretion from stimulated and unstimulated cultures, respectively, during a 3-h chase period. Lane 5, control medium collected from untransfected AtT-20 cells. *b*, Comparison of the effects of the secretagogue 8-Br-cAMP on the secretion of hGH, TG and the hGH–TG hybrid protein. For each protein, the rate of secretion in the presence (+) or absence (−) of 5 mM 8-Br-cAMP was measured after cells had been radiolabelled for 16 h and chased for 6 h as in lanes 3 and 4 of *a*. Radioactivity associated with each protein was quantitated by scanning the autoradiograms, and was corrected for the duration of stimulation. Values plotted have been normalized to the rate of secretion measured immediately before the chase (lanes 1 and 2 in *a*). Sorting indices were calculated as described previously[3]. **Methods.** Two 10-cm dishes of I17 cells were each incubated with 0.5 mCi ^{35}S-methionine for 15 h to approach steady-state labelling. For normalization, proteins secreted into the medium during the ensuing hour were collected in the continuing presence of the radiolabel (lanes 1 and 2 in *a*). To test the effect of 8-Br-cAMP on secretion, the labelled cells were first chased for 6 h. During the next 3-h chase, one dish was stimulated with 5 mM 8-Br-cAMP and the other was not. Samples of medium were collected and immunoprecipitated with excess anti-VSV antiserum (lanes 3 and 4 in *a*). For controls, cells synthesizing unfused hGH or TG protein[3] were analysed in parallel using anti-hGH or anti-TG antiserum, respectively. Immunoprecipitation was carried out with the following modifications. Samples were incubated with excess antiserum and precipitated with *Staphylococcus aureus* cells, then the immunoprecipitates were eluted from the cells in 1% SDS at 37 °C for 20 min. The supernatant was diluted to 0.2% SDS and additional antiserum added. After further precipitation with *S. aureus* cells, the immunoprecipitates were eluted from the cells by boiling in Laemmli gel sample buffer. Under these conditions, the specific binding was not significantly altered but the background was drastically reduced[17].

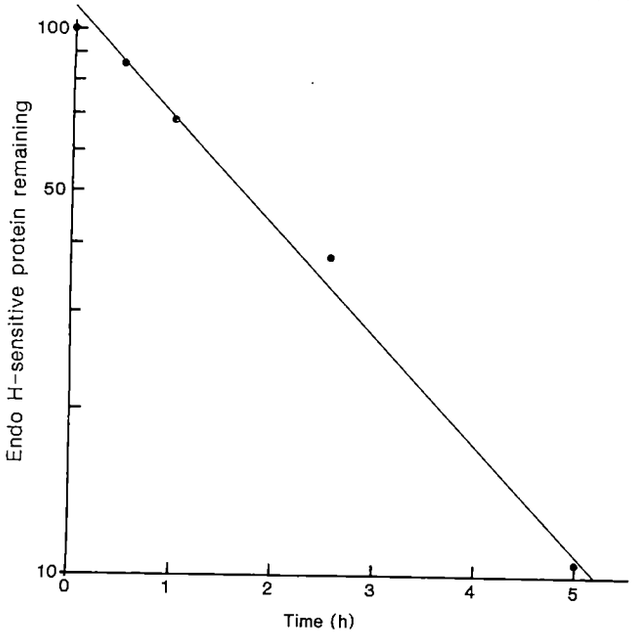

Fig. 4 hGH-TG hybrid protein exits from the RER at a rate characteristic of the TG protein. Cells were pulse-labelled with ^{35}S-methionine and chased for the times indicated. At each time point, the fraction of hybrid protein remaining sensitive to Endo H digestion was calculated from the total hybrid protein recovered in the cell extract and in the medium. Linear regression analysis shows a $t_{0.5}$ of 100 min for the conversion of Endo H-sensitive to Endo H-resistant forms.

Methods. Identical wells of I17 cells were pulse-labelled with ^{35}S-methionine for 10 min, then chased for 30 min, 1 h, 2.5 h and 5 h. At each time point, medium was collected and cells were extracted with detergents[3]. Forty per cent of the extract samples and 100% of the medium samples were immunoprecipitated with an anti-VSV antiserum, digested with Endo H, and analysed by 15% SDS-PAGE. The radioactivity associated with each form was quantitated by scanning the bands and correcting for the amount analysed.

constitutive or the regulated secretory proteins. The other class of proteins would then be transported to the second pathway by a nonspecific, bulk-flow process. Alternatively, both classes may contain sorting signals. Our data support the idea that sorting is effected by active signals on proteins destined for the regulated pathway. The constitutively secreted TG protein may lack any sorting signal, or its sorting domain may be subordinate to those of the peptide hormones. The suggestion that sorting domains are not a mandatory requirement for proteins to exit via the constitutive pathway is consistent with several earlier observations. Under conditions where intracellular targeting is perturbed by drug treatment[13], genetic disorder[14] or overproduction of the transported proteins (T. H. Stevens, G. Payne and R. Schekman, in preparation), the mis-localized proteins from the dense secretory vesicles, lysosomes or vacuoles do not accumulate within the cells, but are secreted continuously into the medium. The constitutive pathway thus appears to be a default route for any soluble protein that cannot find another destination. Therefore, the effective diversion of TG by hGH sequences probably reflects a lack of sorting signals on the VSVG fragment.

While the hGH domain appears to dominate the post-Golgi sorting of the fusion protein, its rate of movement out of the rough endoplasmic reticulum (RER) resembles more closely that of the truncated VSV G protein. In all cell lines examined previously, hGH is transported rapidly out of the RER, the half time ($t_{0.5}$) of RER export in transfected AtT-20 cells being less than 20 min (J. Rose, personal communication, and H.-P.H.M., data not shown). In contrast, TG leaves the RER much more slowly[3,10], with $t_{0.5}$, as measured by the acquisition of Endo H-resistant terminal glycosylation, being 90–100 min. Using similar criteria, we found that conversion of the hGH–TG hybrid from the Endo H-sensitive to the Endo H-resistant forms occurred at a rate comparable to that of TG (Fig. 4): 50% conversion occurred at ~100 min after the chase. Thus the slow movement of the hybrid protein from the RER appears to predominate over the fast movement.

Cellular carriers or receptors have been proposed to explain the different rates at which secreted proteins move from the RER to the Golgi apparatus[15,16]. If such carriers recognize features of newly synthesized proteins, the fusion protein strategy should be equally suited to identifying such features. It is noteworthy, therefore, that the rate at which the fusion protein exits from the RER is determined by a different region from that which determines its sorting into secretory vesicles. If export from the RER were indeed carrier-mediated, it would involve a receptor different from that which effects targeting to the secretory vesicles. An alternative, perhaps more attractive, hypothesis consistent with our observations is that movement out of the RER does not involve specific carriers. In this case, export of TG (and therefore of its fusion product) is retarded simply as a result of its delayed folding as an abnormal secretory protein in the RER.

This work was supported by NIH grant AM 33937 (to R.B.K.), and by Juvenile Diabetes Career Development Award 284087 and NIH grant GM 35239-01 (to H.-P.H.M.). We thank Dr Steve Gardell for assistance in the mutagenesis techniques; Dr Kevin Moore, Dr Peter Walter and Ms Sharon Powell for critical reading of the manuscript; and Mr David Quinn for the graphic work.

The particles of cultures of cucumber mosaic virus (CMV) contain the three genomic species of single-stranded RNA and a subgenomic species that acts as messenger RNA for CMV particle protein. Some cultures also contain a single-stranded linear RNA molecule that is typically ~335 nucleotides long[1,2]. This extra molecule, termed satellite RNA, does not share appreciable nucleotide sequence with CMV genomic RNA[3] but replicates only in

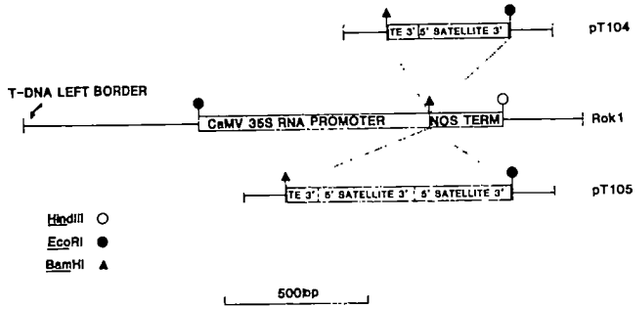

Fig. 1 Structure of the CMV satellite cDNA molecules in the binary Ti plasmid expression vectors. The cloning and nucleotide sequence of the CMV satellite RNA will be presented elsewhere. Briefly, at the 5′ end of the 104 construction there are 51 nucleotides from the polylinker of plasmid pT7-2 extending from the transcriptional start point and including polylinker sequences of pT7-2 and other vectors used in the construction of pT104. On the 3′ end of this, as shown in the diagram, there are 108 nucleotides extending from position 227 of the satellite sequence through to the 3′ nucleotide of the satellite unit at position 335 (TE 3′). Immediately 3′ of this there is a complete satellite unit, in the same orientation as the incomplete unit, flanked at the 3′ end by 16 nucleotides extending between the *Sma*I site and the *Eco*RI site of vector plasmid pT7-2 (ref. 22). The 105 construction is as 104, except that two complete satellite units, in the same orientation, are present. The insertions from 104 and 105 were excised by digestion with restriction endonucleases *Bam*HI and *Eco*RI, rendered blunt-ended by DNA polymerase (Klenow fragment) and inserted into the *Bam*HI site of binary Ti plasmid Rok1. The *Bam*HI site of Rok1 was rendered flush-ended by DNA polymerase (Klenow fragment). Rok1 is a derivative of the binary vector Bin19, described previously[11], containing additionally an expression cassette inserted into the polylinker site. The expression cassette comprised the promoter of cauliflower mosaic virus 35S RNA[23] and the terminator fragment of the nopaline synthase (*nos*) gene of *Agrobacterium* T-DNA[24] (NOS TERM). It is essentially similar to the expression cassette described for the expression of tobacco mosaic virus coat protein gene[12], except that the promoter fragment was deleted back to 6 bp 3′ of the cap site of the 35S transcript using *Bal*31 nuclease. The unique *Bam*HI site was inserted between the promoter and terminator fragments. Transcripts derived from this cassette would contain 10 nucleotides from the promoter and 200 nucleotides from the terminator[24] in addition to the sequence inserted at the *Bam*HI site. The figure shows only the region adjacent to the cDNA insert of pT104 and pT105 and the expression cassette region of Rok1.

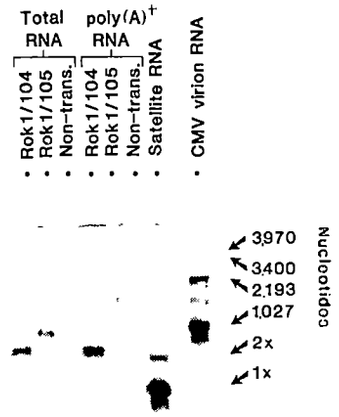

Fig. 2 Northern blot analysis of RNA from transformed plants. Total RNA (20 μg) or poly(A)$^+$ RNA (1 μg) was isolated from leaves of non-transformed plants (non-trans.) or plants transformed with Rok1/104 and Rok1/105 and fractionated on formaldehyde/agarose gels. The transcribed satellite RNA sequences were detected by blotting the gel onto nitrocellulose and hybridization with nick-translated insert from pT105. Total RNA from cells infected with CMV which contained satellite RNA was included as a reference for satellite RNA unit length (1×) and dimer length (2×) molecules. The size markers were virion RNA of CMV, which was detected with a cDNA clone (C20) of CMV genomic RNA (D.C.B., unpublished). This hybridized with CMV RNA-3, CMV RNA-4 and faintly with CMV RNA-1 and RNA-2. The size values given are those of Gould and Symons[25].

Methods. The constructions of pT104 and pT105 in Rok1 were mobilized into *Agrobacterium* strain LBA 4404 using *Escherichia coli* strain HB101 harbouring pRK2013 in a triparental mating, as described previously[11]. The resultant *Agrobacterium* strains containing the binary vector constructions were then used to infect leaf disks from axenically grown *N. tabacum* (cv. Samsun NN). The infected and transformed cells were regenerated into plants by culturing the disks successively on a layer of tobacco feeder cells and then on shoot- and root-inducing medium as described by Horsch *et al.*[26]. The shoot- and root-induction media contained kanamycin at 100 μg ml^{-1} to select for cells expressing the neomycin phosphotransferase gene contained in the T-DNA region of Rok1 (from Bin19)[11]. Transformed plants were propagated by transfer of stem cuttings into root induction medium. RNA isolations were as described by Apel and Kloppstech[27] and electrophoresis and blotting analysis as described by Goldberg[28] and Thomas[29].

plants[1] or protoplasts[4] that are infected with CMV. CMV isolates that do not contain satellite RNA can be cultured repeatedly in plants in a satellite-free state, but when satellite RNA is added to such cultures it is synthesized and persists as a component of the virus isolate[5]. The effect of satellite RNA on CMV infections depends on the strain of satellite: in many cases the usual symptoms of CMV are suppressed and as a result the infected plants show few symptoms of infection[6–8]. However, the presence of other strains of satellite RNA leads to the production of severe symptoms that are quite distinct from those of CMV[8]. Here we describe the transformation of tobacco plants with DNA copies of CMV satellite RNA, the production of satellite RNA transcripts by such plants and the acquisition of satellite RNA by CMV cultures grown in them. These results suggest a means of protecting plants against the effects of CMV and also suggest a method by which satellite RNAs may have evolved.

The satellite RNA used in this work was isolated from CMV strain $I_{17}N$ (ref. 7) and was cloned as complementary DNA. The nucleotide sequence of the cDNA clone was very similar to that of other strains of CMV satellite[2,9,10] and will be presented elsewhere, together with the construction of two head-to-tail concatemer satellite cDNA molecules. These comprised one (pT104) or two (pT105) complete satellite RNA sequence units with incomplete units at the 5′ end (Fig. 1) and were intended to mimic multimeric satellite RNAs that are thought to be replication intermediates (D.C.B., M.A.M., B.D.H. and G.R.S., unpublished results). To achieve expression of these satellite sequences in transformed plants, the cDNA molecules were transferred into an expression vector (Rok1) based on the binary Ti plasmid system of *Agrobacterium tumefaciens*[11,12]. The resultant plasmids are referred to as Rok1/104 and Rok1/105.

Transformed tobacco plants (cv. Samsun NN) were regenerated from *Agrobacterium*-infected leaf disks and were assayed for the presence of the satellite sequence in DNA and RNA by Southern and Northern blot analysis, respectively. The Southern blot analysis showed that the DNA of transformed plants contained the equivalent of 1–3 copies of the satellite cDNA per haploid genome, and also that the cDNA sequence, the promoter site and the RNA termination site had not been rearranged or deleted. The Northern blot analysis (Fig. 2) showed transcripts of ~700 nucleotides (Rok1/104) or 1,000 nucleotides (Rok1/105), which are the approximate sizes predicted from the location of promoter and terminator sequences in the original constructions (Fig. 1) and allowing for the presence of a 3′ polyadenylate tract. These RNA molecules were readily detected in total RNA or in polyadenylated RNA. No virus-like

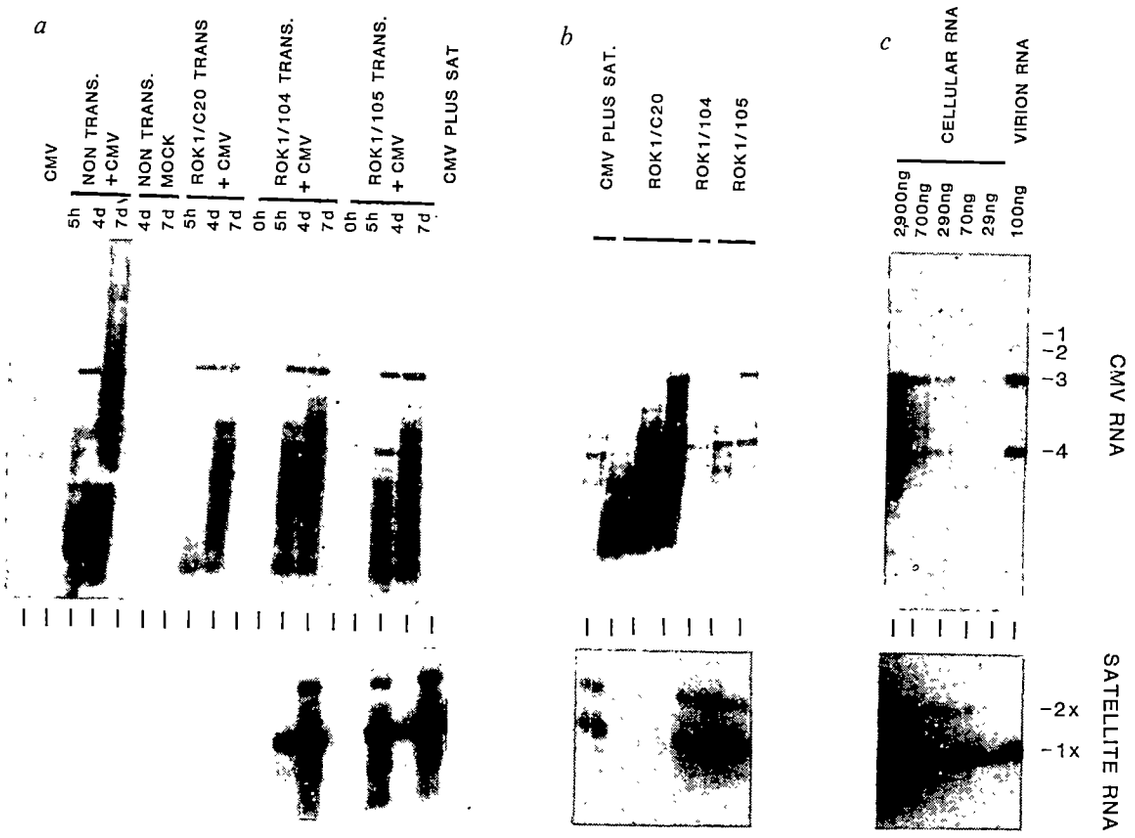

Fig. 3 Effect of CMV infection on the satellite RNA in transformed plants. Leaves of transformed or non-transformed *N. tabacum* (var. Samsun NN) were inoculated with CMV strain R76B and 35-mm disks were cut 5 h later. Batches of five disks were floated on SPS medium (10 g l^{-1} sucrose, 0.2 g l^{-1} Ca $(H_2PO_4)_2 \cdot H_2O$, 0.3 g l^{-1} sulphanilamide). Total RNA (1 μg) was isolated from these samples, or as indicated below, and analysed by Northern blotting as described for Fig. 2 using as probes the insert of pT105 (satellite RNA, lower panels) or C20 (CMV RNA, upper panels). The size markers were RNA of tissue infected with CMV alone or CMV plus satellite to show CMV RNA-1, CMV RNA-2, CMV RNA-3 and CMV RNA-4 or satellite monomer (1×) or dimer units (2×). *a*, RNA in primary infections. RNA was isolated from disks of non-transformed plants or from disks of plants transformed with the indicated derivatives of Rok1 at 5 h, 4 days or 7 days after inoculation with CMV R76B (+CMV) or buffer (mock). In some cases RNA was also isolated before inoculation (0 h). The Rok1/C20 construction was similar to Rok1/104 (Fig. 1) except that the insertion at the *Bam*HI site of Rok1 was a cDNA (C20) of the CMV coat protein mRNA. *b*, RNA in secondary infections. Extracts of CMV-infected leaf disks, similar to those described for *a*, were inoculated onto *N. clevelandii* and RNA was isolated from the systemically infected tissue after 10 days. The RNA (1 μg) was isolated from plants inoculated with extracts of disks of plants transformed with Rok1/C20, Rok1/104 or Rok1/105. *c*, RNA in CMV particles. Disks from CMV (R76B)-infected plants transformed with Rok1/105 were extracted at 7 days after inoculation and the inoculum passaged through non-transformed *N. clevelandii* and re-inoculated onto *N. clevelandii*. After 10 days of infection, CMV particles were isolated from systemically infected leaves[30] and the viral RNA extracted by addition of SDS to 1% and treatment with phenol. Total cellular RNA was also isolated from this tissue for comparison. The samples shown are 100 ng virion RNA or the indicated amounts of total cellular RNA.

symptoms or other abnormalities in growth, flowering or seed production were observed in the transformed plants.

To determine the biological activity of these transcribed RNA molecules, the transformed plants were infected with CMV strain R76B, a satellite-free isolate of CMV obtained originally from a naturally infected raspberry plant in Scotland[13]. In one such test, disks were cut from leaves 5 h after inoculation. RNA was isolated from the disks, either at that time, or after floating the disks on SPS medium for 4 or 7 days. Northern blot analysis of the RNA with a probe for CMV (C20) (Fig. 3*a*) showed that by 4 days the CMV genomic RNAs had accumulated in disks from both the transformed and the non-transformed plants. Many small RNA species which may represent subgenomic RNA species[14] also accumulated over the same period (Fig. 3*a*). Satellite RNA was detected by Northern blot analysis after 4 and 7 days but only in the disks from plants transformed with Rok1/104 or Rok1/105 (Fig. 3*a*). This RNA was present in large amounts and was primarily of unit satellite RNA length although, as is normal for an infection containing satellite, some dimers were also detected (Fig. 3*a*). At the loading of RNA and autoradiographic exposure of Fig. 3*a*, the transcribed satellite RNA molecules of ~700 and 1,000 nucleotides were not detectable. Similar results were obtained from analysis of inoculated leaves of intact plants.

Further tests showed that the satellite produced in transformed plants could be acquired as a permanent feature of the CMV culture. In one such test, sap from leaf disks in the experiments described above was inoculated to *Nicotiana clevelandii* and RNA isolated from the systemically infected leaves after 10 days. The RNA was analysed by Northern blotting and found to contain satellite RNA in monomeric and dimeric forms, at levels typical of natural satellite RNA, when the inoculum had been obtained from disks of plants transformed with Rok1/104 or Rok1/105 (Fig. 3*b*). *N. clevelandii* plants inoculated with CMV which had been passaged through disks of Rok1/C20-transformed plants contained only CMV genomic RNA (Fig. 3*b*).

These experiments also showed that the production of symptoms in *N. clevelandii* was markedly reduced when the inoculum contained satellite RNA acquired from transformed

plants. This was observed in all 12 plants inoculated with CMV R76B that had been passaged through plants transformed with Rok1/104 or Rok1/105 (M.A.M. and B.D.H., unpublished data). The effect of satellite RNA on symptom production could not be assayed in the actual transformed plants as CMV R76B produces very mild symptoms in *Nicotiana tabacum*.

The incorporation of satellite RNA from the transformed plants into virions of CMV was confirmed by Northern blot analysis of RNA isolated from CMV particles. These were isolated from a secondary infection of CMV R76B in *N. clevelandii* following passage of the virus culture through Rok1/105-transformed plants (Fig. 3*c*). Both unit length and dimeric satellite RNA was detected, although there was less satellite RNA per unit of CMV RNA than in cellular RNA from the same plants (Fig. 3*c*). This effect was more marked with the dimer than the monomer satellite.

We also found that monomeric and dimeric satellite RNA accumulated to high levels in systemically infected leaves of CMV (R76B)-inoculated plants which had been transformed with Rok1/104 and Rok1/105 (D.C.B., G.R.S., M.A.M. and B.D.H., unpublished data). Satellite RNA was not detected in the systemically infected leaves of non-transformed or Rok1/C20-transformed plants. Further investigation will determine whether satellite produced in the transformed plants affects CMV replication and accumulation.

Clearly the transcribed satellite RNA in transformed plants can be processed to unit-length molecules following CMV infection and subsequently acquired and perpetuated as a new part of the virus culture. We believe this provides the first proof of the acquisition by a plant virus of genetic material from its host, a process that may be important in the evolution of plant viruses and their satellites. Indeed, although there is no evidence for the occurrence of CMV satellite-like sequences in DNA of non-infected tobacco plants[15], sequences resembling those of the satellite RNA of turnip crinkle virus are reported to occur in the DNA of non-infected turnip plants[16].

The fact that plants infected with CMV cultures containing a benign satellite RNA show milder symptoms than plants infected with satellite-free cultures[8] suggests that satellite RNA might be used to protect crop plants against the effects of CMV infection. Preliminary experiments have shown that pre-infection with a CMV strain containing such a satellite RNA gave protection against CMV symptoms[17] and led to increased yield of pepper plants[18]. It has also been shown that infection of tomato plants with CMV strain containing a benign satellite RNA results in protection against the effects of a CMV culture containing a virulent satellite RNA[19,20]. However, the use of an avirulent virus culture as the prophylactic agent may cause several problems[21]. The protecting strain may itself have adverse effects on growth and yield or spread to other, more sensitive, plant species. It is also possible that the avirulent strain may mutate to virulence or interact with other viruses to cause severe symptoms. However, some of these difficulties may be eliminated by the strategy demonstrated here in which biologically active satellite RNA is maintained in the plant by transcription from the nuclear genome.

We thank Suzanne Mason for technical help and Dr M. Jacquemond (Montfavet, France) for providing strains of CMV. This work was supported in part by the Rockefeller Foundation.

Sequence-directed curvature of DNA

Paul J. Hagerman

Department of Biochemistry, Biophysics and Genetics, University of Colorado School of Medicine, Denver, Colorado 80262, USA

DNAs from both prokaryotic[1–4] and eukaryotic[5–8] organisms have yielded restriction fragments which manifest markedly anomalous electrophoretic behaviour (reduced mobility) when run on polyacrylamide gels. We have shown previously[9] that the abnormal electrophoretic behaviour of one such fragment is a consequence of stable curvature of the helix axis in solution. The molecules involved tend to contain oligo(dA)–oligo(dT) runs which are approximately in-phase with the helix repeat[7,8,10]; however, the precise structural elements responsible for DNA curvature have not been identified. One popular model[11,12] for curvature invokes a non-coplanar 'wedge-like' conformation of ApA/TpT dinucleotide pairs. Despite a lack of direct evidence in support of this model, it has been used to provide quantitative estimates of curvature[4,13,14]. To critically evaluate the ApA wedge model, we have performed an electrophoretic analysis of a series of closely related DNA polymers in which oligo(dA)–oligo(dT) runs of different polarity were compared. We conclude that ApA dinucleotide wedges cannot account for DNA curvature. Therefore, quantitative estimates for ApA wedge deformations, based solely on apparent curvature, cannot be correct.
